Chapter 1

Introduction

Programming languages are notations for describing computations to people and to machines The world as we know it depends on programming languages because all the software running on all the computers was written in some programming language But before a program can be run it rst must be translated into a form in which it can be executed by a computer

The software systems that do this translation are called *compilers*

This book is about how to design and implement compilers. We shall discover that a few basic ideas can be used to construct translators for a wide variety of languages and machines. Besides compilers the principles and techniques for compiler design are applicable to so many other domains that they are likely to be reused many times in the career of a computer scientist. The study of compiler writing touches upon programming languages machine are chitecture, language theory, algorithms, and software engineering.

In this preliminary chapter we introduce the di erent forms of language translators give a high level overview of the structure of a typical compiler and discuss the trends in programming languages and machine architecture that are shaping compilers. We include some observations on the relationship between compiler design and computer science theory and an outline of the applications of compiler technology that go beyond compilation. We end with a brief outline of key programming language concepts that will be needed for our study of compilers

11 Language Processors

Simply stated a compiler is a program that can read a program in one lan guage—the *source* language—and translate it into an equivalent program in another language—the *target* language—see Fig. 1.1—An important role of the compiler is to report any errors in the source program that it detects during the translation process

CHAPTER 1 INTRODUCTION

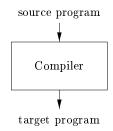

Figure 1 1 A compiler

If the target program is an executable machine language program it can then be called by the user to process inputs and produce outputs see Fig 1 2

Figure 1.2 Running the target program

An *interpreter* is another common kind of language processor. Instead of producing a target program as a translation an interpreter appears to directly execute the operations specified in the source program on inputs supplied by the user as shown in Fig. 1.3

Figure 1 3 An interpreter

The machine language target program produced by a compiler is usually much faster than an interpreter at mapping inputs to outputs. An interpreter however can usually give better error diagnostics than a compiler because it executes the source program statement by statement

Example 1 1 Java language processors combine compilation and interpretation as shown in Fig 1 4 A Java source program may rst be compiled into an intermediate form called *bytecodes* The bytecodes are then interpreted by a virtual machine A bene t of this arrangement is that bytecodes compiled on one machine can be interpreted on another machine perhaps across a network

In order to achieve faster processing of inputs to outputs some Java compilers called *just in time* compilers translate the bytecodes into machine language immediately before they run the intermediate program to process the input \Box

11 LANGUAGE PROCESSORS

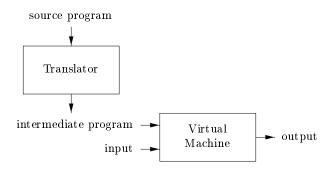

Figure 1 4 A hybrid compiler

In addition to a compiler several other programs may be required to create an executable target program as shown in Fig 1.5. A source program may be divided into modules stored in separate—les—The task of collecting the source program is sometimes entrusted to a separate program called a *preprocessor*. The preprocessor may also expand shorthands—called macros—into source language statements

The modi ed source program is then fed to a compiler The compiler may produce an assembly language program as its output because assembly language is easier to produce as output and is easier to debug. The assembly language is then processed by a program called an *assembler* that produces relocatable machine code as its output

Large programs are often compiled in pieces so the relocatable machine code may have to be linked together with other relocatable object les and library les into the code that actually runs on the machine. The linker resolves external memory addresses where the code in one le may refer to a location in another le. The loader then puts together all of the executable object les into memory for execution

111 Exercises for Section 11

Exercise 1 1 1 What is the difference between a compiler and an interpreter

Exercise 1 1 2 What are the advantages of a a compiler over an interpreter b an interpreter over a compiler

Exercise 1 1 3 What advantages are there to a language processing system in which the compiler produces assembly language rather than machine language

Exercise 1 1 4 A compiler that translates a high level language into another high level language is called a *source to source* translator. What advantages are there to using C as a target language for a compiler

Exercise 1 1 5 Describe some of the tasks that an assembler needs to per form

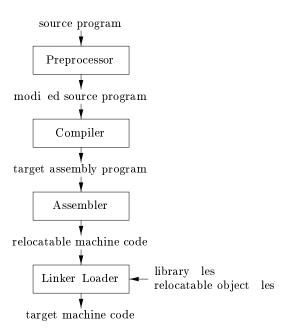

Figure 15 A language processing system

12 The Structure of a Compiler

Up to this point we have treated a compiler as a single box that maps a source program into a semantically equivalent target program. If we open up this box a little we see that there are two parts to this mapping analysis and synthesis

The analysis part breaks up the source program into constituent pieces and imposes a grammatical structure on them. It then uses this structure to cre ate an intermediate representation of the source program. If the analysis part detects that the source program is either syntactically ill formed or semantically unsound then it must provide informative messages so the user can take corrective action. The analysis part also collects information about the source program and stores it in a data structure called a symbol table which is passed along with the intermediate representation to the synthesis part

The *synthesis* part constructs the desired target program from the interme diate representation and the information in the symbol table. The analysis part is often called the *front end* of the compiler, the synthesis part is the *back end*

If we examine the compilation process in more detail we see that it operates as a sequence of *phases* each of which transforms one representation of the source program to another A typical decomposition of a compiler into phases is shown in Fig 1.6. In practice several phases may be grouped together and the intermediate representations between the grouped phases need not be constructed explicitly. The symbol table which stores information about the

12 THE STRUCTURE OF A COMPILER

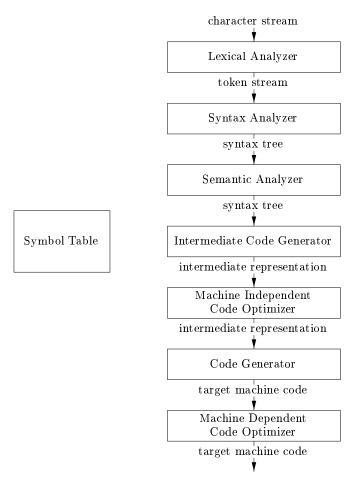

Figure 1 6 Phases of a compiler

entire source program is used by all phases of the compiler

Some compilers have a machine independent optimization phase between the front end and the back end. The purpose of this optimization phase is to perform transformations on the intermediate representation so that the back end can produce a better target program than it would have otherwise produced from an unoptimized intermediate representation. Since optimization is optional one or the other of the two optimization phases shown in Fig. 1.6 may be missing

1 2 1 Lexical Analysis

The rst phase of a compiler is called *lexical analysis* or *scanning* The lex ical analyzer reads the stream of characters making up the source program

and groups the characters into meaningful sequences called *lexemes* For each lexeme the lexical analyzer produces as output a *token* of the form

⟨token name attribute value⟩

that it passes on to the subsequent phase syntax analysis. In the token the rst component token name is an abstract symbol that is used during syntax analysis and the second component attribute value points to an entry in the symbol table for this token. Information from the symbol table entry is needed for semantic analysis and code generation

For example suppose a source program contains the assignment statement

The characters in this assignment could be grouped into the following lexemes and mapped into the following tokens passed on to the syntax analyzer

- 1 position is a lexeme that would be mapped into a token (id 1) where id is an abstract symbol standing for *identi er* and 1 points to the symbol table entry for position. The symbol table entry for an identi er holds information about the identi er such as its name and type
- 2 The assignment symbol—is a lexeme that is mapped into the token 〈 〉 Since this token needs no attribute value—we have omitted the second component—We could have used any abstract symbol such as **assign** for the token name—but for notational convenience we have chosen to use the lexeme itself as the name of the abstract symbol
- 3 initial is a lexeme that is mapped into the token (id 2) where 2 points to the symbol table entry for initial
- 4 is a lexeme that is mapped into the token $\langle \rangle$
- 5 rate is a lexeme that is mapped into the token (id 3) where 3 points to the symbol table entry for rate
- 6 is a lexeme that is mapped into the token $\langle \rangle$
- 7 60 is a lexeme that is mapped into the token $\langle 60 \rangle^{-1}$

Blanks separating the lexemes would be discarded by the lexical analyzer

Figure 1 7 shows the representation of the assignment statement 1 1 after lexical analysis as the sequence of tokens

$$\langle \mathbf{id} \ 1 \rangle \ \langle \ \rangle \ \langle \mathbf{id} \ 2 \rangle \ \langle \ \rangle \ \langle \mathbf{id} \ 3 \rangle \ \langle \ \rangle \ \langle 60 \rangle$$
 1 2

In this representation the token names and are abstract symbols for the assignment addition and multiplication operators respectively

 $^{^1}$ Technically speaking for the lexeme 60 we should make up a token like $\langle number\ 4 \rangle$ where 4 points to the symbol table for the internal representation of integer 60 but we shall defer the discussion of tokens for numbers until Chapter 2 Chapter 3 discusses techniques for building lexical analyzers

12 THE STRUCTURE OF A COMPILER

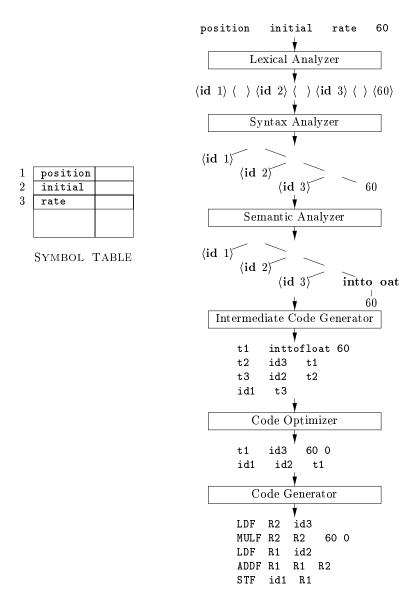

Figure 1 7 Translation of an assignment statement

1 2 2 Syntax Analysis

The second phase of the compiler is *syntax analysis* or *parsing* The parser uses the rst components of the tokens produced by the lexical analyzer to create a tree like intermediate representation that depicts the grammatical structure of the token stream. A typical representation is a *syntax tree* in which each interior node represents an operation and the children of the node represent the arguments of the operation. A syntax tree for the token stream 1.2 is shown as the output of the syntactic analyzer in Fig. 1.7

This tree shows the order in which the operations in the assignment

position initial rate 60

are to be performed. The tree has an interior node labeled with $\langle id 3 \rangle$ as its left child and the integer 60 as its right child. The node $\langle id 3 \rangle$ represents the identi er rate. The node labeled makes it explicit that we must rst multiply the value of rate by 60. The node labeled indicates that we must add the result of this multiplication to the value of initial. The root of the tree labeled indicates that we must store the result of this addition into the location for the identi er position. This ordering of operations is consistent with the usual conventions of arithmetic which tell us that multiplication has higher precedence than addition and hence that the multiplication is to be performed before the addition

The subsequent phases of the compiler use the grammatical structure to help analyze the source program and generate the target program. In Chapter 4 we shall use context free grammars to specify the grammatical structure of programming languages and discuss algorithms for constructing e-cient syntax analyzers automatically from certain classes of grammars. In Chapters 2 and 5 we shall see that syntax directed de nitions can help specify the translation of programming language constructs

1 2 3 Semantic Analysis

The semantic analyzer uses the syntax tree and the information in the symbol table to check the source program for semantic consistency with the language de nition. It also gathers type information and saves it in either the syntax tree or the symbol table for subsequent use during intermediate code generation.

An important part of semantic analysis is type checking where the compiler checks that each operator has matching operands. For example, many program ming language de nitions require an array index to be an integer, the compiler must report an error if a oating point number is used to index an array

The language speci cation may permit some type conversions called *coer cions* For example a binary arithmetic operator may be applied to either a pair of integers or to a pair of oating point numbers. If the operator is applied to a oating point number and an integer the compiler may convert or coerce the integer into a oating point number.

1 2 THE STRUCTURE OF A COMPILER

Such a coercion appears in Fig 1.7 Suppose that position initial and rate have been declared to be oating point numbers and that the lexeme 60 by itself forms an integer. The type checker in the semantic analyzer in Fig 1.7 discovers that the operator—is applied to a oating point number rate and an integer 60. In this case, the integer may be converted into a oating point number. In Fig 1.7 notice that the output of the semantic analyzer has an extra node for the operator intto oat—which explicitly converts its integer argument into a oating point number. Type checking and semantic analysis are discussed in Chapter 6

1 2 4 Intermediate Code Generation

In the process of translating a source program into target code a compiler may construct one or more intermediate representations which can have a variety of forms Syntax trees are a form of intermediate representation they are commonly used during syntax and semantic analysis

After syntax and semantic analysis of the source program many compil ers generate an explicit low level or machine like intermediate representation which we can think of as a program for an abstract machine. This intermediate representation should have two important properties it should be easy to produce and it should be easy to translate into the target machine.

In Chapter 6 we consider an intermediate form called *three address code* which consists of a sequence of assembly like instructions with three operands per instruction. Each operand can act like a register. The output of the intermediate code generator in Fig. 1.7 consists of the three address code sequence.

There are several points worth noting about three address instructions. First each three address assignment instruction has at most one operator on the right side. Thus, these instructions is at the order in which operations are to be done the multiplication precedes the addition in the source program 1.1. Second the compiler must generate a temporary name to hold the value computed by a three address instruction. Third some three address instructions like the right and last in the sequence 1.3 above have fewer than three operands

In Chapter 6 we cover the principal intermediate representations used in compilers Chapter 5 introduces techniques for syntax directed translation that are applied in Chapter 6 to type checking and intermediate code generation for typical programming language constructs such as expressions—ow of control constructs and procedure calls

1 2 5 Code Optimization

The machine independent code optimization phase attempts to improve the intermediate code so that better target code will result. Usually better means faster but other objectives may be desired, such as shorter code or target code that consumes less power. For example, a straightforward algorithm generates the intermediate code 1.3 using an instruction for each operator in the tree representation that comes from the semantic analyzer.

A simple intermediate code generation algorithm followed by code optimization is a reasonable way to generate good target code. The optimizer can deduce that the conversion of 60 from integer to oating point can be done once and for all at compile time so the **intto oat** operation can be eliminated by replacing the integer 60 by the oating point number 60 0. Moreover t3 is used only once to transmit its value to id1 so the optimizer can transform 13 into the shorter sequence

There is a great variation in the amount of code optimization di erent com pilers perform. In those that do the most the so called optimizing compilers a signi cant amount of time is spent on this phase. There are simple optimizations that signi cantly improve the running time of the target program without slowing down compilation too much. The chapters from 8 on discuss machine independent and machine dependent optimizations in detail

1 2 6 Code Generation

The code generator takes as input an intermediate representation of the source program and maps it into the target language. If the target language is machine code registers or memory locations are selected for each of the variables used by the program. Then the intermediate instructions are translated into sequences of machine instructions that perform the same task. A crucial aspect of code generation is the judicious assignment of registers to hold variables.

For example using registers R1 and R2 the intermediate code in 1.4 might get translated into the machine code

The rst operand of each instruction speci es a destination The F in each instruction tells us that it deals with oating point numbers The code in

12 THE STRUCTURE OF A COMPILER

15 loads the contents of address id3 into register R2 then multiplies it with oating point constant 600. The signi es that 600 is to be treated as an immediate constant. The third instruction moves id2 into register R1 and the fourth adds to it the value previously computed in register R2. Finally, the value in register R1 is stored into the address of id1 so the code correctly implements the assignment statement. 11. Chapter 8 covers code generation.

This discussion of code generation has ignored the important issue of stor age allocation for the identi ers in the source program. As we shall see in Chapter 7 the organization of storage at run time depends on the language be ing compiled. Storage allocation decisions are made either during intermediate code generation or during code generation.

1 2 7 Symbol Table Management

An essential function of a compiler is to record the variable names used in the source program and collect information about various attributes of each name. These attributes may provide information about the storage allocated for a name its type its scope where in the program its value may be used and in the case of procedure names such things as the number and types of its arguments the method of passing each argument for example by value or by reference and the type returned

The symbol table is a data structure containing a record for each variable name with elds for the attributes of the name. The data structure should be designed to allow the compiler to $\,$ nd the record for each name quickly and to store or retrieve data from that record quickly. Symbol tables are discussed in Chapter 2

1 2 8 The Grouping of Phases into Passes

The discussion of phases deals with the logical organization of a compiler In an implementation activities from several phases may be grouped together into a pass that reads an input le and writes an output le For example the front end phases of lexical analysis syntax analysis semantic analysis and intermediate code generation might be grouped together into one pass Code optimization might be an optional pass Then there could be a back end pass consisting of code generation for a particular target machine

Some compiler collections have been created around carefully designed in termediate representations that allow the front end for a particular language to interface with the back end for a certain target machine. With these collections we can produce compilers for dierent source languages for one target machine by combining dierent front ends with the back end for that target machine. Similarly, we can produce compilers for dierent target machines by combining a front end with back ends for dierent target machines.

1 2 9 Compiler Construction Tools

The compiler writer like any software developer can pro tably use modern software development environments containing tools such as language editors debuggers version managers pro lers test harnesses and so on In addition to these general software development tools other more specialized tools have been created to help implement various phases of a compiler

These tools use specialized languages for specifying and implementing spe ci c components and many use quite sophisticated algorithms. The most suc cessful tools are those that hide the details of the generation algorithm and produce components that can be easily integrated into the remainder of the compiler. Some commonly used compiler construction tools include

- 1 Parser generators that automatically produce syntax analyzers from a grammatical description of a programming language
- 2 Scanner generators that produce lexical analyzers from a regular expres sion description of the tokens of a language
- 3 Syntax directed translation engines that produce collections of routines for walking a parse tree and generating intermediate code
- 4 Code generator generators that produce a code generator from a collection of rules for translating each operation of the intermediate language into the machine language for a target machine
- 5 Data ow analysis engines that facilitate the gathering of information about how values are transmitted from one part of a program to each other part Data ow analysis is a key part of code optimization
- 6 Compiler construction toolkits that provide an integrated set of routines for constructing various phases of a compiler

We shall describe many of these tools throughout this book

1 3 The Evolution of Programming Languages

The rst electronic computers appeared in the 1940 s and were programmed in machine language by sequences of 0 s and 1 s that explicitly told the computer what operations to execute and in what order. The operations themselves were very low level move data from one location to another add the contents of two registers compare two values and so on. Needless to say this kind of programming was slow tedious and error prone. And once written the programs were hard to understand and modify

1 3 1 The Move to Higher level Languages

The rst step towards more people friendly programming languages was the development of mnemonic assembly languages in the early 1950 s. Initially the instructions in an assembly language were just mnemonic representations of machine instructions. Later macro instructions were added to assembly languages so that a programmer could de ne parameterized shorthands for frequently used sequences of machine instructions

A major step towards higher level languages was made in the latter half of the 1950 s with the development of Fortran for scientic computation. Cobol for business data processing and Lisp for symbolic computation. The philos ophy behind these languages was to create higher level notations with which programmers could more easily write numerical computations business applications and symbolic programs. These languages were so successful that they are still in use today

In the following decades many more languages were created with innovative features to help make programming easier more natural and more robust Later in this chapter we shall discuss some key features that are common to many modern programming languages

Today there are thousands of programming languages. They can be classi ed in a variety of ways. One classi cation is by generation First generation languages are the machine languages second generation the assembly languages and third generation the higher level languages like Fortran. Cobol. Lisp. C. C. and Java. Fourth generation languages are languages designed for special capplications like NOMAD for report generation. SQL for database queries and Postscript for text formatting. The term. fth generation language has been applied to logic and constraint based languages like Prolog and OPS5.

Another classi cation of languages uses the term imperative for languages in which a program speci es how a computation is to be done and declarative for languages in which a program speci es what computation is to be done Languages such as C C C and Java are imperative languages. In imperative languages there is a notion of program state and statements that change the state. Functional languages such as ML and Haskell and constraint logic languages such as Prolog are often considered to be declarative languages.

The term $von\ Neumann\ language$ is applied to programming languages whose computational model is based on the von Neumann computer architecture. Many of today's languages such as Fortran and C are von Neumann languages

An object oriented language is one that supports object oriented program ming a programming style in which a program consists of a collection of objects that interact with one another Simula 67 and Smalltalk are the earliest major object oriented languages Languages such as C C Java and Ruby are more recent object oriented languages

Scripting languages are interpreted languages with high level operators de signed for gluing together computations These computations were originally

called scripts Awk JavaScript Perl PHP Python Ruby and Tcl are popular examples of scripting languages Programs written in scripting languages are often much shorter than equivalent programs written in languages like C

1 3 2 Impacts on Compilers

Since the design of programming languages and compilers are intimately related the advances in programming languages placed new demands on compiler writ ers. They had to devise algorithms and representations to translate and support the new language features. Since the 1940 s computer architecture has evolved as well. Not only did the compiler writers have to track new language features they also had to devise translation algorithms that would take maximal advantage of the new hardware capabilities.

Compilers can help promote the use of high level languages by minimizing the execution overhead of the programs written in these languages. Compilers are also critical in making high performance computer architectures elective on users applications. In fact, the performance of a computer system is so dependent on compiler technology that compilers are used as a tool in evaluating architectural concepts before a computer is built

Compiler writing is challenging A compiler by itself is a large program Moreover many modern language processing systems handle several source lan guages and target machines within the same framework that is they serve as collections of compilers possibly consisting of millions of lines of code Con sequently good software engineering techniques are essential for creating and evolving modern language processors

A compiler must translate correctly the potentially in nite set of programs that could be written in the source language. The problem of generating the optimal target code from a source program is undecidable in general, thus compiler writers must evaluate tradeo is about what problems to tackle and what heuristics to use to approach the problem of generating experience cient code.

A study of compilers is also a study of how theory meets practice $% \left(1\right) =\left(1\right) +\left(1\right) +$

The purpose of this text is to teach the methodology and fundamental ideas used in compiler design. It is not the intention of this text to teach all the algorithms and techniques that could be used for building a state of the art language processing system. However, readers of this text will acquire the basic knowledge and understanding to learn how to build a compiler relatively easily

6 Lisp 7 ML 8 Perl 9 Python 10 VB
```

14 The Science of Building a Compiler

Compiler design is full of beautiful examples where complicated real world problems are solved by abstracting the essence of the problem mathematically. These serve as excellent illustrations of how abstractions can be used to solve problems take a problem formulate a mathematical abstraction that captures the key characteristics and solve it using mathematical techniques. The problem formulation must be grounded in a solid understanding of the characteristics of computer programs and the solution must be validated and refined empirically

A compiler must accept all source programs that conform to the speci-cation of the language the set of source programs is in nite and any program can be very large consisting of possibly millions of lines of code. Any transformation performed by the compiler while translating a source program must preserve the meaning of the program being compiled. Compiler writers thus have in uence over not just the compilers they create but all the programs that their compilers compile. This leverage makes writing compilers particularly rewarding however it also makes compiler development challenging.

141 Modeling in Compiler Design and Implementation

The study of compilers is mainly a study of how we design the right mathe matical models and choose the right algorithms while balancing the need for generality and power against simplicity and e ciency

Some of most fundamental models are nite state machines and regular expressions which we shall meet in Chapter 3 These models are useful for de scribing the lexical units of programs keywords identi ers and such and for describing the algorithms used by the compiler to recognize those units. Also among the most fundamental models are context free grammars used to de scribe the syntactic structure of programming languages such as the nesting of parentheses or control constructs. We shall study grammars in Chapter 4 Sim ilarly trees are an important model for representing the structure of programs and their translation into object code as we shall see in Chapter 5

1 4 2 The Science of Code Optimization

The term optimization in compiler design refers to the attempts that a compiler makes to produce code that is more e-cient than the obvious code. Optimization is thus a misnomer since there is no way that the code produced by a compiler can be guaranteed to be as fast or faster than any other code that performs the same task

CHAPTER 1 INTRODUCTION

In modern times the optimization of code that a compiler performs has become both more important and more complex. It is more complex because processor architectures have become more complex yielding more opportunities to improve the way code executes. It is more important because massively par allel computers require substantial optimization or their performance su ers by orders of magnitude. With the likely prevalence of multicore machines computers with chips that have large numbers of processors on them, all compilers will have to face the problem of taking advantage of multiprocessor machines.

It is hard if not impossible to build a robust compiler out of hacks. Thus an extensive and useful theory has been built up around the problem of optimizing code. The use of a rigorous mathematical foundation allows us to show that an optimization is correct and that it produces the desirable e ect for all possible inputs. We shall see starting in Chapter 9 how models such as graphs matrices and linear programs are necessary if the compiler is to produce well optimized code.

On the other hand pure theory alone is insuccient. Like many real world problems there are no perfect answers. In fact, most of the questions that we ask in compiler optimization are undecidable. One of the most important skills in compiler design is the ability to formulate the right problem to solve. We need a good understanding of the behavior of programs to start with and thorough experimentation and evaluation to validate our intuitions.

Compiler optimizations must meet the following design objectives

The optimization must be correct that is preserve the meaning of the compiled program

The optimization must improve the performance of many programs

The compilation time must be kept reasonable and

The engineering e ort required must be manageable

It is impossible to overemphasize the importance of correctness. It is trivial to write a compiler that generates fast code if the generated code need not be correct. Optimizing compilers are so discult to get right that we dare say that no optimizing compiler is completely error free. Thus, the most important objective in writing a compiler is that it is correct.

The second goal is that the compiler must be e ective in improving the per formance of many input programs. Normally performance means the speed of the program execution. Especially in embedded applications, we may also wish to minimize the size of the generated code. And in the case of mobile devices it is also desirable that the code minimizes power consumption. Typically, the same optimizations that speed up execution time also conserve power. Besides performance usability aspects such as error reporting and debugging are also important.

Third we need to keep the compilation time short to support a rapid devel opment and debugging cycle This requirement has become easier to meet as

15 APPLICATIONS OF COMPILER TECHNOLOGY

machines get faster Often a program is rst developed and debugged without program optimizations. Not only is the compilation time reduced but more importantly unoptimized programs are easier to debug because the optimizations introduced by a compiler often obscure the relationship between the source code and the object code. Turning on optimizations in the compiler sometimes exposes new problems in the source program thus testing must again be performed on the optimized code. The need for additional testing sometimes deters the use of optimizations in applications especially if their performance is not critical.

Finally a compiler is a complex system we must keep the system simple to assure that the engineering and maintenance costs of the compiler are manageable. There is an in nite number of program optimizations that we could implement and it takes a nontrivial amount of e ort to create a correct and e ective optimization. We must prioritize the optimizations implementing only those that lead to the greatest bene to on source programs encountered in practice.

Thus in studying compilers we learn not only how to build a compiler but also the general methodology of solving complex and open ended problems. The approach used in compiler development involves both theory and experimentation. We normally start by formulating the problem based on our intuitions on what the important issues are

15 Applications of Compiler Technology

Compiler design is not only about compilers and many people use the technol ogy learned by studying compilers in school yet have never strictly speaking written even part of a compiler for a major programming language Compiler technology has other important uses as well Additionally compiler design im pacts several other areas of computer science. In this section we review the most important interactions and applications of the technology

1 5 1 Implementation of High Level Programming Languages

A high level programming language de nes a programming abstraction the programmer expresses an algorithm using the language and the compiler must translate that program to the target language Generally higher level program ming languages are easier to program in but are less e-cient that is the target programs run more slowly Programmers using a low level language have more control over a computation and can in principle produce more e-cient code Unfortunately lower level programs are harder to write and — worse still less portable more prone to errors and harder to maintain Optimizing compilers include techniques to improve the performance of generated code thus o setting the ine-ciency introduced by high level abstractions

Example 1 2 The **register** keyword in the C programming language is an early example of the interaction between compiler technology and language evo lution. When the C language was created in the mid 1970s it was considered necessary to let a programmer control which program variables reside in registers. This control became unnecessary as elective register allocation techniques were developed and most modern programs no longer use this language feature.

In fact programs that use the **register** keyword may lose e-ciency because programmers often are not the best judge of very low level matters like register allocation. The optimal choice of register allocation depends greatly on the speci-cs of a machine architecture. Hardwiring low level resource management decisions like register allocation may in fact hurt performance especially if the program is run on machines other than the one for which it was written. \Box

The many shifts in the popular choice of programming languages have been in the direction of increased levels of abstraction. C was the predominant systems programming language of the 80 s many of the new projects started in the 90 s chose C. Java introduced in 1995 gained popularity quickly in the late 90 s. The new programming language features introduced in each round spurred new research in compiler optimization. In the following, we give an overview on the main language features that have stimulated significant advances in compiler technology.

Practically all common programming languages including C Fortran and Cobol support user de ned aggregate data types such as arrays and structures and high level control ow such as loops and procedure invocations. If we just take each high level construct or data access operation and translate it directly to machine code the result would be very ine cient. A body of compiler optimizations known as data ow optimizations has been developed to analyze the ow of data through the program and removes redundancies across these constructs. They are elective in generating code that resembles code written by a skilled programmer at a lower level

Object orientation was rst introduced in Simula in 1967 and has been incorporated in languages such as Smalltalk C C and Java The key ideas behind object orientation are

- 1 Data abstraction and
- 2 Inheritance of properties

both of which have been found to make programs more modular and easier to maintain Object oriented programs are di erent from those written in many other languages in that they consist of many more but smaller procedures called methods in object oriented terms. Thus compiler optimizations must be able to perform well across the procedural boundaries of the source program. Procedure inlining which is the replacement of a procedure call by the body of the procedure is particularly useful here. Optimizations to speed up virtual method dispatches have also been developed

15 APPLICATIONS OF COMPILER TECHNOLOGY

Java has many features that make programming easier many of which have been introduced previously in other languages. The Java language is type safe that is an object cannot be used as an object of an unrelated type. All array accesses are checked to ensure that they lie within the bounds of the array Java has no pointers and does not allow pointer arithmetic. It has a built in garbage collection facility that automatically frees the memory of variables that are no longer in use. While all these features make programming easier, they incur a run time overhead. Compiler optimizations have been developed to reduce the overhead for example by eliminating unnecessary range checks and by allocating objects that are not accessible beyond a procedure on the stack instead of the heap. E. ective algorithms also have been developed to minimize the overhead of garbage collection.

In addition Java is designed to support portable and mobile code Programs are distributed as Java bytecode which must either be interpreted or compiled into native code dynamically that is at run time Dynamic compilation has also been studied in other contexts where information is extracted dynamically at run time and used to produce better optimized code In dynamic optimization it is important to minimize the compilation time as it is part of the execution overhead A common technique used is to only compile and optimize those parts of the program that will be frequently executed

152 Optimizations for Computer Architectures

The rapid evolution of computer architectures has also led to an insatiable demand for new compiler technology. Almost all high performance systems take advantage of the same two basic techniques parallelism and memory hierarchies. Parallelism can be found at several levels at the instruction level where multiple operations are executed simultaneously and at the processor level where dierent threads of the same application are run on dierent processors. Memory hierarchies are a response to the basic limitation that we can build very fast storage or very large storage but not storage that is both fast and large

Parallelism

All modern microprocessors exploit instruction level parallelism. However, this parallelism can be hidden from the programmer. Programs are written as if all instructions were executed in sequence, the hardware dynamically checks for dependencies in the sequential instruction stream and issues them in parallel when possible. In some cases, the machine includes a hardware scheduler that can change the instruction ordering to increase the parallelism in the program. Whether the hardware reorders the instructions or not compilers can rearrange the instructions to make instruction level parallelism more elective.

Instruction level parallelism can also appear explicitly in the instruction set VLIW Very Long Instruction Word machines have instructions that can issue

multiple operations in parallel The Intel IA64 is a well known example of such an architecture All high performance general purpose microprocessors also include instructions that can operate on a vector of data at the same time Compiler techniques have been developed to generate code automatically for such machines from sequential programs

Multiprocessors have also become prevalent even personal computers of ten have multiple processors. Programmers can write multithreaded code for multiprocessors or parallel code can be automatically generated by a compiler from conventional sequential programs. Such a compiler hides from the programmers the details of inding parallelism in a program distributing the computation across the machine and minimizing synchronization and communication among the processors. Many sciential computing and engineering applications are computation intensive and can bene to greatly from parallel processing. Parallelization techniques have been developed to translate automatically sequential sciential computation multiprocessor code.

Memory Hierarchies

A memory hierarchy consists of several levels of storage with di erent speeds and sizes with the level closest to the processor being the fastest but small est. The average memory access time of a program is reduced if most of its accesses are satisfied by the faster levels of the hierarchy. Both parallelism and the existence of a memory hierarchy improve the potential performance of a machine but they must be harnessed electively by the compiler to deliver real performance on an application

Memory hierarchies are found in all machines A processor usually has a small number of registers consisting of hundreds of bytes several levels of caches containing kilobytes to megabytes physical memory containing mega bytes to gigabytes and nally secondary storage that contains gigabytes and beyond Correspondingly the speed of accesses between adjacent levels of the hierarchy can di er by two or three orders of magnitude. The performance of a system is often limited not by the speed of the processor but by the performance of the memory subsystem. While compilers traditionally focus on optimizing the processor execution more emphasis is now placed on making the memory hierarchy more elective.

Using registers e ectively is probably the single most important problem in optimizing a program. Unlike registers that have to be managed explicitly in software caches and physical memories are hidden from the instruction set and are managed by hardware. It has been found that cache management policies implemented by hardware are not e ective in some cases especially in scientic code that has large data structures arrays typically. It is possible to improve the e ectiveness of the memory hierarchy by changing the layout of the data or changing the order of instructions accessing the data. We can also change the layout of code to improve the e ectiveness of instruction caches

15 APPLICATIONS OF COMPILER TECHNOLOGY

153 Design of New Computer Architectures

In the early days of computer architecture design compilers were developed after the machines were built. That has changed. Since programming in high level languages is the norm the performance of a computer system is determined not by its raw speed but also by how well compilers can exploit its features. Thus, in modern computer architecture development, compilers are developed in the processor design stage, and compiled code running on simulators is used to evaluate the proposed architectural features.

RISC

One of the best known examples of how compilers in uenced the design of computer architecture was the invention of the RISC Reduced Instruction Set Computer architecture Prior to this invention the trend was to develop pro gressively complex instruction sets intended to make assembly programming easier these architectures were known as CISC Complex Instruction Set Computer For example CISC instruction sets include complex memory addressing modes to support data structure accesses and procedure invocation instructions that save registers and pass parameters on the stack

Compiler optimizations often can reduce these instructions to a small num ber of simpler operations by eliminating the redundancies across complex in structions. Thus it is desirable to build simple instruction sets compilers can use them electively and the hardware is much easier to optimize

Most general purpose processor architectures including PowerPC SPARC MIPS Alpha and PA RISC are based on the RISC concept. Although the x86 architecture—the most popular microprocessor—has a CISC instruction set—many of the ideas developed for RISC machines are used in the imple mentation of the processor itself—Moreover the most e ective way to use a high performance x86 machine is to use just its simple instructions

Specialized Architectures

Over the last three decades many architectural concepts have been proposed. They include data ow machines vector machines VLIW. Very Long Instruction Word machines SIMD Single Instruction Multiple Data arrays of processors systolic arrays multiprocessors with shared memory and multiprocessors with distributed memory. The development of each of these architectural concepts was accompanied by the research and development of corresponding compiler technology.

Some of these ideas have made their way into the designs of embedded machines. Since entire systems can toon a single chip processors need no longer be prepackaged commodity units but can be tailored to achieve better cost electiveness for a particular application. Thus, in contrast to general purpose processors where economies of scale have led computer architectures

to converge application specic processors exhibit a diversity of computer ar chitectures. Compiler technology is needed not only to support programming for these architectures but also to evaluate proposed architectural designs

154 Program Translations

While we normally think of compiling as a translation from a high level lan guage to the machine level the same technology can be applied to translate between di erent kinds of languages The following are some of the important applications of program translation techniques

Binary Translation

Compiler technology can be used to translate the binary code for one machine to that of another allowing a machine to run programs originally compiled for another instruction set Binary translation technology has been used by various computer companies to increase the availability of software for their machines In particular because of the domination of the x86 personal computer market most software titles are available as x86 code Binary translators have been developed to convert x86 code into both Alpha and Sparc code Binary translation was also used by Transmeta Inc in their implementation of the x86 instruction set Instead of executing the complex x86 instruction set directly in hardware the Transmeta Crusoe processor is a VLIW processor that relies on binary translation to convert x86 code into native VLIW code

Binary translation can also be used to provide backward compatibility When the processor in the Apple Macintosh was changed from the Motorola MC 68040 to the PowerPC in 1994 binary translation was used to allow PowerPC processors run legacy MC 68040 code

Hardware Synthesis

Not only is most software written in high level languages even hardware de signs are mostly described in high level hardware description languages like Verilog and VHDL Very high speed integrated circuit Hardware Description Language Hardware designs are typically described at the register trans fer level RTL where variables represent registers and expressions represent combinational logic Hardware synthesis tools translate RTL descriptions auto matically into gates which are then mapped to transistors and eventually to a physical layout Unlike compilers for programming languages these tools often take hours optimizing the circuit Techniques to translate designs at higher levels such as the behavior or functional level also exist

Database Query Interpreters

Besides specifying software and hardware languages are useful in many other applications. For example, query languages, especially SQL. Structured Query

15 APPLICATIONS OF COMPILER TECHNOLOGY

Language are used to search databases Database queries consist of predicates containing relational and boolean operators. They can be interpreted or compiled into commands to search a database for records satisfying that predicate

Compiled Simulation

Simulation is a general technique used in many scienti c and engineering disciplines to understand a phenomenon or to validate a design Inputs to a simula tor usually include the description of the design and speci-c input parameters for that particular simulation run. Simulations can be very expensive. We typically need to simulate many possible design alternatives on many different input sets and each experiment may take days to complete on a high performance machine. Instead of writing a simulator that interprets the design it is faster to compile the design to produce machine code that simulates that particular design natively. Compiled simulation can run orders of magnitude faster than an interpreter based approach. Compiled simulation is used in many state of the art tools that simulate designs written in Verilog or VHDL.

155 Software Productivity Tools

Programs are arguably the most complicated engineering artifacts ever produced they consist of many many details every one of which must be correct before the program will work completely. As a result errors are rampant in programs errors may crash a system produce wrong results render a system vulnerable to security attacks or even lead to catastrophic failures in critical systems. Testing is the primary technique for locating errors in programs

An interesting and promising complementary approach is to use data ow analysis to locate errors statically that is before the program is run Data ow analysis can nd errors along all the possible execution paths and not just those exercised by the input data sets as in the case of program testing Many of the data ow analysis techniques originally developed for compiler optimizations can be used to create tools that assist programmers in their software engineering tasks

The problem of nding all program errors is undecidable A data ow anal ysis may be designed to warn the programmers of all possible statements with a particular category of errors But if most of these warnings are false alarms users will not use the tool. Thus practical error detectors are often neither sound nor complete. That is they may not all the errors in the program and not all errors reported are guaranteed to be real errors. Nonetheless various static analyses have been developed and shown to be elective in anding errors such as dereferencing null or freed pointers in real programs. The fact that error detectors may be unsound makes them significantly different from compiler optimizations. Optimizers must be conservative and cannot alter the semantics of the program under any circumstances.

In the balance of this section we shall mention several ways in which program analysis building upon techniques originally developed to optimize code in compilers have improved software productivity. Of special importance are techniques that detect statically when a program might have a security vulner ability

Type Checking

Type checking is an e ective and well established technique to catch inconsis tencies in programs. It can be used to catch errors for example where an operation is applied to the wrong type of object or if parameters passed to a procedure do not match the signature of the procedure. Program analysis can go beyond anding type errors by analyzing the ow of data through a program. For example, if a pointer is assigned null and then immediately dereferenced the program is clearly in error.

The same technology can be used to catch a variety of security holes in which an attacker supplies a string or other data that is used carelessly by the program. A user supplied string can be labeled with a type dangerous. If this string is not checked for proper format, then it remains dangerous and if a string of this type is able to in uence the control ow of the code at some point in the program, then there is a potential security aw

Bounds Checking

It is easier to make mistakes when programming in a lower level language than a higher level one. For example, many security breaches in systems are caused by bu er over ows in programs written in C. Because C does not have array bounds checks it is up to the user to ensure that the arrays are not accessed out of bounds. Failing to check that the data supplied by the user can over ow a bu er the program may be tricked into storing user data outside of the bu er. An attacker can manipulate the input data that causes the program to misbehave and compromise the security of the system. Techniques have been developed to and bu er over owe in programs but with limited success.

Had the program been written in a safe language that includes automatic range checking this problem would not have occurred. The same data ow analysis that is used to eliminate redundant range checks can also be used to locate bu er over ows. The major difference however is that failing to eliminate a range check would only result in a small run time cost while failing to identify a potential bu er over ow may compromise the security of the system. Thus while it is adequate to use simple techniques to optimize range checks so phisticated analyses such as tracking the values of pointers across procedures are needed to get high quality results in error detection tools.

1.6 PROGRAMMING LANGUAGE BASICS

Memory Management Tools

Garbage collection is another excellent example of the tradeo between e ciency and a combination of ease of programming and software reliability. Au tomatic memory management obliterates all memory management errors e.g. memory leaks—which are a major source of problems in C and C—programs—Various tools have been developed to help programmers—nd memory management errors—For example—Purify is a widely used tool that dynamically catches memory management errors as they occur—Tools that help identify some of these problems statically have also been developed

1 6 Programming Language Basics

In this section we shall cover the most important terminology and distinctions that appear in the study of programming languages. It is not our purpose to cover all concepts or all the popular programming languages. We assume that the reader is familiar with at least one of C. C. or Java, and may have encountered other languages as well

161 The Static Dynamic Distinction

Among the most important issues that we face when designing a compiler for a language is what decisions can the compiler make about a program. If a language uses a policy that allows the compiler to decide an issue then we say that the language uses a *static* policy or that the issue can be decided at *compile time*. On the other hand, a policy that only allows a decision to be made when we execute the program is said to be a *dynamic policy* or to require a decision at *run time*.

One issue on which we shall concentrate is the scope of declarations. The scope of a declaration of x is the region of the program in which uses of x refer to this declaration. A language uses $static\ scope$ or $lexical\ scope$ if it is possible to determine the scope of a declaration by looking only at the program. Otherwise the language uses $dynamic\ scope$. With dynamic scope as the program runs the same use of x could refer to any of several different declarations of x

Most languages $\,$ such as C and Java $\,$ use static scope $\,$ We shall discuss static scoping in Section 1 6 3

Example 1 3 As another example of the static dynamic distinction consider the use of the term static as it applies to data in a Java class declaration In Java a variable is a name for a location in memory used to hold a data value Here—static—refers not to the scope of the variable but rather to the ability of the compiler to determine the location in memory where the declared variable can be found. A declaration like

public static int x

makes x a class variable and says that there is only one copy of x no matter how many objects of this class are created. Moreover, the compiler can determine a location in memory where this integer x will be held. In contrast, had, static been omitted from this declaration, then each object of the class would have its own location where x would be held, and the compiler could not determine all these places in advance of running the program.

1 6 2 Environments and States

Another important distinction we must make when discussing programming languages is whether changes occurring as the program runs a ect the values of data elements or a ect the interpretation of names for that data. For example the execution of an assignment such as $\mathbf{x} - \mathbf{y} - \mathbf{1}$ changes the value denoted by the name x. More specifically, the assignment changes the value in whatever location is denoted by x

It may be less clear that the location denoted by x can change at run time For instance as we discussed in Example 1.3 if x is not a static or class variable then every object of the class has its own location for an instance of variable x. In that case the assignment to x can change any of those in stance variables depending on the object to which a method containing that assignment is applied

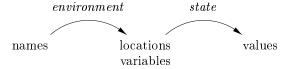

Figure 1 8 Two stage mapping from names to values

The association of names with locations in memory the *store* and then with values can be described by two mappings that change as the program runs see Fig. 1.8

- 1 The *environment* is a mapping from names to locations in the store Since variables refer to locations—I values—in the terminology of C—we could alternatively de—ne an environment as a mapping from names to variables
- 2 The *state* is a mapping from locations in store to their values. That is the state maps I values to their corresponding r values in the terminology of C

Environments change according to the scope rules of a language

Example 1 4 Consider the C program fragment in Fig. 1.9 Integer i is declared a global variable and also declared as a variable local to function f. When f is executing the environment adjusts so that name i refers to the

16 PROGRAMMING LANGUAGE BASICS

```
int i global i

void f

int i local i

i 3 use of local i

x i 1 use of global i
```

Figure 1.9 Two declarations of the name i

location reserved for the i that is local to f and any use of i such as the assignment i 3 shown explicitly refers to that location. Typically the local i is given a place on the run time stack

Whenever a function g other than f is executing uses of i cannot refer to the i that is local to f Uses of name i in g must be within the scope of some other declaration of i An example is the explicitly shown statement $\mathbf{x} = \mathbf{i} = \mathbf{1}$ which is inside some procedure whose de nition is not shown. The i in i 1 presumably refers to the global i As in most languages declarations in C must precede their use so a function that comes before the global i cannot refer to it. \Box

The environment and state mappings in Fig $\,1\,8$ are dynamic $\,$ but there are a few exceptions

- 1 Static versus dynamic binding of names to locations Most binding of names to locations is dynamic and we discuss several approaches to this binding throughout the section Some declarations such as the global i in Fig 1 9 can be given a location in the store once and for all as the compiler generates object code 2
- 2 Static versus dynamic binding of locations to values The binding of locations to values the second stage in Fig 1.8 is generally dynamic as well since we cannot tell the value in a location until we run the program Declared constants are an exception For instance the C de nition

define ARRAYSIZE 1000

²Technically the C compiler will assign a location in virtual memory for the global i leaving it to the loader and the operating system to determine where in the physical memory of the machine i will be located. However we shall not worry about relocation issues such as these which have no impact on compiling. Instead we treat the address space that the compiler uses for its output code as if it gave physical memory locations

Names Identi ers and Variables

Although the terms name and variable often refer to the same thing we use them carefully to distinguish between compile time names and the run time locations denoted by names

An *identi* er is a string of characters typically letters or digits that refers to identi es an entity such as a data object a procedure a class or a type. All identi ers are names but not all names are identi ers. Names can also be expressions. For example, the name x y might denote the eld y of a structure denoted by x. Here x and y are identi ers while x y is a name, but not an identi er. Composite names like x y are called quali ed names.

A variable refers to a particular location of the store. It is common for the same identifier to be declared more than once each such declaration introduces a new variable. Even if each identifier is declared just once an identifier local to a recursive procedure will refer to different locations of the store at different times.

binds the name ARRAYSIZE to the value 1000 statically. We can determine this binding by looking at the statement and we know that it is impossible for this binding to change when the program executes

1 6 3 Static Scope and Block Structure

Most languages including C and its family use static scope. The scope rules for C are based on program structure the scope of a declaration is determined implicitly by where the declaration appears in the program. Later languages such as C. Java and C. also provide explicit control over scopes through the use of keywords like **public private** and **protected**.

In this section we consider static scope rules for a language with blocks where a block is a grouping of declarations and statements. C uses braces—and to delimit a block—the alternative use of begin and end for the same purpose dates back to Algol

Example 1 5 To a rst approximation the C static scope policy is as follows

- 1 A C program consists of a sequence of top level declarations of variables and functions
- 2 Functions may have variable declarations within them where variables include local variables and parameters. The scope of each such declaration is restricted to the function in which it appears

Procedures Functions and Methods

To avoid saying procedures functions or methods each time we want to talk about a subprogram that may be called we shall usually refer to all of them as procedures. The exception is that when talking explicitly of programs in languages like C that have only functions we shall refer to them as functions. Or if we are discussing a language like Java that has only methods we shall use that term instead

A function generally returns a value of some type—the—return type—while a procedure does not return any value—C and similar languages which have only functions—treat procedures as functions that have a special return type—void—to signify no return value—Object oriented languages like Java and C—use the term—methods—These can behave like either functions or procedures—but are associated with a particular class

3 The scope of a top level declaration of a name x consists of the entire program that follows with the exception of those statements that lie within a function that also has a declaration of x

The additional detail regarding the C static scope policy deals with variable declarations within statements. We examine such declarations next and in Example 1.6 $\quad\Box$

In C the syntax of blocks is given by

- 1 One type of statement is a block Blocks can appear anywhere that other types of statements such as assignment statements can appear
- 2 A block is a sequence of declarations followed by a sequence of statements all surrounded by braces

Note that this syntax allows blocks to be nested inside each other. This nesting property is referred to as *block structure*. The C family of languages has block structure, except that a function may not be defined inside another function.

We say that a declaration D—belongs—to a block B if B is the most closely nested block containing D—that is—D—is located within B—but not within any block that is nested within B

The static scope rule for variable declarations in block structured languages is as follows. If declaration D of name x belongs to block B, then the scope of D is all of B except for any blocks B' nested to any depth within B in which x is redeclared. Here x is redeclared in B' if some other declaration D' of the same name x belongs to B'

An equivalent way to express this rule is to focus on a use of a name x Let B_1 B_2 B_k be all the blocks that surround this use of x with B_k the smallest nested within B_{k-1} which is nested within B_{k-2} and so on Search for the largest i such that there is a declaration of x belonging to B_i . This use of x refers to the declaration in B_i . Alternatively this use of x is within the scope of the declaration in B_i

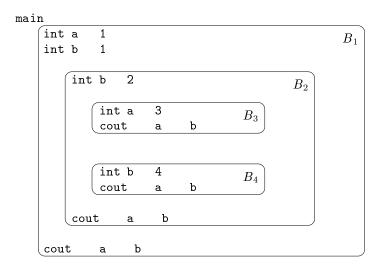

Figure 1 10 Blocks in a C program

Example 1 6 The C program in Fig 1 10 has four blocks with several de nitions of variables a and b As a memory aid each declaration initializes its variable to the number of the block to which it belongs

For instance consider the declaration int a 1 in block B_1 Its scope is all of B_1 except for those blocks nested perhaps deeply within B_1 that have their own declaration of a B_2 nested immediately within B_1 does not have a declaration of a but B_3 does B_4 does not have a declaration of a so block B_3 is the only place in the entire program that is outside the scope of the declaration of the name a that belongs to B_1 That is this scope includes B_4 and all of B_2 except for the part of B_2 that is within B_3 The scopes of all ve declarations are summarized in Fig. 1.11

From another point of view let us consider the output statement in block B_4 and bind the variables a and b used there to the proper declarations. The list of surrounding blocks in order of increasing size is B_4 B_2 B_1 . Note that B_3 does not surround the point in question B_4 has a declaration of b so it is to this declaration that this use of b refers and the value of b printed is 4. However B_4 does not have a declaration of a so we next look at B_2 . That block does not have a declaration of a either so we proceed to B_1 . Fortunately

16 PROGRAMMING LANGUAGE BASICS

DECLAR	RATION	SCOPE
int a	1	B_1 B_3
int b	1	B_1 B_2
int b	2	B_2 B_4
int a	3	B_3
int b	4	B_4

Figure 1 11 Scopes of declarations in Example 1 6

there is a declaration int a 1 belonging to that block so the value of a printed is 1 Had there been no such declaration the program would have been erroneous \Box

164 Explicit Access Control

Classes and structures introduce a new scope for their members. If p is an object of a class with a eld member x then the use of x in p x refers to eld x in the class de nition. In analogy with block structure, the scope of a member declaration x in a class C extends to any subclass C' except if C' has a local declaration of the same name x

Through the use of keywords like **public private** and **protected** object oriented languages such as C or Java provide explicit control over access to member names in a superclass. These keywords support *encapsulation* by restricting access. Thus private names are purposely given a scope that includes only the method declarations and definitions associated with that class and any friend classes the C term. Protected names are accessible to subclasses. Public names are accessible from outside the class.

In C — a class de nition may be separated from the de nitions of some or all of its methods—Therefore a name x associated with the class C may have a region of the code that is outside its scope—followed by another region—a method de nition—that is within its scope—In fact—regions inside and outside the scope may alternate—until all the methods have been de—ned

165 Dynamic Scope

Technically any scoping policy is dynamic if it is based on factor s that can be known only when the program executes The term $dynamic\ scope$ however usually refers to the following policy a use of a name x refers to the declaration of x in the most recently called not yet terminated procedure with such a declaration Dynamic scoping of this type appears only in special situations. We shall consider two examples of dynamic policies macro expansion in the C preprocessor and method resolution in object oriented programming

Declarations and De nitions

The apparently similar terms declaration and de nition for program ming language concepts are actually quite di erent. Declarations tell us about the types of things while de nitions tell us about their values. Thus int i is a declaration of i while i 1 is a de nition of i

The difference is more significant when we deal with methods or other procedures. In C — a method is declared in a class definition by giving the types of the arguments and result of the method often called the signature for the method. The method is then defined if eithe code for executing the method is given in another place. Similarly, it is common to define a C function in one left and declare it in other less where the function is used.

Example 1 7 In the C program of Fig. 1.12 identifier a is a macro that stands for expression x 1. But what is x. We cannot resolve x statically that is in terms of the program text

```
define a x 1
int x 2
void b int x 1 printf d n a
void c printf d n a
void main b c
```

Figure 1 12 A macro whose names must be scoped dynamically

In fact in order to interpret x we must use the usual dynamic scope rule We examine all the function calls that are currently active and we take the most recently called function that has a declaration of x It is to this declaration that the use of x refers

In the example of Fig. 1.12 the function main rst calls function b. As b executes it prints the value of the macro a. Since x 1 must be substituted for a we resolve this use of x to the declaration int x 1 in function b. The reason is that b has a declaration of x so the x 1 in the printf in b refers to this x. Thus the value printed is 2

After b nishes and c is called we again need to print the value of macro a. However, the only x accessible to c is the global x. The printf statement in c thus refers to this declaration of x and value x is printed. x

Dynamic scope resolution is also essential for polymorphic procedures those that have two or more de nitions for the same name depending only on the

Analogy Between Static and Dynamic Scoping

While there could be any number of static or dynamic policies for scoping there is an interesting relationship between the normal block structured static scoping rule and the normal dynamic policy. In a sense, the dynamic rule is to time as the static rule is to space. While the static rule asks us to and the declaration whose unit block most closely surrounds the physical location of the use, the dynamic rule asks us to and the declaration whose unit procedure invocation most closely surrounds the time of the use.

types of the arguments In some languages such as ML see Section 7 3 3 it is possible to determine statically types for all uses of names in which case the compiler can replace each use of a procedure name p by a reference to the code for the proper procedure. However, in other languages, such as Java and C there are times when the compiler cannot make that determination

Example 1 8 A distinguishing feature of object oriented programming is the ability of each object to invoke the appropriate method in response to a message In other words the procedure called when x m is executed depends on the class of the object denoted by x at that time A typical example is as follows

- 1 There is a class C with a method named m
- 2 D is a subclass of C and D has its own method named m
- 3 There is a use of m of the form x m where x is an object of class C

Normally it is impossible to tell at compile time whether x will be of class C or of the subclass D. If the method application occurs several times it is highly likely that some will be on objects denoted by x that are in class C but not D while others will be in class D. It is not until run time that it can be decided which de nition of m is the right one. Thus, the code generated by the compiler must determine the class of the object x and call one or the other method named m. \square

1 6 6 Parameter Passing Mechanisms

All programming languages have a notion of a procedure but they can di er in how these procedures get their arguments. In this section, we shall consider how the actual parameters the parameters used in the call of a procedure are associated with the formal parameters, those used in the procedure de nition. Which mechanism is used determines how the calling sequence code treats parameters. The great majority of languages use either call by value or call by reference or both. We shall explain these terms and another method known as call by name, that is primarily of historical interest.

Call by Value

In call by value the actual parameter is evaluated if it is an expression or copied if it is a variable. The value is placed in the location belonging to the corresponding formal parameter of the called procedure. This method is used in C and Java and is a common option in C — as well as in most other languages. Call by value has the elect that all computation involving the formal parameters done by the called procedure is local to that procedure and the actual parameters themselves cannot be changed.

Note however that in C we can pass a pointer to a variable to allow that variable to be changed by the callee Likewise array names passed as parameters in C C or Java give the called procedure what is in e ect a pointer or reference to the array itself. Thus if a is the name of an array of the calling procedure and it is passed by value to corresponding formal parameter x then an assignment such as x i 2 really changes the array element a i to 2. The reason is that although x gets a copy of the value of a that value is really a pointer to the beginning of the area of the store where the array named a is located

Similarly in Java many variables are really references or pointers to the things they stand for This observation applies to arrays strings and objects of all classes. Even though Java uses call by value exclusively whenever we pass the name of an object to a called procedure the value received by that procedure is in e ect a pointer to the object. Thus, the called procedure is able to a ect the value of the object itself

Call by Reference

In call by reference the address of the actual parameter is passed to the callee as the value of the corresponding formal parameter. Uses of the formal parameter in the code of the callee are implemented by following this pointer to the location indicated by the caller. Changes to the formal parameter thus appear as changes to the actual parameter.

If the actual parameter is an expression however then the expression is evaluated before the call and its value stored in a location of its own Changes to the formal parameter change the value in this location but can have no e ect on the data of the caller

Call by reference is used for ref parameters in C and is an option in many other languages. It is almost essential when the formal parameter is a large object array or structure. The reason is that strict call by value requires that the caller copy the entire actual parameter into the space belonging to the corresponding formal parameter. This copying gets expensive when the parameter is large. As we noted when discussing call by value languages such as Java solve the problem of passing arrays strings or other objects by copying only a reference to those objects. The elect is that Java behaves as if it used call by reference for anything other than a basic type such as an integer or real

16 PROGRAMMING LANGUAGE BASICS

Call by Name

A third mechanism call by name was used in the early programming language Algol 60 It requires that the callee execute as if the actual parameter were substituted literally for the formal parameter in the code of the callee as if the formal parameter were a macro standing for the actual parameter with renaming of local names in the called procedure to keep them distinct. When the actual parameter is an expression rather than a variable some unintuitive behaviors occur which is one reason this mechanism is not favored today.

167 Aliasing

There is an interesting consequence of call by reference parameter passing or its simulation as in Java where references to objects are passed by value. It is possible that two formal parameters can refer to the same location such variables are said to be *aliases* of one another. As a result any two variables which may appear to take their values from two distinct formal parameters can become aliases of each other as well

It turns out that understanding aliasing and the mechanisms that create it is essential if a compiler is to optimize a program. As we shall see starting in Chapter 9, there are many situations where we can only optimize code if we can be sure certain variables are not aliased. For instance, we might determine that $\mathbf{x} = 2$ is the only place that variable x is ever assigned. If so, then we can replace a use of x by a use of 2 for example replace a $\mathbf{x} = 3$ by the simpler a $\mathbf{x} = 5$ But suppose there were another variable \mathbf{y} that was aliased to \mathbf{x} . Then an assignment $\mathbf{y} = 4$ might have the unexpected eject of changing \mathbf{x} . It might also mean that replacing a $\mathbf{x} = 3$ by a $\mathbf{x} = 5$ was a mistake, the proper value of $\mathbf{x} = 4$ could be 7 there.

17 Summary of Chapter 1

- → Language Processors An integrated software development environment includes many di erent kinds of language processors such as compilers interpreters assemblers linkers loaders debuggers pro lers
- ◆ Compiler Phases A compiler operates as a sequence of phases each of which transforms the source program from one intermediate representation to another

17 SUMMARY OF CHAPTER 1

- ♦ Machine and Assembly Languages Machine languages were the rst generation programming languages followed by assembly languages Programming in these languages was time consuming and error prone
- ◆ Modeling in Compiler Design Compiler design is one of the places where theory has had the most impact on practice Models that have been found useful include automata grammars regular expressions trees and many others
- ◆ Code Optimization Although code cannot truly be optimized the sci ence of improving the e ciency of code is both complex and very important It is a major portion of the study of compilation
- ♦ Higher Level Languages As time goes on programming languages take on progressively more of the tasks that formerly were left to the program mer such as memory management type consistency checking or parallel execution of code
- ◆ Compilers and Computer Architecture Compiler technology in uences computer architecture as well as being in uenced by the advances in ar chitecture Many modern innovations in architecture depend on compilers being able to extract from source programs the opportunities to use the hardware capabilities e ectively
- ◆ Software Productivity and Software Security The same technology that allows compilers to optimize code can be used for a variety of program analysis tasks ranging from detecting common program bugs to discovering that a program is vulnerable to one of the many kinds of intrusions that hackers have discovered
- ightharpoonup Scope Rules The scope of a declaration of x is the context in which uses of x refer to this declaration. A language uses static scope or lexical scope if it is possible to determine the scope of a declaration by looking only at the program. Otherwise, the language uses dynamic scope
- ◆ Environments The association of names with locations in memory and then with values can be described in terms of environments which map names to locations in store and states which map locations to their values
- ightharpoonup Block Structure Languages that allow blocks to be nested are said to have block structure A name x in a nested block B is in the scope of a declaration D of x in an enclosing block if there is no other declaration of x in an intervening block
- ◆ Parameter Passing Parameters are passed from a calling procedure to the callee either by value or by reference When large objects are passed by value the values passed are really references to the objects themselves resulting in an elective call by reference

◆ Aliasing When parameters are electively passed by reference two for mal parameters can refer to the same object. This possibility allows a change in one variable to change another.

Chapter 2

A Simple Syntax Directed Translator

This chapter is an introduction to the compiling techniques in Chapters 3 through 6 of this book. It illustrates the techniques by developing a working Java program that translates representative programming language statements into three address code an intermediate representation. In this chapter, the emphasis is on the front end of a compiler in particular on lexical analysis parsing, and intermediate code generation. Chapters 7 and 8 show how to generate machine instructions from three address code.

We start small by creating a syntax directed translator that maps in $\, x$ arith metic expressions into post $\, x$ expressions. We then extend this translator to map code fragments as shown in Fig. 2.1 into three address code of the form in Fig. 2.2

The working Java translator appears in Appendix A
The use of Java is convenient but not essential
In fact the ideas in this chapter predate the creation of both Java and C

```
int i int j float 100 a float v float x
while true
   do i i 1 while a i v
   do j j 1 while a j v
   if i j break
   x a i a i a j a j x
```

Figure 2 2 Simpli ed intermediate code for the program fragment in Fig 2 1

2.1 Introduction

The analysis phase of a compiler breaks up a source program into constituent pieces and produces an internal representation for it called intermediate code The synthesis phase translates the intermediate code into the target program

Analysis is organized around the syntax of the language to be compiled The syntax of a programming language describes the proper form of its programs while the semantics of the language denes what its programs mean that is what each program does when it executes For specifying syntax we present a widely used notation called context free grammars or BNF for Backus Naur Form in Section 2.2 With the notations currently available the semantics of a language is much more discult to describe than the syntax. For specifying semantics we shall therefore use informal descriptions and suggestive examples

Besides specifying the syntax of a language a context free grammar can be used to help guide the translation of programs. In Section 2.3 we introduce a grammar oriented compiling technique known as *syntax directed translation* Parsing or syntax analysis is introduced in Section 2.4

The rest of this chapter is a quick tour through the model of a compiler front end in Fig. 2.3. We begin with the parser. For simplicity, we consider the syntax directed translation of in x expressions to post x form a notation in which operators appear after their operands. For example, the post x form of the expression 9 5 2 is 95 2. Translation into post x form is rich enough to illustrate syntax analysis, yet simple enough that the translator is shown in full in Section 2.5. The simple translator handles expressions like 9 5 2 consisting of digits separated by plus and minus signs. One reason for starting with such simple expressions is that the syntax analyzer can work directly with the individual characters for operators and operands

2.1 INTRODUCTION

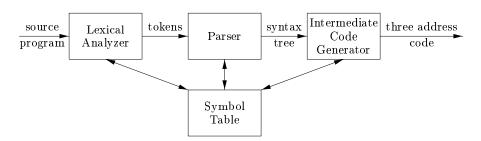

Figure 2 3 A model of a compiler front end

A lexical analyzer allows a translator to handle multicharacter constructs like identi ers which are written as sequences of characters but are treated as units called *tokens* during syntax analysis for example in the expression count 1 the identi er count is treated as a unit. The lexical analyzer in Section 2 6 allows numbers identi ers and white space blanks tabs and newlines to appear within expressions

Next we consider intermediate code generation. Two forms of intermediate code are illustrated in Fig. 2.4. One form called abstract syntax trees or simply syntax trees represents the hierarchical syntactic structure of the source program. In the model in Fig. 2.3, the parser produces a syntax tree that is further translated into three address code. Some compilers combine parsing and intermediate code generation into one component

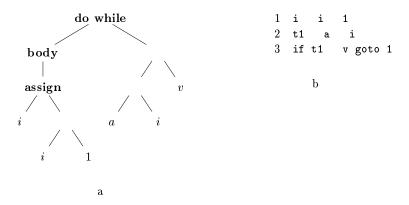

Figure 2 4 Intermediate code for do i i 1 while a i v

The root of the abstract syntax tree in Fig 2 4 a represents an entire do while loop. The left child of the root represents the body of the loop which consists of only the assignment i i 1. The right child of the root represents the condition a i v. An implementation of syntax trees appears in Section 2 8.

The other common intermediate representation shown in Fig 2 4 b is a

sequence of three address instructions a more complete example appears in Fig 2.2. This form of intermediate code takes its name from instructions of the form x-y op z where op is a binary operator y and z are the addresses for the operands and x is the address for the result of the operation. A three address instruction carries out at most one operation typically a computation a comparison or a branch

In Appendix A we put the techniques in this chapter together to build a compiler front end in Java The front end translates statements into assembly level instructions

2 2 Syntax De nition

In this section we introduce a notation the context free grammar or grammar for short that is used to specify the syntax of a language Gram mars will be used throughout this book to organize compiler front ends

A grammar naturally describes the hierarchical structure of most program ming language constructs For example an if else statement in Java can have the form

if expression statement else statement

That is an if else statement is the concatenation of the keyword **if** an open ing parenthesis an expression a closing parenthesis a statement the keyword **else** and another statement. Using the variable expr to denote an expression and the variable stmt to denote a statement this structuring rule can be expressed as

stmt if expr stmt else stmt

in which the arrow may be read as can have the form. Such a rule is called a production. In a production, lexical elements like the keyword if and the parentheses are called terminals. Variables like expr and stmt represent sequences of terminals and are called nonterminals.

2 2 1 De nition of Grammars

A context free grammar has four components

- 1 A set of *terminal* symbols sometimes referred to as tokens. The terminals are the elementary symbols of the language denied by the grammar
- 2 A set of *nonterminals* sometimes called syntactic variables Each non terminal represents a set of strings of terminals in a manner we shall describe
- 3 A set of *productions* where each production consists of a nonterminal called the *head* or *left side* of the production an arrow and a sequence of

Tokens Versus Terminals

In a compiler the lexical analyzer reads the characters of the source program groups them into lexically meaningful units called lexemes and produces as output tokens representing these lexemes. A token consists of two components a token name and an attribute value. The token names are abstract symbols that are used by the parser for syntax analysis. Often we shall call these token names terminals since they appear as terminal symbols in the grammar for a programming language. The attribute value if present is a pointer to the symbol table that contains additional information about the token. This additional information is not part of the grammar so in our discussion of syntax analysis often we refer to tokens and terminals synonymously

terminals and or nonterminals called the body or right side of the production. The intuitive intent of a production is to specify one of the written forms of a construct if the head nonterminal represents a construct then the body represents a written form of the construct

4 A designation of one of the nonterminals as the start symbol

We specify grammars by listing their productions with the productions for the start symbol listed rst We assume that digits signs such as and and boldface strings such as **while** are terminals. An italicized name is a nonterminal and any nonitalicized name or symbol may be assumed to be a terminal ¹ For notational convenience productions with the same nonterminal as the head can have their bodies grouped with the alternative bodies separated by the symbol | which we read as or

Example 2.1 Several examples in this chapter use expressions consisting of digits and plus and minus signs e.g. strings such as 9 5 2 3 1 or 7 Since a plus or minus sign must appear between two digits we refer to such expressions as lists of digits separated by plus or minus signs. The following grammar describes the syntax of these expressions. The productions are

list	$list \qquad digit$	2 1
list	$list \qquad digit$	2 2
list	digit	2 3
digit	0 1 2 3 4 5 6 7 8 9	$2\ 4$

 $^{^1\}mathrm{Individual}$ italic letters will be used for additional purposes especially when grammars are studied in detail in Chapter 4. For example, we shall use X . Y and Z to talk about a symbol that is either a terminal or a nonterminal. However, any italicized name containing two or more characters will continue to represent a nonterminal.

The bodies of the three productions with nonterminal list as head equivalently can be grouped

list list digit | list digit | digit

According to our conventions the terminals of the grammar are the symbols

0 1 2 3 4 5 6 7 8 9

The nonterminals are the italicized names list and digit with list being the start symbol because its productions are given—rst—

We say a production is for a nonterminal if the nonterminal is the head of the production. A string of terminals is a sequence of zero or more terminals. The string of zero terminals written as for is called the for is called the for is called the for is called the for is for in for is for in for in for in for is for in for

2 2 2 Derivations

A grammar derives strings by beginning with the start symbol and repeatedly replacing a nonterminal by the body of a production for that nonterminal The terminal strings that can be derived from the start symbol form the *language* de ned by the grammar

Example 2 2 The language de ned by the grammar of Example 2 1 consists of lists of digits separated by plus and minus signs. The ten productions for the nonterminal *digit* allow it to stand for any of the terminals 0 1 9 From production 2 3 a single digit by itself is a list. Productions 2 1 and 2 2 express the rule that any list followed by a plus or minus sign and then another digit makes up a new list.

Productions 2.1 to 2.4 are all we need to de ne the desired language For example we can deduce that 9.5 2 is a *list* as follows

- a 9 is a *list* by production 2.3 since 9 is a *digit*
- b 9 5 is a list by production 2 2 since 9 is a list and 5 is a digit
- c 9 5 2 is a list by production 2 1 since 9 5 is a list and 2 is a digit

Example 2 3 A somewhat di erent sort of list is the list of parameters in a function call In Java the parameters are enclosed within parentheses as in the call max x y of function max with parameters x and y One nuance of such lists is that an empty list of parameters may be found between the terminals and We may start to develop a grammar for such sequences with the productions

²Technically can be a string of zero symbols from any alphabet collection of symbols

2 2 SYNTAX DEFINITION

 $egin{array}{lll} call & {f id} & optparams \ optparams & params & | \ params & params & param & param \end{array}$

Note that the second possible body for optparams optional parameter list is which stands for the empty string of symbols. That is optparams can be replaced by the empty string so a call can consist of a function name followed by the two terminal string. Notice that the productions for params are analogous to those for list in Example 2.1 with comma in place of the arithmetic operator or and param in place of digit. We have not shown the productions for param since parameters are really arbitrary expressions. Shortly, we shall discuss the appropriate productions for the various language constructs such as expressions statements and so on \Box

Parsing is the problem of taking a string of terminals and guring out how to derive it from the start symbol of the grammar and if it cannot be derived from the start symbol of the grammar then reporting syntax errors within the string Parsing is one of the most fundamental problems in all of compiling the main approaches to parsing are discussed in Chapter 4. In this chapter for simplicity we begin with source programs like 9.5.2 in which each character is a terminal in general a source program has multicharacter lexemes that are grouped by the lexical analyzer into tokens whose rst components are the terminals processed by the parser

2 2 3 Parse Trees

A parse tree pictorially shows how the start symbol of a grammar derives a string in the language. If nonterminal A has a production A XYZ then a parse tree may have an interior node labeled A with three children labeled X Y and Z from left to right

Formally given a context free grammar a parse tree according to the gram mar is a tree with the following properties

- 1 The root is labeled by the start symbol
- 2 Each leaf is labeled by a terminal or by
- 3 Each interior node is labeled by a nonterminal
- 4 If A is the nonterminal labeling some interior node and X_1 X_2 X_n are the labels of the children of that node from left to right then there must be a production A X_1X_2 X_n Here X_1 X_2 X_n each stand

Tree Terminology

Tree data structures gure prominently in compiling

A tree consists of one or more *nodes* Nodes may have *labels* which in this book typically will be grammar symbols. When we draw a tree we often represent the nodes by these labels only

Exactly one node is the *root* All nodes except the root have a unique *parent* the root has no parent. When we draw trees we place the parent of a node above that node and draw an edge between them. The root is then the highest top node

If node N is the parent of node M then M is a *child* of N. The children of one node are called *siblings*. They have an order *from the left* and when we draw trees we order the childen of a given node in this manner.

A node with no children is called a *leaf* Other nodes those with one or more children are *interior nodes*

A descendant of a node N is either N itself a child of N a child of a child of N and so on for any number of levels. We say node N is an ancestor of node M if M is a descendant of N

for a symbol that is either a terminal or a nonterminal As a special case if A is a production then a node labeled A may have a single child labeled

Example 2 4 The derivation of 9 5 2 in Example 2 2 is illustrated by the tree in Fig 2 5 Each node in the tree is labeled by a grammar symbol An interior node and its children correspond to a production the interior node corresponds to the head of the production the children to the body

In Fig 2.5 the root is labeled list the start symbol of the grammar in Example 2.1. The children of the root are labeled from left to right list and digit. Note that

list list digit

is a production in the grammar of Example 2.1 The left child of the root is similar to the root with a child labeled instead of The three nodes labeled digit each have one child that is labeled by a digit \Box

From left to right the leaves of a parse tree form the *yield* of the tree which is the string *generated* or *derived* from the nonterminal at the root of the parse

2 2 SYNTAX DEFINITION

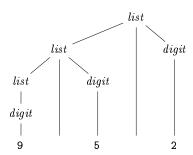

Figure 2.5 Parse tree for 9.5.2 according to the grammar in Example 2.1

tree In Fig 2.5 the yield is 9.5.2 for convenience all the leaves are shown at the bottom level. Henceforth, we shall not necessarily line up the leaves in this way. Any tree imparts a natural left to right order to its leaves based on the idea that if X and Y are two children with the same parent, and X is to the left of Y, then all descendants of X are to the left of descendants of Y.

Another de nition of the language generated by a grammar is as the set of strings that can be generated by some parse tree. The process of inding a parse tree for a given string of terminals is called *parsing* that string

2 2 4 Ambiguity

We have to be careful in talking about the structure of a string according to a grammar A grammar can have more than one parse tree generating a given string of terminals Such a grammar is said to be ambiguous. To show that a grammar is ambiguous all we need to do is not a terminal string that is the yield of more than one parse tree. Since a string with more than one parse tree usually has more than one meaning we need to design unambiguous grammars for compiling applications or to use ambiguous grammars with additional rules to resolve the ambiguities

Example 2 5 Suppose we used a single nonterminal *string* and did not distinguish between digits and lists as in Example 2 1 We could have written the grammar

string string string string string | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9

Merging the notion of digit and list into the nonterminal string makes super cial sense because a single digit is a special case of a list

However Fig 2.6 shows that an expression like 9.5.2 has more than one parse tree with this grammar. The two trees for 9.5.2 correspond to the two ways of parenthesizing the expression. 9.5.2 and 9.5.2. This second parenthesization gives the expression the unexpected value 2 rather than the customary value 6. The grammar of Example 2.1 does not permit this interpretation. \Box

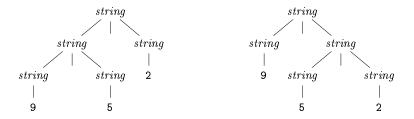

Figure 2.6 Two parse trees for 9.5.2

2 2 5 Associativity of Operators

By convention 9 5 2 is equivalent to 9 5 2 and 9 5 2 is equivalent to 9 5 2 When an operand like 5 has operators to its left and right conventions are needed for deciding which operator applies to that operand We say that the operator associates to the left because an operand with plus signs on both sides of it belongs to the operator to its left. In most programming languages the four arithmetic operators addition subtraction multiplication and division are left associative

Some common operators such as exponentiation are right associative. As another example, the assignment operator $\,$ in C and its descendants is right associative, that is, the expression a b c is treated in the same way as the expression a b c

Strings like ${\tt a}$ ${\tt b}$ ${\tt c}$ with a right associative operator are generated by the following grammar

$$egin{array}{lll} right & letter & right & letter \\ letter & a & b & z \\ \end{array}$$

The contrast between a parse tree for a left associative operator like and a parse tree for a right associative operator like is shown by Fig 2.7 Note that the parse tree for 9.5 2 grows down towards the left whereas the parse tree for a b c grows down towards the right

2 2 6 Precedence of Operators

Consider the expression 9 5 2 There are two possible interpretations of this expression 9 5 2 or 9 5 2 The associativity rules for and apply to occurrences of the same operator so they do not resolve this ambiguity Rules de ning the relative precedence of operators are needed when more than one kind of operator is present

We say that has higher precedence than if takes its operands before does In ordinary arithmetic multiplication and division have higher precedence than addition and subtraction Therefore 5 is taken by in both 9 5 2 and 9 5 2 ie the expressions are equivalent to 9 5 2 and 9 5 2 respectively

2 2 SYNTAX DEFINITION

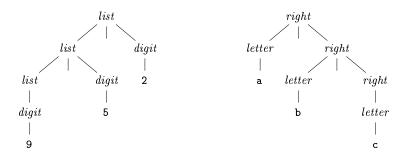

Figure 2 7 Parse trees for left and right associative grammars

Example 2 6 A grammar for arithmetic expressions can be constructed from a table showing the associativity and precedence of operators. We start with the four common arithmetic operators and a precedence table showing the operators in order of increasing precedence. Operators on the same line have the same associativity and precedence

left associative left associative

We create two nonterminals *expr* and *term* for the two levels of precedence and an extra nonterminal *factor* for generating basic units in expressions. The basic units in expressions are presently digits and parenthesized expressions

Now consider the binary operators and that have the highest prece dence Since these operators associate to the left the productions are similar to those for lists that associate to the left

$$egin{array}{lll} term & term & factor \ & term & factor \ & factor \end{array}$$

Similarly expr generates lists of terms separated by the additive operators

The resulting grammar is therefore

Generalizing the Expression Grammar of Example 2 6

We can think of a factor as an expression that cannot be torn apart by any operator By torn apart we mean that placing an operator next to any factor on either side does not cause any piece of the factor other than the whole to become an operand of that operator If the factor is a parenthesized expression the parentheses protect against such tearing while if the factor is a single operand it cannot be torn apart

A term that is not also a factor is an expression that can be torn apart by operators of the highest precedence and but not by the lower precedence operators. An expression that is not a term or factor can be torn apart by any operator

We can generalize this idea to any number n of precedence levels. We need n-1 nonterminals. The rst like factor in Example 2.6 can never be torn apart. Typically, the production bodies for this nonterminal are only single operands and parenthesized expressions. Then, for each precedence level, there is one nonterminal representing expressions that can be torn apart only by operators at that level or higher. Typically, the productions for this nonterminal have bodies representing uses of the operators at that level plus one body that is just the nonterminal for the next higher level.

With this grammar an expression is a list of terms separated by either or signs and a term is a list of factors separated by or signs Notice that any parenthesized expression is a factor so with parentheses we can develop expressions that have arbitrarily deep nesting and arbitrarily deep trees

Example 2 7 Keywords allow us to recognize statements since most state ment begin with a keyword or a special character Exceptions to this rule include assignments and procedure calls The statements de ned by the am biguous grammar in Fig 2 8 are legal in Java

In the rst production for *stmt* the terminal **id** represents any identi er The productions for *expression* are not shown. The assignment statements specified by the rst production are legal in Java although Java treats as an assignment operator that can appear within an expression. For example, Java allows a b c which this grammar does not

The nonterminal stmts generates a possibly empty list of statements. The second production for stmts generates the empty list. The rst production generates a possibly empty list of statements followed by a statement

The placement of semicolons is subtle they appear at the end of every body that does not end in stmt This approach prevents the build up of semicolons after statements such as if and while which end with nested substatements When the nested substatement is an assignment or a do while a semicolon will be generated as part of the substatement \Box

2 2 SYNTAX DEFINITION

```
stmt id expression
| if expression stmt
| if expression stmt else stmt
| while expression stmt
| do stmt while expression
| stmts
| stmts stmt
```

2 2 7 Exercises for Section 2 2

Exercise 2 2 1 Consider the context free grammar

$$S$$
 S S S S S S S

- a Show how the string aa a can be generated by this grammar
- b Construct a parse tree for this string
- c What language does this grammar generate Justify your answer

Exercise 2 2 2 What language is generated by the following grammars In each case justify your answer

Exercise 2 2 3 Which of the grammars in Exercise 2 2 2 are ambiguous

Exercise 2 2 4 Construct unambiguous context free grammars for each of the following languages In each case show that your grammar is correct

- a Arithmetic expressions in post x notation
- b Left associative lists of identi ers separated by commas
- c Right associative lists of identi ers separated by commas
- d Arithmetic expressions of integers and identi ers with the four binary operators

e Add unary plus and minus to the arithmetic operators of d

Exercise 2 2 5

a Show that all binary strings generated by the following grammar have values divisible by 3 *Hint* Use induction on the number of nodes in a parse tree

num 11 | 1001 | $num \circ$ | num num

b Does the grammar generate all binary strings with values divisible by 3

Exercise 2 2 6 Construct a context free grammar for roman numerals

2 3 Syntax Directed Translation

Syntax directed translation is done by attaching rules or program fragments to productions in a grammar For example consider an expression expr generated by the production

expr $expr_1$ term

Here expr is the sum of the two subexpressions $expr_1$ and term The subscript in $expr_1$ is used only to distinguish the instance of expr in the production body from the head of the production We can translate expr by exploiting its structure as in the following pseudo code

translate $expr_1$ translate termhandle

Using a variant of this pseudocode we shall build a syntax tree for expr in Section 2 8 by building syntax trees for $expr_1$ and term and then handling by constructing a node for it For convenience the example in this section is the translation of in x expressions into post x notation

This section introduces two concepts related to syntax directed translation

Attributes An attribute is any quantity associated with a programming construct Examples of attributes are data types of expressions the num ber of instructions in the generated code or the location of the rst in struction in the generated code for a construct among many other possibilities. Since we use grammar symbols nonterminals and terminals to represent programming constructs we extend the notion of attributes from constructs to the symbols that represent them

2 3 SYNTAX DIRECTED TRANSLATION

Syntax directed translation schemes A translation scheme is a notation for attaching program fragments to the productions of a grammar The program fragments are executed when the production is used during syntax analysis. The combined result of all these fragment executions in the order induced by the syntax analysis produces the translation of the program to which this analysis synthesis process is applied

Syntax directed translations will be used throughout this chapter to trans late in x expressions into post x notation to evaluate expressions and to build syntax trees for programming constructs A more detailed discussion of syntax directed formalisms appears in Chapter 5

2 3 1 Post x Notation

The examples in this section deal with translation into post x notation. The $post\ x\ notation$ for an expression E can be defined inductively as follows

- 1 If E is a variable or constant then the post x notation for E is E itself
- 2 If E is an expression of the form E_1 op E_2 where op is any binary operator then the post x notation for E is E'_1 E'_2 op where E'_1 and E'_2 are the post x notations for E_1 and E_2 respectively
- 3 If E is a parenthesized expression of the form E_1 then the post x notation for E is the same as the post x notation for E_1

Example 2.8 The post x notation for 9.5 2 is 95.2 That is the translations of 9.5 and 2 are the constants themselves by rule 1. Then the translation of 9.5 is 95 by rule 2. The translation of 9.5 is the same by rule 3. Having translated the parenthesized subexpression we may apply rule 2 to the entire expression with 9.5 in the role of E_1 and 2 in the role of E_2 to get the result 95.2

As another example the post x notation for 9 5 2 is 952 That is 5 2 is rst translated into 52 and this expression becomes the second argument of the minus sign \Box

No parentheses are needed in post x notation because the position and arity number of arguments of the operators permits only one decoding of a post x expression. The trick is to repeatedly scan the post x string from the left until you and an operator. Then look to the left for the proper number of operands and group this operator with its operands. Evaluate the operator on the operands and replace them by the result. Then repeat the process continuing to the right and searching for another operator.

Example 2 9 Consider the post x expression 952 3 Scanning from the left we rst encounter the plus sign Looking to its left we nd operands 5 and 2 Their sum 7 replaces 52 and we have the string 97 3 Now the leftmost

operator is the minus sign and its operands are 9 and 7 Replacing these by the result of the subtraction leaves 23 Last the multiplication sign applies to 2 and 3 giving the result 6 \Box

2 3 2 Synthesized Attributes

The idea of associating quantities with programming constructs for example values and types with expressions can be expressed in terms of grammars. We associate attributes with nonterminals and terminals. Then we attach rules to the productions of the grammar these rules describe how the attributes are computed at those nodes of the parse tree where the production in question is used to relate a node to its children

A syntax directed de nition associates

- 1 With each grammar symbol a set of attributes and
- 2 With each production a set of *semantic rules* for computing the values of the attributes associated with the symbols appearing in the production

Attributes can be evaluated as follows. For a given input string x construct a parse tree for x. Then, apply the semantic rules to evaluate attributes at each node in the parse tree, as follows

Suppose a node N in a parse tree is labeled by the grammar symbol X. We write X a to denote the value of attribute a of X at that node. A parse tree showing the attribute values at each node is called an annotated parse tree. For example, Fig. 2.9 shows an annotated parse tree for 9.5.2 with an attribute t associated with the nonterminals expr and expr. The value 95.2 of the attribute at the root is the post x notation for 9.5.2. We shall see shortly how these expressions are computed

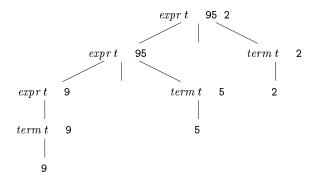

Figure 2 9 Attribute values at nodes in a parse tree

An attribute is said to be synthesized if its value at a parse tree node N is determined from attribute values at the children of N and at N itself. Synthesized

2 3 SYNTAX DIRECTED TRANSLATION

attributes have the desirable property that they can be evaluated during a sin gle bottom up traversal of a parse tree In Section 5 1 1 we shall discuss another important kind of attribute the inherited attribute Informally inherited at tributes have their value at a parse tree node determined from attribute values at the node itself its parent and its siblings in the parse tree

Example 2 10 The annotated parse tree in Fig 2 9 is based on the syntax directed de nition in Fig 2 10 for translating expressions consisting of digits separated by plus or minus signs into post x notation. Each nonterminal has a string valued attribute t that represents the post x notation for the expression generated by that nonterminal in a parse tree. The symbol || in the semantic rule is the operator for string concatenation

PRODUCTION			SEMANTIC RULES	
expr	$expr_1$	term	$expr\ t$	$expr_1 t \mid\mid term t \mid\mid ' \mid '$
expr	$expr_1$	term	$expr\ t$	$expr_1\ t\ \ term\ t\ \ '\ '$
expr	term		$expr\ t$	$term\ t$
term	0		$term\ t$	'0'
term	1		$term\ t$	11'
term	9		$term\ t$	'9'

Figure 2 10 Syntax directed de nition for in x to post x translation

The post x form of a digit is the digit itself e g the semantic rule associ ated with the production term 9 de nes $term\ t$ to be 9 itself whenever this production is used at a node in a parse tree. The other digits are translated similarly. As another example when the production expr term is applied the value of $term\ t$ becomes the value of $expr\ t$

The production expr $expr_1$ term derives an expression containing a plus operator ³ The left operand of the plus operator is given by $expr_1$ and the right operand by term The semantic rule

$$expr t$$
 $expr_1 t \mid\mid term t \mid\mid '$ '

associated with this production constructs the value of attribute $expr\ t$ by concatenating the post x forms $expr_1\ t$ and $term\ t$ of the left and right operands respectively and then appending the plus sign. This rule is a formalization of the de nition of post x expression.

 $^{^3}$ In this and many other rules the same nonterminal expr here appears several times. The purpose of the subscript 1 in $expr_1$ is to distinguish the two occurrences of expr in the production the 1 is not part of the nonterminal. See the box on Convention Distinguishing Uses of a Nonterminal for more details

Convention Distinguishing Uses of a Nonterminal

In rules we often have a need to distinguish among several uses of the same nonterminal in the head and or body of a production e.g. see Ex ample 2.10. The reason is that in the parse tree di erent nodes labeled by the same nonterminal usually have di erent values for their translations. We shall adopt the following convention the nonterminal appears unsubscripted in the head and with distinct subscripts in the body. These are all occurrences of the same nonterminal and the subscript is not part of its name. However, the reader should be alert to the di erence be tween examples of special content translations where this convention is used and generic productions like $A = X_1 X_2 = X_n$, where the subscripted X is represent an arbitrary list of grammar symbols, and are not instances of one particular nonterminal called X

2 3 3 Simple Syntax Directed De nitions

The syntax directed de nition in Example 2 10 has the following important property the string representing the translation of the nonterminal at the head of each production is the concatenation of the translations of the nonterminals in the production body in the same order as in the production with some optional additional strings interleaved A syntax directed de nition with this property is termed *simple*

Example 2 11 Consider the rst production and semantic rule from Fig 2 10

PRODUCTION SEMANTIC RULE
$$expr \ expr_1 \ term \ expr \ t \ expr_1 \ t \ || \ term \ t \ || \ ' \ '$$

Here the translation $expr\ t$ is the concatenation of the translations of $expr_1$ and term followed by the symbol — Notice that $expr_1$ and term appear in the same order in both the production body and the semantic rule — There are no additional symbols before or between their translations — In this example — the only extra symbol occurs at the end —

When translation schemes are discussed we shall see that a simple syntax directed de nition can be implemented by printing only the additional strings in the order they appear in the de nition

2 3 4 Tree Traversals

Tree traversals will be used for describing attribute evaluation and for specifying the execution of code fragments in a translation scheme A traversal of a tree starts at the root and visits each node of the tree in some order

2 3 SYNTAX DIRECTED TRANSLATION

A depth rst traversal starts at the root and recursively visits the children of each node in any order not necessarily from left to right. It is called depth rst because it visits an unvisited child of a node whenever it can so it visits nodes as far away from the root as deep as quickly as it can

The procedure $visit\ N$ in Fig. 2.11 is a depth - rst traversal that visits the children of a node in left to right order as shown in Fig. 2.12. In this traversal we have included the action of evaluating translations at each node just before we - nish with the node - that is after translations at the children have surely been computed - In general - the actions associated with a traversal can be whatever we choose or nothing at all

Figure 2 11 A depth sts traversal of a tree

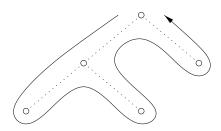

Figure 2 12 Example of a depth rst traversal of a tree

A syntax directed de nition does not impose any specic corder for the evaluation of attributes on a parse tree any evaluation order that computes an attribute a after all the other attributes that a depends on is acceptable. Synthesized attributes can be evaluated during any bottom up traversal that is a traversal that evaluates attributes at a node after having evaluated attributes at its children. In general, with both synthesized and inherited attributes, the matter of evaluation order is quite complex. See Section 5.2

2 3 5 Translation Schemes

The syntax directed de nition in Fig 2 10 builds up a translation by attaching strings as attributes to the nodes in the parse tree. We now consider an alter native approach that does not need to manipulate strings it produces the same translation incrementally by executing program fragments

Preorder and Postorder Traversals

Preorder and postorder traversals are two important special cases of depth rst traversals in which we visit the children of each node from left to right

Often we traverse a tree to perform some particular action at each node. If the action is done when we rst visit a node then we may refer to the traversal as a preorder traversal. Similarly, if the action is done just before we leave a node for the last time, then we say it is a postorder traversal of the tree. The procedure $visit\ N$ in Fig. 2.11 is an example of a postorder traversal

Preorder and postorder traversals de ne corresponding orderings on nodes based on when the action at a node would be performed. The preorder of a sub-tree rooted at node N consists of N followed by the preorders of the subtrees of each of its children if any from the left. The postorder of a sub-tree rooted at N consists of the postorders of each of the subtrees for the children of N if any from the left followed by N itself

A syntax directed translation scheme is a notation for specifying a translation by attaching program fragments to productions in a grammar A translation scheme is like a syntax directed denition except that the order of evaluation of the semantic rules is explicitly specified

Program fragments embedded within production bodies are called *semantic actions* The position at which an action is to be executed is shown by enclosing it between curly braces and writing it within the production body as in

$$rest$$
 $term$ {print ''} $rest_1$

We shall see such rules when we consider an alternative form of grammar for expressions where the nonterminal rest represents everything but the rst term of an expression. This form of grammar is discussed in Section 2.4.5 Again the subscript in $rest_1$ distinguishes this instance of nonterminal rest in the production body from the instance of rest at the head of the production

When drawing a parse tree for a translation scheme we indicate an action by constructing an extra child for it connected by a dashed line to the node that corresponds to the head of the production. For example, the portion of the parse tree for the above production and action is shown in Fig. 2.13. The node for a semantic action has no children, so the action is performed when that node is rst seen.

Example 2 12 The parse tree in Fig 2 14 has print statements at extra leaves which are attached by dashed lines to interior nodes of the parse tree The translation scheme appears in Fig 2 15 The underlying grammar gen erates expressions consisting of digits separated by plus and minus signs. The

2 3 SYNTAX DIRECTED TRANSLATION

Figure 2 13 An extra leaf is constructed for a semantic action

actions embedded in the production bodies translate such expressions into post \mathbf{x} notation provided we perform a left to right depth—rst traversal of the tree and execute each print statement when we visit its leaf

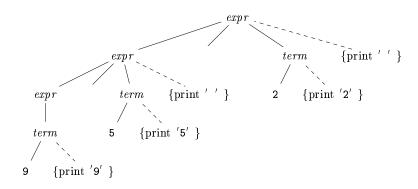

Figure 2 14 Actions translating 9 5 2 into 95 2

$egin{array}{c} expr \ expr \end{array}$	$egin{array}{c} expr_1 \ expr_1 \ term \end{array}$	term $term$	{print ' ' } {print ' ' }
term term	0 1		{print '0' } {print '1' }
term	9		{print '9' }

Figure 2 15 Actions for translating into post x notation

The root of Fig 2.14 represents the rst production in Fig 2.15. In a postorder traversal we rst perform all the actions in the leftmost subtree of the root for the left operand also labeled expr like the root. We then visit the leaf—at which there is no action. We next perform the actions in the subtree for the right operand term and—nally the semantic action { print ' '} at the extra node

Since the productions for term have only a digit on the right side that digit is printed by the actions for the productions. No output is necessary for the production expr term and only the operator needs to be printed in the

action for each of the $\,$ rst two productions. When executed during a postorder traversal of the parse tree $\,$ the actions in Fig. 2.14 print 95. 2.

Note that although the schemes in Fig 2 10 and Fig 2 15 produce the same translation they construct it di erently Fig 2 10 attaches strings as attributes to the nodes in the parse tree while the scheme in Fig 2 15 prints the translation incrementally through semantic actions

The semantic actions in the parse tree in Fig 2 14 translate the in x ex pression 9 5 2 into 95 2 by printing each character in 9 5 2 exactly once without using any storage for the translation of subexpressions. When the out put is created incrementally in this fashion, the order in which the characters are printed is significant.

The implementation of a translation scheme must ensure that semantic actions are performed in the order they would appear during a postorder traversal of a parse tree. The implementation need not actually construct a parse tree often it does not as long as it ensures that the semantic actions are performed as if we constructed a parse tree and then executed the actions during a postorder traversal

2 3 6 Exercises for Section 2 3

Exercise 2 3 1 Construct a syntax directed translation scheme that translates arithmetic expressions from in x notation into pre x notation in which an operator appears before its operands e.g. xy is the pre x notation for x y Give annotated parse trees for the inputs 9 5 2 and 9 5 2

Exercise 2 3 2 Construct a syntax directed translation scheme that translates arithmetic expressions from post x notation into in x notation Give annotated parse trees for the inputs 95 2 and 952

Exercise 2 3 3 Construct a syntax directed translation scheme that translates integers into roman numerals

Exercise 2 3 4 Construct a syntax directed translation scheme that translates roman numerals up to 2000 into integers

Exercise 2 3 5 Construct a syntax directed translation scheme to translate post x arithmetic expressions into equivalent pre x arithmetic expressions

2 4 Parsing

Parsing is the process of determining how a string of terminals can be generated by a grammar In discussing this problem it is helpful to think of a parse tree being constructed even though a compiler may not construct one in practice However a parser must be capable of constructing the tree in principle or else the translation cannot be guaranteed correct

2 4 PARSING

This section introduces a parsing method called recursive descent which can be used both to parse and to implement syntax directed translators. A complete Java program implementing the translation scheme of Fig. 2.15 appears in the next section. A viable alternative is to use a software tool to generate a translator directly from a translation scheme. Section 4.9 describes such a tool. Yacc it can implement the translation scheme of Fig. 2.15 without modi cation.

For any context free grammar there is a parser that takes at most O n^3 time to parse a string of n terminals. But cubic time is generally too expensive. Fortunately for real programming languages we can generally design a grammar that can be parsed quickly. Linear time algorithms sunce to parse essentially all languages that arise in practice. Programming language parsers almost always make a single left to right scan over the input clooking ahead one terminal at a time, and constructing pieces of the parse tree as they go

Most parsing methods fall into one of two classes called the *top down* and *bottom up* methods. These terms refer to the order in which nodes in the parse tree are constructed. In top down parsers construction starts at the root and proceeds towards the leaves while in bottom up parsers construction starts at the leaves and proceeds towards the root. The popularity of top down parsers is due to the fact that excient parsers can be constructed more easily by hand using top down methods. Bottom up parsing however can handle a larger class of grammars and translation schemes so software tools for generating parsers directly from grammars often use bottom up methods.

2 4 1 Top Down Parsing

We introduce top down parsing by considering a grammar that is well suited for this class of methods. Later in this section, we consider the construction of top down parsers in general. The grammar in Fig. 2.16 generates a subset of the statements of C or Java. We use the boldface terminals if and for for the keywords if and for respectively to emphasize that these character sequences are treated as units it is a single terminal symbols. Further the terminal expr represents expressions a more complete grammar would use a nonterminal expr and have productions for nonterminal expr. Similarly other is a terminal representing other statement constructs

The top down construction of a parse tree like the one in Fig 2 17 is done by starting with the root labeled with the starting nonterminal stmt and repeatedly performing the following two steps

- 1 At node N labeled with nonterminal A select one of the productions for A and construct children at N for the symbols in the production body
- 2 Find the next node at which a subtree is to be constructed typically the leftmost unexpanded nonterminal of the tree

For some grammars the above steps can be implemented during a single left to right scan of the input string The current terminal being scanned in the

```
        stmt
        expr

        if expr stmt

        for optexpr optexpr optexpr stmt

        other

optexpr

expr
```

Figure 2 16 A grammar for some statements in C and Java

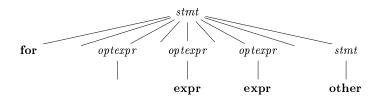

Figure 2 17 A parse tree according to the grammar in Fig 2 16

input is frequently referred to as the *lookahead* symbol Initially the lookahead symbol is the rst i e leftmost terminal of the input string Figure 2.18 illustrates the construction of the parse tree in Fig. 2.17 for the input string

for expr expr other

Initially the terminal **for** is the lookahead symbol and the known part of the parse tree consists of the root labeled with the starting nonterminal stmt in Fig. 2.18 a. The objective is to construct the remainder of the parse tree in such a way that the string generated by the parse tree matches the input string

For a match to occur the nonterminal *stmt* in Fig 2 18 a must derive a string that starts with the lookahead symbol **for** In the grammar of Fig 2 16 there is just one production for *stmt* that can derive such a string so we select it and construct the children of the root labeled with the symbols in the production body. This expansion of the parse tree is shown in Fig 2 18 b

Each of the three snapshots in Fig 2 18 has arrows marking the lookahead symbol in the input and the node in the parse tree that is being considered Once children are constructed at a node we next consider the leftmost child In Fig 2 18 b children have just been constructed at the root and the leftmost child labeled with **for** is being considered

When the node being considered in the parse tree is for a terminal and the terminal matches the lookahead symbol then we advance in both the parse tree and the input. The next terminal in the input becomes the new lookahead symbol and the next child in the parse tree is considered. In Fig. 2.18 c. the arrow in the parse tree has advanced to the next child of the root and the arrow

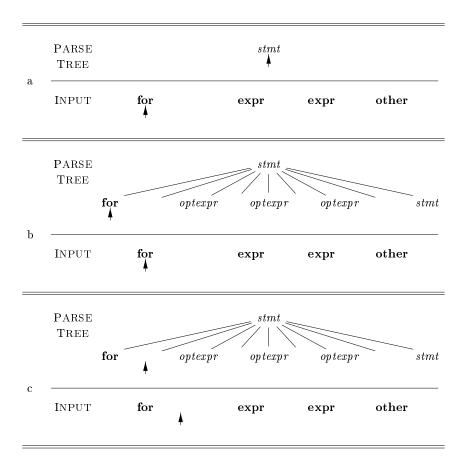

Figure 2 18 Top down parsing while scanning the input from left to right

in the input has advanced to the next terminal which is A further advance will take the arrow in the parse tree to the child labeled with nonterminal optexpr and take the arrow in the input to the terminal

At the nonterminal node labeled optexpr we repeat the process of selecting a production for a nonterminal Productions with as the body productions require special treatment. For the moment, we use them as a default when no other production can be used, we return to them in Section 2.4.3. With nonterminal optexpr and lookahead, the production is used since, does not match the only other production for optexpr which has terminal expr as its body

In general the selection of a production for a nonterminal may involve trial and error that is we may have to try a production and backtrack to try another production if the rst is found to be unsuitable A production is unsuitable if after using the production we cannot complete the tree to match the input string Backtracking is not needed however in an important special case called predictive parsing which we discuss next

2 4 2 Predictive Parsing

Recursive descent parsing is a top down method of syntax analysis in which a set of recursive procedures is used to process the input. One procedure is associated with each nonterminal of a grammar. Here we consider a simple form of recursive descent parsing called predictive parsing in which the lookahead symbol unambiguously determines the ow of control through the procedure body for each nonterminal. The sequence of procedure calls during the analysis of an input string implicitly defines a parse tree for the input and can be used to build an explicit parse tree if desired

The predictive parser in Fig. 2.19 consists of procedures for the nonterminals stmt and optexpr of the grammar in Fig. 2.16 and an additional procedure match used to simplify the code for stmt and optexpr. Procedure match t compares its argument t with the lookahead symbol and advances to the next input terminal if they match. Thus match changes the value of variable lookahead a global variable that holds the currently scanned input terminal.

Parsing begins with a call of the procedure for the starting nonterminal stmt With the same input as in Fig. 2.18 lookahead is initially the rst terminal for Procedure stmt executes code corresponding to the production

```
stmt for optexpr optexpr optexpr stmt
```

In the code for the production body that is the **for** case of procedure *stmt* each terminal is matched with the lookahead symbol and each nonterminal leads to a call of its procedure in the following sequence of calls

```
match for match'' optexpr match'' optexpr match'' stmt
```

Predictive parsing relies on information about the st symbols that can be generated by a production body. More precisely let so be a string of grammar symbols terminals and or nonterminals. We do not precisely let so be the set of terminals that appear as the string of one or more strings of terminals generated from. If is or can generate then is also in FIRST.

The details of how one computes FIRST—are in Section 4.4.2 Here we shall just use ad hoc reasoning to deduce the symbols in FIRST—typically will either begin with a terminal—which is therefore the only symbol in FIRST or—will begin with a nonterminal whose production bodies begin with terminals in which case these terminals are the only members of FIRST

For example with respect to the grammar of Fig $2\,16$ the following are correct calculations of FIRST

24 PARSING

```
void stmt
     switch lookahead {
     case expr
            match expr match ' ' break
     case if
            match if match ' ' match expr match ' ' stmt
           break
     case for
            match for match ' '
            optexpr match ' ' optexpr match ' '
            match'' stmt break
     case other
            match other break
     default
           report syntax error
}
void optexpr {
     if lookahead
                      \mathbf{expr} match \mathbf{expr}
void match terminal t {
     if lookahead
                     t lookahead
                                     nextTerminal
     else report syntax error
}
```

Figure 2 19 Pseudocode for a predictive parser

```
FIRST stmt {expr if for other}
FIRST expr {expr}
```

The first sets must be considered if there are two productions A and A Ignoring productions for the moment predictive parsing requires first and first to be disjoint. The lookahead symbol can then be used to decide which production to use if the lookahead symbol is in first then is used. Otherwise if the lookahead symbol is in first then is used.

2 4 3 When to Use Productions

Our predictive parser uses an production as a default when no other production can be used. With the input of Fig. 2.18 after the terminals ${\bf for}$ and are matched the lookahead symbol is. At this point procedure ${\it optexpr}$ is called and the code

if lookahead expr match expr

in its body is executed Nonterminal optexpr has two productions with bodies expr and The lookahead symbol does not match the terminal expr so the production with body expr cannot apply In fact the procedure returns without changing the lookahead symbol or doing anything else Doing nothing corresponds to applying an production

More generally consider a variant of the productions in Fig $2\,16$ where optexpr generates an expression nonterminal instead of the terminal expr

 $optexpr \hspace{1cm} expr \hspace{1cm} | \hspace{1cm}$

Thus optexpr either generates an expression using nonterminal expr or it generates. While parsing optexpr if the lookahead symbol is not in FIRST expr then the production is used

For more on when to use $\,$ productions see the discussion of LL 1 $\,$ grammars in Section 4 4 3

2 4 4 Designing a Predictive Parser

We can generalize the technique introduced informally in Section 2 4 2 to apply to any grammar that has disjoint FIRST sets for the production bodies belonging to any nonterminal We shall also see that when we have a translation scheme that is a grammar with embedded actions it is possible to execute those actions as part of the procedures designed for the parser

Recall that a *predictive parser* is a program consisting of a procedure for every nonterminal The procedure for nonterminal A does two things

- 1 It decides which A production to use by examining the lookahead symbol The production with body—where—is not—the empty string—is used if the lookahead symbol is in FIRST—If there is a con—ict between two nonempty bodies for any lookahead symbol—then we cannot use this parsing method on this grammar—In addition—the—production for A—if it exists—is used if the lookahead symbol is not in the FIRST set for any other production body for A
- 2 The procedure then mimics the body of the chosen production That is the symbols of the body are executed in turn from the left A nonterminal is executed by a call to the procedure for that nonterminal and a terminal matching the lookahead symbol is executed by reading the next input symbol If at some point the terminal in the body does not match the lookahead symbol a syntax error is reported

Figure 2 19 is the result of applying these rules to the grammar in Fig 2 16

2 4 PARSING

Just as a translation scheme is formed by extending a grammar a syntax directed translator can be formed by extending a predictive parser An algorithm for this purpose is given in Section 5.4. The following limited construction su ces for the present

- 1 Construct a predictive parser ignoring the actions in productions
- 2 Copy the actions from the translation scheme into the parser If an action appears after grammar symbol X in production p then it is copied after the implementation of X in the code for p Otherwise if it appears at the beginning of the production then it is copied just before the code for the production body

We shall construct such a translator in Section 2 5

2 4 5 Left Recursion

It is possible for a recursive descent parser to loop forever A problem arises with left recursive productions like

$$expr$$
 $expr$ $term$

where the leftmost symbol of the body is the same as the nonterminal at the head of the production. Suppose the procedure for expr decides to apply this production. The body begins with expr so the procedure for expr is called recursively. Since the lookahead symbol changes only when a terminal in the body is matched no change to the input took place between recursive calls of expr. As a result, the second call to expr does exactly what the rest call did which means a third call to expr and so on forever

A left recursive production can be eliminated by rewriting the o ending production Consider a nonterminal A with two productions

$$A \qquad A \quad |$$

where $\,$ and $\,$ are sequences of terminals and nonterminals that do not start with A For example in

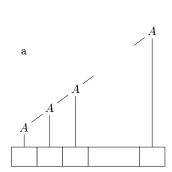

$$expr$$
 $expr$ $term$ | $term$

nonterminal A expr string term and string term

The nonterminal A and its production are said to be $left\ recursive$ because the production A A has A itself as the leftmost symbol on the right side 4 Repeated application of this production builds up a sequence of s to the right of A as in Fig. 2.20 a. When A is nally replaced by we have a followed by a sequence of zero or more s

The same e ect can be achieved as in Fig 2 20 b by rewriting the productions for A in the following manner using a new nonterminal R

 $^{^4}$ In a general left recursive grammar instead of a production A-A the nonterminal A may derive A through intermediate productions

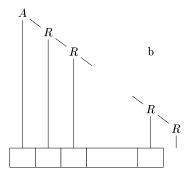

Figure 2 20 Left and right recursive ways of generating a string

Nonterminal R and its production R are right recursive because this production for R has R itself as the last symbol on the right side Right recursive productions lead to trees that grow down towards the right as in Fig 2 20 b Trees growing down to the right make it harder to translate expressions containing left associative operators such as minus. In Section 2.5.2 however we shall see that the proper translation of expressions into post x notation can still be attained by a careful design of the translation scheme

In Section 4 3 3 we shall consider more general forms of left recursion and show how all left recursion can be eliminated from a grammar

2 4 6 Exercises for Section 2 4

Exercise 2 4 1 Construct recursive descent parsers starting with the following grammars

2 5 A Translator for Simple Expressions

Using the techniques of the last three sections we now construct a syntax directed translator in the form of a working Java program that translates arithmetic expressions into post x form. To keep the initial program manage ably small we start with expressions consisting of digits separated by binary plus and minus signs. We extend the program in Section 2.6 to translate expressions that include numbers and other operators. It is worth studying the

2 5 A TRANSLATOR FOR SIMPLE EXPRESSIONS

translation of expressions in detail since they appear as a construct in so many languages

A syntax directed translation scheme often serves as the speci cation for a translator. The scheme in Fig. $2\,21$ repeated from Fig. $2\,15$ de nes the translation to be performed here

Figure 2 21 Actions for translating into post x notation

Often the underlying grammar of a given scheme has to be modi ed before it can be parsed with a predictive parser. In particular, the grammar underlying the scheme in Fig. 2.21 is left recursive, and as we saw in the last section a predictive parser cannot handle a left recursive grammar.

We appear to have a con ict on the one hand we need a grammar that facilitates translation on the other hand we need a signi cantly di erent gram mar that facilitates parsing. The solution is to begin with the grammar for easy translation and carefully transform it to facilitate parsing. By eliminating the left recursion in Fig. 2.21 we can obtain a grammar suitable for use in a predictive recursive descent translator.

2 5 1 Abstract and Concrete Syntax

A useful starting point for designing a translator is a data structure called an abstract syntax tree. In an abstract syntax tree for an expression each interior node represents an operator the children of the node represent the operands of the operator. More generally any programming construct can be handled by making up an operator for the construct and treating as operands the semantically meaningful components of that construct

In the abstract syntax tree for 9 5 2 in Fig 2 22 the root represents the operator — The subtrees of the root represent the subexpressions 9 5 and 2 The grouping of 9 5 as an operand re ects the left to right evaluation of operators at the same precedence level Since and have the same precedence 9 5 2 is equivalent to 9 5 2

Abstract syntax trees or simply syntax trees resemble parse trees to an extent. However in the syntax tree interior nodes represent programming constructs while in the parse tree, the interior nodes represent nonterminals. Many nonterminals of a grammar represent programming constructs but others

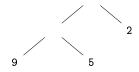

Figure 2 22 Syntax tree for 9 5 2

are helpers of one sort of another such as those representing terms factors or other variations of expressions. In the syntax tree, these helpers typically are not needed and are hence dropped. To emphasize the contrast a parse tree is sometimes called a *concrete syntax tree* and the underlying grammar is called a *concrete syntax* for the language.

In the syntax tree in Fig 2 22 each interior node is associated with an operator with no helper nodes for *single productions* a production whose body consists of a single nonterminal and nothing else like *expr* term or for productions like *rest*

It is desirable for a translation scheme to be based on a grammar whose parse trees are as close to syntax trees as possible. The grouping of subexpressions by the grammar in Fig. 2 21 is similar to their grouping in syntax trees. For example, subexpressions of the addition operator are given by expr and term in the production body expr term

2 5 2 Adapting the Translation Scheme

Second we need to transform productions that have embedded actions not just terminals and nonterminals Semantic actions embedded in the productions are simply carried along in the transformation as if they were terminals

Example 2 13 Consider the translation scheme of Fig 2 21 Let

$$A \hspace{1cm} expr \\ term \left\{ \hspace{1cm} \operatorname{print} \hspace{1cm} ' \hspace{1cm} ' \hspace{1cm} \right\} \\ term \left\{ \hspace{1cm} \operatorname{print} \hspace{1cm} ' \hspace{1cm} ' \hspace{1cm} \right\}$$

2 5 A TRANSLATOR FOR SIMPLE EXPRESSIONS

Then the left recursion eliminating transformation produces the translation scheme in Fig 2 23. The expr productions in Fig 2 21 have been transformed into one production for expr and a new nonterminal rest plays the role of R. The productions for term are repeated from Fig 2 21. Figure 2 24 shows how 9 5 2 is translated using the grammar in Fig 2 23.

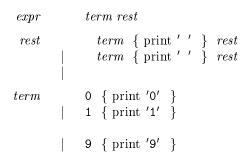

Figure 2 23 Translation scheme after left recursion elimination

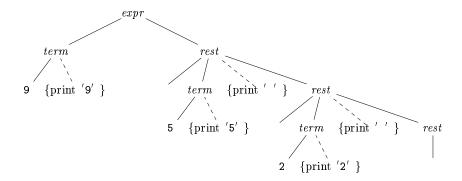

Figure 2 24 Translation of 9 5 2 to 95 2

Left recursion elimination must be done carefully to ensure that we preserve the ordering of semantic actions. For example, the transformed scheme in Fig. 2.23 has the actions { print ' ' } and { print ' ' } in the middle of a production body in each case between nonterminals term and rest. If the actions were to be moved to the end after rest then the translations would become incorrect. We leave it to the reader to show that 9.5.2 would then be translated incorrectly into 952. the post x notation for 9.5.2 instead of the desired 95.2. the post x notation for 9.5.2.

2 5 3 Procedures for the Nonterminals

Functions expr rest and term in Fig 2 25 implement the syntax directed trans lation scheme in Fig 2 23. These functions mimic the production bodies of the corresponding nonterminals. Function expr implements the production expr term rest by the calls term followed by rest

```
void expr
      term
              rest
void rest {
      if lookahead
             match''
                                  print ''
      else if lookahead
             match \ ' \ '
                                  print ''
      else { }
                  do nothing with the input
}
void term \{
      if lookahead is a digit {
             t \quad lookahead \quad match \ lookahead
                                                print t
      else report syntax error
}
```

Figure 2 25 Pseudocode for nonterminals expr rest and term

Function rest implements the three productions for nonterminal rest in Fig 2 23. It applies the rst production if the lookahead symbol is a plus sign the second production if the lookahead symbol is a minus sign and the production rest — in all other cases. The rst two productions for rest are implemented by the rst two branches of the if statement in procedure rest. If the lookahead symbol is — the plus sign is matched by the call match ' '. After the call term — the semantic action is implemented by writing a plus character. The second production is similar with — instead of — Since the third production for rest has — as its right side the last else clause in function rest does nothing

The ten productions for term generate the ten digits Since each of these productions generates a digit and prints it the same code in Fig 2 25 imple ments them all If the test succeeds variable t saves the digit represented by lookahead so it can be written after the call to match Note that match changes

2 5 A TRANSLATOR FOR SIMPLE EXPRESSIONS

the lookahead symbol so the digit needs to be saved for later printing ⁵

2 5 4 Simplifying the Translator

Before showing a complete program we shall make two simplifying transfor mations to the code in Fig 2.25 The simplications will fold procedure rest into procedure expr When expressions with multiple levels of precedence are translated such simplications reduce the number of procedures needed

First certain recursive calls can be replaced by iterations When the last statement executed in a procedure body is a recursive call to the same procedure the call is said to be *tail recursive*. For example, in function *rest*, the calls of *rest*, with lookahead, and are tail recursive because in each of these branches the recursive call to *rest* is the last statement executed by the given call of *rest*.

For a procedure without parameters a tail recursive call can be replaced simply by a jump to the beginning of the procedure. The code for rest can be rewritten as the pseudocode of Fig. 2.26. As long as the lookahead symbol is a plus or a minus sign procedure rest matches the sign calls term to match a digit and continues the process. Otherwise it breaks out of while loop and returns from rest

```
void rest {
    while true {
        if lookahead '' {
            match'' term print'' continue
        }
        else if lookahead '' {
            match'' term print'' continue
        }
        break
    }
}
```

Figure 2 26 Eliminating tail recursion in the procedure rest of Fig 2 25

Second the complete Java program will include one more change. Once the tail recursive calls to rest in Fig. 2.25 are replaced by iterations the only remaining call to rest is from within procedure expr. The two procedures can therefore be integrated into one by replacing the call rest by the body of procedure rest

 $^{^5}$ As a minor optimization we could print before calling match to avoid the need to save the digit. In general, changing the order of actions and grammar symbols is risky since it could change what the translation does

2 5 5 The Complete Program

The complete Java program for our translator appears in Fig 2 27 The rst line of Fig 2 27 beginning with import provides access to the package java io for system input and output. The rest of the code consists of the two classes Parser and Postfix Class Parser contains variable lookahead and functions Parser expr term and match.

Execution begins with function main which is de ned in class Postfix Function main creates an instance parse of class Parser and calls its function expr to parse an expression

The function Parser with the same name as its class is a *constructor* it is called automatically when an object of the class is created Notice from its de nition at the beginning of class Parser that the constructor Parser initializes variable lookahead by reading a token. Tokens consisting of single characters are supplied by the system input routine read which reads the next character from the input—le. Note that lookahead is declared to be an integer rather than a character—to anticipate the fact that additional tokens other than single characters will be introduced in later sections

Function expr is the result of the simplications discussed in Section 2 5 4 it implements nonterminals expr and rest in Fig 2 23. The code for expr in Fig 2 27 calls term and then has a while loop that forever tests whether lookahead matches either or Control exits from this while loop when it reaches the return statement. Within the loop, the input output facilities of the System class are used to write a character.

Function term uses the routine isDigit from the Java class Character to test if the lookahead symbol is a digit. The routine isDigit expects to be applied to a character however lookahead is declared to be an integer anticipating future extensions. The construction char lookahead casts or coerces lookahead to be a character. In a small change from Fig. 2.25, the semantic action of writing the lookahead character occurs before the call to match

The function match checks terminals it reads the next input terminal if the lookahead symbol is matched and signals an error otherwise by executing

throw new Error syntax error

This code creates a new exception of class $\tt Error$ and supplies it the string $\tt syntax error$ as an error message $\tt Java$ does not require $\tt Error$ exceptions to be declared in a $\tt throws$ clause since they are meant to be used only for abnormal events that should never occur 6

⁶Error handling can be streamlined using the exception handling facilities of Java One ap proach is to de nea new exception say SyntaxError that extends the system class Exception Then throw SyntaxError instead of Error when an error is detected in either term or match Further handle the exception in main by enclosing the call parse expr within a try state ment that catches exception SyntaxError writes a message and terminates. We would need to add a class SyntaxError to the program in Fig. 2.27. To complete the extension in addition to IOException functions match and term must now declare that they can throw SyntaxError Function expr which calls them must also declare that it can throw SyntaxError

2 5 A TRANSLATOR FOR SIMPLE EXPRESSIONS

```
import java io
class Parser
    static int lookahead
    public Parser
                   throws IOException
        lookahead System in read
    void expr
               throws IOException
        term
        while true
            if lookahead
                \mathtt{match}
                            term
                                    System out write
            else if lookahead
               \mathtt{match}
                          term
                                    System out write
            else return
    void term throws IOException
        if Character isDigit char lookahead
            System out write char lookahead match lookahead
        else throw new Error syntax error
    {\tt void\ match\ int\ t\ \ throws\ IOException}
                                         System in read
        if lookahead
                        t lookahead
        else throw new Error syntax error
public class Postfix
    public static void main String args throws IOException
        Parser parse new Parser
        parse expr System out write n
```

Figure 2 27 Java program to translate in x expressions into post x form

A Few Salient Features of Java

Those unfamiliar with Java may $\,$ nd the following notes on Java helpful in reading the code in Fig. 2.27

A class in Java consists of a sequence of variable and function de nitions

Parentheses enclosing function parameter lists are needed even if there are no parameters hence we write expr and term. These functions are actually procedures because they do not return values signi ed by the keyword void before the function name

Functions communicate either by passing parameters by value or by accessing shared data. For example, the functions expr and term—examine the lookahead symbol using the class variable lookahead that they can all access since they all belong to the same class Parser

Like C Java uses for assignment for equality and for in equality

The clause throws IOException in the de nition of term de clares that an exception called IOException can occur Such an exception occurs if there is no input to be read when the function match uses the routine read Any function that calls match must also declare that an IOException can occur during its own execution

2 6 Lexical Analysis

A lexical analyzer reads characters from the input and groups them into token objects. Along with a terminal symbol that is used for parsing decisions a token object carries additional information in the form of attribute values. So far there has been no need to distinguish between the terms token and terminal since the parser ignores the attribute values that are carried by a token. In this section, a token is a terminal along with additional information

A sequence of input characters that comprises a single token is called a *lexeme* Thus we can say that the lexical analyzer insulates a parser from the lexeme representation of tokens

The lexical analyzer in this section allows numbers identi ers and white space blanks tabs and newlines to appear within expressions. It can be used to extend the expression translator of the previous section. Since the expression grammar of Fig. 2.21 must be extended to allow numbers and identi ers we

2 6 LEXICAL ANALYSIS

shall take this opportunity to allow multiplication and division as well $\,$ The extended translation scheme appears in Fig. 2.28

```
{ print ' ' } { print ' ' }
  expr
                      term
               expr
                      term
               term
                                { print ' '
 term
               term
                       factor
                                { print ' '
               term
                      factor
               factor
factor
                 expr
                                { print num value }
               num
                                { print id lexeme }
```

Figure 2 28 Actions for translating into post x notation

In Fig 2 28 the terminal **num** is assumed to have an attribute **num** value which gives the integer value corresponding to this occurrence of **num** Termi nal **id** has a string valued attribute written as **id** lexeme we assume this string is the actual lexeme comprising this instance of the token **id**

The pseudocode fragments used to illustrate the workings of a lexical ana lyzer will be assembled into Java code at the end of this section. The approach in this section is suitable for hand written lexical analyzers. Section 3.5 describes a tool called Lex that generates a lexical analyzer from a specification Symbol tables or data structures for holding information about identifiers are considered in Section 2.7

2 6 1 Removal of White Space and Comments

The expression translator in Section 2 5 sees every character in the input so extraneous characters such as blanks will cause it to fail Most languages allow arbitrary amounts of white space to appear between tokens Comments are likewise ignored during parsing so they may also be treated as white space

If white space is eliminated by the lexical analyzer the parser will never have to consider it The alternative of modifying the grammar to incorporate white space into the syntax is not nearly as easy to implement

The pseudocode in Fig. 2.29 skips white space by reading input characters as long as it sees a blank a tab or a newline. Variable peek holds the next input character. Line numbers and context are useful within error messages to help pinpoint errors the code uses variable line to count newline characters in the input

Figure 2 29 Skipping white space

2 6 2 Reading Ahead

A lexical analyzer may need to read ahead some characters before it can decide on the token to be returned to the parser. For example, a lexical analyzer for C or Java must read ahead after it sees the character. If the next character is then is part of the character sequence, the lexeme for the token for the greater than or equal to operator. Otherwise, itself forms the greater than operator, and the lexical analyzer has read one character too many.

A general approach to reading ahead on the input is to maintain an input bu er from which the lexical analyzer can read and push back characters. Input bu ers can be justiled on exciency grounds alone since fetching a block of characters is usually more excient than fetching one character at a time. A pointer keeps track of the portion of the input that has been analyzed pushing back a character is implemented by moving back the pointer. Techniques for input bu ering are discussed in Section 3.2

One character read ahead usually su ces so a simple solution is to use a variable say peek to hold the next input character. The lexical analyzer in this section reads ahead one character while it collects digits for numbers or characters for identifiers e.g. it reads past 1 to distinguish between 1 and 10 and it reads past t to distinguish between t and true

The lexical analyzer reads ahead only when it must. An operator like—can be identified without reading ahead. In such cases, peek is set to a blank which will be skipped when the lexical analyzer is called to—nd the next token. The invariant assertion in this section is that when the lexical analyzer returns a token variable peek either holds the character beyond the lexeme for the current token—or it holds a blank

2 6 3 Constants

Anytime a single digit appears in a grammar for expressions it seems reasonable to allow an arbitrary integer constant in its place. Integer constants can be allowed either by creating a terminal symbol say **num** for such constants or by incorporating the syntax of integer constants into the grammar. The job of collecting characters into integers and computing their collective numerical value is generally given to a lexical analyzer so numbers can be treated as single units during parsing and translation

2 6 LEXICAL ANALYSIS

When a sequence of digits appears in the input stream the lexical analyzer passes to the parser a token consisting of the terminal **num** along with an integer valued attribute computed from the digits If we write tokens as tuples enclosed between $\langle \rangle$ the input 31 28 59 is transformed into the sequence

```
\langle \mathbf{num} \ 31 \rangle \ \langle \ \rangle \ \langle \mathbf{num} \ 28 \rangle \ \langle \ \rangle \ \langle \mathbf{num} \ 59 \rangle
```

Here the terminal symbol—has no attributes so its tuple is simply $\langle \ \rangle$ —The pseudocode in Fig. 2-30 reads the digits in an integer and accumulates the value of the integer using variable v

Figure 2 30 Grouping digits into integers

2 6 4 Recognizing Keywords and Identi ers

Most languages use xed character strings such as for do and if as punctua tion marks or to identify constructs Such character strings are called keywords

Character strings are also used as identifiers to name variables arrays functions and the like Grammars routinely treat identifiers as terminals to simplify the parser which can then expect the same terminal say **id** each time any identifier appears in the input. For example, on input

```
count count increment 2 6
```

the parser works with the terminal stream **id id id** The token for **id** has an attribute that holds the lexeme Writing tokens as tuples we see that the tuples for the input stream 2 6 are

```
\langle id \quad count \rangle \langle \rangle \langle id \quad count \rangle \langle \rangle \langle id \quad increment \rangle \langle \rangle
```

Keywords generally satisfy the rules for forming identi ers so a mechanism is needed for deciding when a lexeme forms a keyword and when it forms an identi er The problem is easier to resolve if keywords are reserved i e if they cannot be used as identi ers Then a character string forms an identi er only if it is not a keyword

The lexical analyzer in this section solves two problems by using a table to hold character strings

Single Representation A string table can insulate the rest of the compiler from the representation of strings since the phases of the compiler can work with references or pointers to the string in the table References can also be manipulated more exciently than the strings themselves

Reserved Words Reserved words can be implemented by initializing the string table with the reserved strings and their tokens. When the lexical analyzer reads a string or lexeme that could form an identi er it rst checks whether the lexeme is in the string table. If so it returns the token from the table otherwise it returns a token with terminal id

In Java a string table can be implemented as a hash table using a class called *Hashtable* The declaration

Hashtable words new Hashtable

sets up words as a default hash table that maps keys to values. We shall use it to map lexemes to tokens. The pseudocode in Fig. 2-31 uses the operation get to look up reserved words

```
if peek holds a letter {
    collect letters or digits into a bu er b
    s string formed from the characters in b
    w token returned by words get s
    if w is not null return w
    else {
        Enter the key value pair s \langle id s \rangle into words
        return token \langle id s \rangle
    }
}
```

Figure 2 31 Distinguishing keywords from identi ers

This pseudocode collects from the input a string s consisting of letters and digits beginning with a letter. We assume that s is made as long as possible i.e. the lexical analyzer will continue reading from the input as long as it encounters letters and digits. When something other than a letter or digit e.g. white space is encountered the lexeme is copied into a buner s. If the table has an entry for s, then the token retrieved by s words s is returned. Here s could be either a keyword with which the s words table was initially seeded or it could be an identified in the table and returned. Otherwise token in the same installed in the table and returned.

2 6 5 A Lexical Analyzer

The pseudocode fragments so far in this section t together to form a function scan that returns token objects as follows

```
Token scan {
    skip white space as in Section 2 6 1
    handle numbers as in Section 2 6 3
    handle reserved words and identifiers as in Section 2 6 4
    if we get here treat read ahead character peek as a token
    Token t new Token peek
    peek blank initialization as discussed in Section 2 6 2
    return t
}
```

The rest of this section implements function *scan* as part of a Java package for lexical analysis. The package called lexer has classes for tokens and a class Lexer containing function scan

The classes for tokens and their elds are illustrated in Fig 2 32 their methods are not shown Class Token has a eld tag that is used for parsing decisions Subclass Num adds a eld value for an integer value Subclass Word adds a eld lexeme that is used for reserved words and identifiers

Figure 2 32 Class Token and subclasses Num and Word

Each class is in a le by itself The le for class Token is as follows

Line 1 identi es the package lexer Field tag is declared on line 3 to be final so it cannot be changed once it is set The constructor Token on line 4 is used to create token objects as in

```
new Token
```

which creates a new object of class Token and sets its eld tag to an integer representation of For brevity we omit the customary method toString which would return a string suitable for printing

Where the pseudocode had terminals like **num** and **id** the Java code uses integer constants. Class Tag implements such constants

In addition to the integer valued $\,$ elds NUM and ID this class de nes two additional $\,$ elds TRUE and FALSE for future use they will be used to illustrate the treatment of reserved keywords 7

The elds in class Tag are public so they can be used outside the package They are static so there is just one instance or copy of these elds. The elds are final so they can be set just once. In elds are these elds represent constants. A similar elect is achieved in C by using delene statements to allow names such as NUM to be used as symbolic constants.

define NUM 256

The Java code refers to Tag NUM and Tag ID in places where the pseudocode referred to terminals **num** and **id** The only requirement is that Tag NUM and Tag ID must be initialized with distinct values that di er from each other and from the constants representing single character tokens such as

```
package lexer
                                    File Num java
  public class Num extends Token
3
      public final int value
4
      public Num int v
                           super Tag NUM
                                           value
5
                                    File Word java
  package lexer
  public class Word extends Token
3
      public final String lexeme
4
      public Word int t String s
5
         super t
                   lexeme
                           new String s
6
7
```

Figure 2 33 Subclasses Num and Word of Token

Classes Num and Word appear in Fig 233 Class Num extends Token by declaring an integer eld value on line 3 The constructor Num on line 4 calls super Tag NUM which sets eld tag in the superclass Token to Tag NUM

 $^{^7\}mathrm{ASCII}$ characters are typically converted into integers between 0 and 255. We therefore use integers greater than 255 for terminals

2 6 LEXICAL ANALYSIS

```
package lexer
                                      File Lexer java
 2
    import java io
                       import java util
 3
    public class Lexer
       public int line
 4
 5
       private char peek
 6
       private Hashtable words
                                   new Hashtable
 7
       void reserve Word t
                               words put t lexeme t
 8
       public Lexer
 9
          reserve new Word Tag TRUE
                                          true
10
          reserve new Word Tag FALSE
                                          false
11
12
       public Token scan
                            throws IOException
13
                            char System in read
          for
                    peek
14
              if peek
                                 peek
                                            t
                                                  continue
15
             else if peek
                                              line
                                 n
                                       line
16
              else break
17
             continues in Fig 2 35
```

Figure 2 34 Code for a lexical analyzer part 1 of 2

Class Word is used for both reserved words and identifiers so the constructor Word on line 4 expects two parameters a lexeme and a corresponding integer value for tag. An object for the reserved word true can be created by executing

```
new Word Tag TRUE true
```

which creates a new object with eld tag set to Tag TRUE and eld lexeme set to the string true

Class Lexer for lexical analysis appears in Figs 2 34 and 2 35 The integer variable line on line 4 counts input lines and character variable peek on line 5 holds the next input character

Reserved words are handled on lines 6 through 11 The table words is declared on line 6 The helper function reserve on line 7 puts a string word pair in the table Lines 9 and 10 in the constructor Lexer initialize the table They use the constructor Word to create word objects which are passed to the helper function reserve The table is therefore initialized with reserved words true and false before the rst call of scan

The code for scan in Fig 2 34 2 35 implements the pseudocode fragments in this section. The for statement on lines 13 through 17 skips blank tab and newline characters. Control leaves the for statement with peek holding a non white space character.

The code for reading a sequence of digits is on lines 18 through 25. The function isDigit is from the built in Java class Character. It is used on line 18 to check whether peek is a digit. If so the code on lines 19 through 24.

```
18
          if Character isDigit peek
19
             int v
20
             do
21
                            Character digit peek 10
                     10 v
22
                         char System in read
                peek
23
                      Character isDigit peek
               while
             return new Num v
24
25
26
          if Character isLetter peek
27
             StringBuffer b new StringBuffer
28
^{29}
                b append peek
30
                peek
                         char System in read
31
               while Character isLetterOrDigit peek
32
             String s
                        b toString
33
             Word w
                       Word words get s
34
                      null
                             return w
35
                 new Word Tag ID s
36
             words put s w
37
             return w
38
39
          Token t
                    new Token peek
40
          peek
41
          return t
42
43
```

Figure 2 35 Code for a lexical analyzer part 2 of 2

accumulates the integer value of the sequence of digits in the input and returns a new \mathtt{Num} object

Lines 26 through 38 analyze reserved words and identifiers. Keywords **true** and **false** have already been reserved on lines 9 and 10. Therefore line 35 is reached if string s is not reserved so it must be the lexeme for an identifier Line 35 therefore returns a new word object with lexeme set to s and tag set to Tag ID. Finally lines 39 through 41 return the current character as a token and set peek to a blank that will be stripped the next time scan is called

2 6 6 Exercises for Section 2 6

Exercise 2 6 1 Extend the lexical analyzer in Section 2 6 5 to remove comments de ned as follows

2 7 SYMBOL TABLES

- a A comment begins with and includes all characters until the end of that line
- b A comment begins with and includes all characters through the next occurrence of the character sequence

Exercise 2 6 2 Extend the lexical analyzer in Section 2 6 5 to recognize the relational operators

Exercise 2 6 3 Extend the lexical analyzer in Section 2 6 5 to recognize oat ing point numbers such as 2 3 14 and 5

2 7 Symbol Tables

Symbol tables are data structures that are used by compilers to hold information about source program constructs. The information is collected incrementally by the analysis phases of a compiler and used by the synthesis phases to generate the target code. Entries in the symbol table contain information about an identifier such as its character string or lexeme its type its position in storage and any other relevant information. Symbol tables typically need to support multiple declarations of the same identifier within a program.

From Section 1 6 1 the scope of a declaration is the portion of a program to which the declaration applies We shall implement scopes by setting up a separate symbol table for each scope. A program block with declarations⁸ will have its own symbol table with an entry for each declaration in the block. This approach also works for other constructs that set up scopes for example a class would have its own table with an entry for each eld and method

This section contains a symbol table module suitable for use with the Java translator fragments in this chapter. The module will be used as is when we put together the translator in Appendix A. Meanwhile for simplicity, the main example of this section is a stripped down language with just the key constructs that touch symbol tables namely blocks declarations and factors. All of the other statement and expression constructs are omitted so we can focus on the symbol table operations. A program consists of blocks with optional declarations and statements consisting of single identi ers. Each such statement represents a use of the identi er. Here is a sample program in this language

The examples of block structure in Section 1 6 3 dealt with the de nitions and uses of names the input 2 7 consists solely of de nitions and uses of names

The task we shall perform is to print a revised program in which the decla rations have been removed and each statement has its identi er followed by a colon and its type

 $^{^8{\}rm In~C}$ for instance program blocks are either functions or sections of functions that are separated by curly braces and that have one or more declarations within them

Who Creates Symbol Table Entries

Symbol table entries are created and used during the analysis phase by the lexical analyzer the parser and the semantic analyzer. In this chapter we have the parser create entries. With its knowledge of the syntactic structure of a program a parser is often in a better position than the lexical analyzer to distinguish among different declarations of an identifier.

In some cases a lexical analyzer can create a symbol table entry as soon as it sees the characters that make up a lexeme More often the lexical analyzer can only return to the parser a token say **id** along with a pointer to the lexeme Only the parser however can decide whether to use a previously created symbol table entry or create a new one for the identi er

Example 2 14 On the above input 2 7 the goal is to produce

x int y bool x int y char

The rst x and y are from the inner block of input 27 Since this use of x refers to the declaration of x in the outer block it is followed by int the type of that declaration. The use of y in the inner block refers to the declaration of y in that very block and therefore has boolean type. We also see the uses of x and y in the outer block with their types as given by declarations of the outer block integer and character respectively. \Box

2 7 1 Symbol Table Per Scope

The term scope of identi er x really refers to the scope of a particular declaration of x. The term scope by itself refers to a portion of a program that is the scope of one or more declarations

Scopes are important because the same identi er can be declared for di er ent purposes in di erent parts of a program. Common names like i and x often have multiple uses. As another example, subclasses can redeclare a method name to override a method in a superclass.

If blocks can be nested several declarations of the same identifier can appear within a single block. The following syntax results in nested blocks when stmts can generate a block

block ' ' decls stmts ' '

We quote curly braces in the syntax to distinguish them from curly braces for semantic actions. With the grammar in Fig. 2 38 decls generates an optional sequence of declarations and stmts generates an optional sequence of statements.

Optimization of Symbol Tables for Blocks

Implementations of symbol tables for blocks can take advantage of the most closely nested rule. Nesting ensures that the chain of applicable symbol tables forms a stack. At the top of the stack is the table for the current block. Below it in the stack are the tables for the enclosing blocks. Thus symbol tables can be allocated and deallocated in a stack like fashion.

Some compilers maintain a single hash table of accessible entries that is of entries that are not hidden by a declaration in a nested block. Such a hash table supports essentially constant time lookups at the expense of inserting and deleting entries on block entry and exit. Upon exit from a block B the compiler must undo any changes to the hash table due to declarations in block B. It can do so by using an auxiliary stack to keep track of changes to the hash table while block B is processed

Moreover a statement can be a block so our language allows nested blocks where an identi er can be redeclared

The most closely nested rule for blocks is that an identier x is in the scope of the most closely nested declaration of x that is the declaration of x found by examining blocks inside out starting with the block in which x appears

Example 2 15 The following pseudocode uses subscripts to distinguish a mong distinct declarations of the same identi er

The subscript is not part of an identi er it is in fact the line number of the declaration that applies to the identi er. Thus all occurrences of x are within the scope of the declaration on line 1. The occurrence of y on line 3 is in the scope of the declaration of y on line 2 since y is redeclared within the inner block. The occurrence of y on line 5 however is within the scope of the declaration of y on line 1.

The occurrence of w on line 5 is presumably within the scope of a declaration of w outside this program fragment its subscript 0 denotes a declaration that is global or external to this block

Finally z is declared and used within the nested block but cannot be used on line 5 since the nested declaration applies only to the nested block

The most closely nested rule for blocks can be implemented by chaining symbol tables. That is the table for a nested block points to the table for its enclosing block

Example 2 16 Figure 2 36 shows symbol tables for the pseudocode in Exam ple 2 15 B_1 is for the block starting on line 1 and B_2 is for the block starting at line 2. At the top of the gure is an additional symbol table B_0 for any global or default declarations provided by the language. During the time that we are analyzing lines 2 through 4 the environment is represented by a reference to the lowest symbol table — the one for B_2 . When we move to line 5 the symbol table for B_2 becomes inaccessible and the environment refers instead to the symbol table for B_1 from which we can reach the global symbol table but not the table for B_2 .

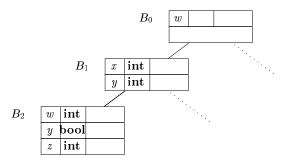

Figure 2 36 Chained symbol tables for Example 2 15

The Java implementation of chained symbol tables in Fig 2 37 de nes a class Env short for *environment* 9 Class Env supports three operations

Create a new symbol table The constructor Env p on lines 6 through 8 of Fig 2 37 creates an Env object with a hash table named table The object is chained to the environment valued parameter p by setting eld prev to p Although it is the Env objects that form a chain it is convenient to talk of the tables being chained

Put a new entry in the current table The hash table holds key value pairs where

The *key* is a string or rather a reference to a string. We could alternatively use references to token objects for identifiers as keys

The value is an entry of class Symbol The code on lines 9 through 11 does not need to know the structure of an entry that is the code is independent of the elds and methods in class Symbol

 $^{^{9}}$ Environment is another term for the collection of symbol tables that are relevant at a point in the program

2 7 SYMBOL TABLES

```
1
   package symbols
                                       File Env java
   import java util
3
   public class Env
4
      private Hashtable table
5
      protected Env prev
6
      public Env Env p
7
          table
                 new Hashtable
                                   prev
8
9
       public void put String s Symbol sym
10
          table put s sym
11
12
      public Symbol get String s
13
          for Env e this e
                                  null e
                                             e prev
14
             Symbol found
                             Symbol e table get s
15
             if found
                          null
                                 return found
16
17
          return null
18
19
```

Figure 2 37 Class *Env* implements chained symbol tables

Get an entry for an identi er by searching the chain of tables starting with the table for the current block. The code for this operation on lines 12 through 18 returns either a symbol table entry or null

Chaining of symbol tables results in a tree structure since more than one block can be nested inside an enclosing block. The dotted lines in Fig. 2 36 are a reminder that chained symbol tables can form a tree

2 7 2 The Use of Symbol Tables

In e ect the role of a symbol table is to pass information from declarations to uses A semantic action puts information about identi er x into the symbol table when the declaration of x is analyzed Subsequently a semantic action associated with a production such as factor id gets information about the identi er from the symbol table Since the translation of an expression E_1 op E_2 for a typical operator op depends only on the translations of E_1 and E_2 and does not directly depend on the symbol table we can add any number of operators without changing the basic ow of information from declarations to uses through the symbol table

Example 2 17 The translation scheme in Fig 2 38 illustrates how class *Env* can be used The translation scheme concentrates on scopes declarations and

uses It implements the translation described in Example 2 14 As noted earlier on input

```
\{ top \}
                                            null }
program
                 block
   block
                                    \{ saved \}
                                               top
                                      top
                                             new Env top
                                      print
                 decls stmts '
                                    \{ top \}
                                            saved
                                      print
   decls
                 decls \ decl
                 type id
                                          new Symbol
     decl
                                      s type type lexeme
                                      top \ put \ id \ lexeme \ s  }
   stmts
                 stmts\ stmt
                 block
    stmt
                                                    }
                 factor
                                   { print
  factor
                 id
                                   \{s
                                          top get id lexeme
                                      print id lexeme
                                      print
                                      print s type
```

Figure 2 38 The use of symbol tables for translating a language with blocks

int x char y bool y x y x y

the translation scheme strips the declarations and produces

x int y bool x int y char

Notice that the bodies of the productions have been aligned in Fig 2 38 so that all the grammar symbols appear in one column and all the actions in a second column. As a result components of the body are often spread over several lines

Now consider the semantic actions. The translation scheme creates and discards symbol tables upon block entry and exit respectively. Variable top denotes the top table at the head of a chain of tables. The rst production of

28 INTERMEDIATE CODE GENERATION

the underlying grammar is program block The semantic action before block initializes top to null with no entries

The second production block ' 'decls stmts' has actions upon block entry and exit. On block entry before decls a semantic action saves a reference to the current table using a local variable saved. Each use of this production has its own local variable saved distinct from the local variable for any other use of this production. In a recursive descent parser saved would be local to the procedure for block. The treatment of local variables of a recursive function is discussed in Section 7.2. The code

top **new** Env top

sets variable top to a newly created new table that is chained to the previous value of top just before block entry Variable top is an object of class Env the code for the constructor Env appears in Fig. 2.37

On block exit after $^{\prime}$ a semantic action restores top to its value saved on block entry. In e. ect. the tables form a stack restoring top to its saved value pops the e. ect of the declarations in the block. Thus, the declarations in the block are not visible outside the block.

A declaration decl **type id** results in a new entry for the declared iden ti er We assume that tokens **type** and **id** each have an associated attribute which is the type and lexeme respectively of the declared identi er We shall not go into all the elds of a symbol object s but we assume that there is a eld type that gives the type of the symbol We create a new symbol object s and assign its type properly by s type **type** lexeme The complete entry is put into the top symbol table by top put **id** lexeme s

The semantic action in the production factor id uses the symbol table to get the entry for the identifier. The get operation searches for the first entry in the chain of tables starting with top. The retrieved entry contains any information needed about the identifier such as the type of the identifier.

2 8 Intermediate Code Generation

The front end of a compiler constructs an intermediate representation of the source program from which the back end generates the target program. In this section we consider intermediate representations for expressions and state ments and give tutorial examples of how to produce such representations

281 Two Kinds of Intermediate Representations

As was suggested in Section 2 1 and especially Fig $\,2$ 4 the two most important intermediate representations are

 $^{^{10}}$ Instead of explicitly saving and restoring tables we could alternatively add static operations push and pop to class ${\tt Env}$

Trees including parse trees and abstract syntax trees

Linear representations especially three address code

Abstract syntax trees or simply syntax trees were introduced in Section 2 5 1 and in Section 5 3 1 they will be reexamined more formally. During parsing syntax tree nodes are created to represent significant programming constructs. As analysis proceeds information is added to the nodes in the form of attributes associated with the nodes. The choice of attributes depends on the translation to be performed.

Three address code on the other hand is a sequence of elementary program steps such as the addition of two values. Unlike the tree, there is no hierarchical structure. As we shall see in Chapter 9, we need this representation if we are to do any significant optimization of code. In that case, we break the long sequence of three address statements that form a program into basic blocks which are sequences of statements that are always executed one after the other with no branching

In addition to creating an intermediate representation a compiler front end checks that the source program follows the syntactic and semantic rules of the source language. This checking is called *static checking* in general static means done by the compiler ¹¹ Static checking assures that certain kinds of programming errors including type mismatches are detected and reported during compilation

It is possible that a compiler will construct a syntax tree at the same time it emits steps of three address code. However, it is common for compilers to emit the three address code while the parser—goes through the motions—of constructing a syntax tree—without actually constructing the complete tree data structure. Rather—the compiler stores nodes and their attributes needed for semantic checking or other purposes—along with the data structure used for parsing. By so doing—those parts of the syntax tree that are needed to construct the three address code are available when needed—but disappear when no longer needed. We take up the details of this process in Chapter 5

2 8 2 Construction of Syntax Trees

We shall st give a translation scheme that constructs syntax trees and later in Section 2.8.4 show how the scheme can be modiled to emit three address code along with or instead of the syntax tree

Recall from Section 2 5 1 that the syntax tree

¹¹ Its opposite dynamic means while the program is running Many languages also make certain dynamic checks. For instance, an object oriented language like Java sometimes must check types during program execution, since the method applied to an object may depend on the particular subclass of the object.

28 INTERMEDIATE CODE GENERATION

represents an expression formed by applying the operator \mathbf{op} to the subexpressions represented by E_1 and E_2 Syntax trees can be created for any construct not just expressions. Each construct is represented by a node with children for the semantically meaningful components of the construct. For example, the semantically meaningful components of a C while statement.

while
$$expr$$
 $stmt$

are the expression expr and the statement stmt ¹² The syntax tree node for such a while statement has an operator which we call **while** and two children—the syntax trees for the expr and the stmt

The translation scheme in Fig 2 39 constructs syntax trees for a representative but very limited language of expressions and statements. All the nonterminals in the translation scheme have an attribute n which is a node of the syntax tree. Nodes are implemented as objects of class Node

Class Node has two immediate subclasses Expr for all kinds of expressions and Stmt for all kinds of statements. Each type of statement has a corresponding subclass of Stmt for example operator **while** corresponds to subclass While. A syntax tree node for operator **while** with children x and y is created by the pseudocode

new While
$$x y$$

which creates an object of class While by calling constructor function While with the same name as the class Just as constructors correspond to operators constructor parameters correspond to operands in the abstract syntax

When we study the detailed code in Appendix A we shall see how methods are placed where they belong in this hierarchy of classes. In this section we shall discuss only a few of the methods informally

We shall consider each of the productions and rules of Fig 2 39 in turn First the productions de ning di erent types of statements are explained fol lowed by the productions that de ne our limited types of expressions

Syntax Trees for Statements

For each statement construct we de ne an operator in the abstract syntax For constructs that begin with a keyword we shall use the keyword for the operator Thus there is an operator **while** for while statements and an operator **do** for do while statements Conditionals can be handled by de ning two operators

 $^{^{12}}$ The right parenthesis serves only to separate the expression from the statement. The left parenthesis actually has no meaning it is there only to please the eye since without it. C would allow unbalanced parentheses

```
block
                                    \{ \text{ return } block n \}
program
               ' ' stmts ' '
                                    \{ block n \}
   block
                                                  stmts n }
                stmts_1 stmt
                                    \{ stmts n \}
                                                   new Seq \ stmts_1 \ n \ stmt \ n }
   stmts
                                    \{ stmts n \}
                                                   null }
    stmt
                                    \{ stmt n \}
                                                  new Eval \ expr \ n }
                expr
                 if expr
                                    \{ stmt n 
                                                  new If expr n \ stmt_1 \ n }
                 while expr
                                    stmt_1
                                                  new While expr n \ stmt_1 \ n }
                                    \{ stmt n \}
                 do stmt_1 while
                                       expr
                                                  new Do stmt_1 n expr n 
                                    \{ stmt n \}
               block
                                    \{ stmt n \}
                                                  block n  }
                                                  \mathbf{new} \ Assign \ ' \ ' \ rel \ n \ expr_1 \ n \ \ \}
    expr
                rel
                      expr_1
                                    \{ expr n \}
                                                  rel n  }
                                    \{ expr n \}
               rel
                                                rel
                       add

               num
```

Figure 2 39 Construction of syntax trees for expressions and statements

28 INTERMEDIATE CODE GENERATION

ifelse and if for if statements with and without an else part respectively. In our simple example language we do not use else and so have only an if statement Adding else presents some parsing issues which we discuss in Section 4.8.2

Each statement operator has a corresponding class of the same name with a capital rst letter e.g. class If corresponds to **if** In addition we de ne the subclass Seq which represents a sequence of statements. This subclass corresponds to the nonterminal stmts of the grammar Each of these classes are subclasses of Stmt which in turn is a subclass of Node

The translation scheme in Fig. 2.39 illustrates the construction of syntax tree nodes. A typical rule is the one for if statements

```
stmt if expr stmt_1 { stmt n new If expr n stmt_1 n }
```

The meaningful components of the if statement are expr and $stmt_1$. The se mantic action de nest he node stmt n as a new object of subclass If. The code for the constructor If is not shown. It creates a new node labeled **if** with the nodes expr n and $stmt_1$ n as children

Expression statements do not begin with a keyword so we de ne a new operator **eval** and class Eval which is a subclass of Stmt to represent expressions that are statements. The relevant rule is

```
stmt expr { stmt n new Eval expr n }
```

Representing Blocks in Syntax Trees

The remaining statement construct in Fig 2 39 is the block consisting of a sequence of statements Consider the rules

The rst says that when a statement is a block it has the same syntax tree as the block. The second rule says that the syntax tree for nonterminal block is simply the syntax tree for the sequence of statements in the block

For simplicity the language in Fig 2 39 does not include declarations. Even when declarations are included in Appendix A we shall see that the syntax tree for a block is still the syntax tree for the statements in the block. Since information from declarations is incorporated into the symbol table, they are not needed in the syntax tree. Blocks with or without declarations therefore appear to be just another statement construct in intermediate code.

A sequence of statements is represented by using a leaf **null** for an empty statement and a operator **seq** for a sequence of statements as in

```
stmts stmts_1 stmt { stmts n new Seq stmts_1 n stmt n }
```

Example 2 18 In Fig 2 40 we see part of a syntax tree representing a block or statement list. There are two statements in the list, the first an if statement and the second a while statement. We do not show the portion of the tree above this statement list, and we show only as a triangle each of the necessary subtrees, two expression trees for the conditions of the if and while statements and two statement trees for their substatements. \Box

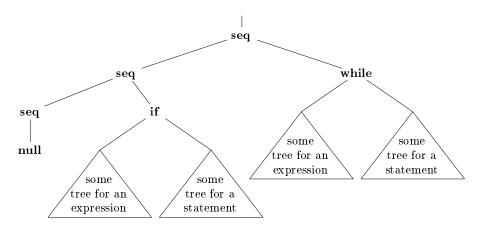

Figure 2 40 Part of a syntax tree for a statement list consisting of an if statement and a while statement

Syntax Trees for Expressions

Previously we handled the higher precedence of over by using three non terminals expr term and factor The number of nonterminals is precisely one plus the number of levels of precedence in expressions as we suggested in Section 2 2 6 In Fig 2 39 we have two comparison operators and at one precedence level as well as the usual and operators so we have added one additional nonterminal called add

Abstract syntax allows us to group similar operators to reduce the number of cases and subclasses of nodes in an implementation of expressions. In this chapter we take similar to mean that the type checking and code generation rules for the operators are similar. For example, typically, the operators, and can be grouped since they can be handled in the same way—their requirements regarding the types of operands are the same—and they each result in a single three address instruction that applies one operator to two values. In general, the grouping of operators in the abstract syntax is based on the needs of the later phases of the compiler. The table in Fig. 2.41 species the correspondence between the concrete and abstract syntax for several of the operators of Java

In the concrete syntax all operators are left associative except the assign ment operator—which is right associative—The operators on a line have the

2.8 INTERMEDIATE CODE GENERATION

```

not

unary

minus
access
```

Figure 2 41 Concrete and abstract syntax for several Java operators

same precedence that is and have the same precedence. The lines are in order of increasing precedence e.g. has higher precedence than the oper ators and The subscript unary in unary is solely to distinguish a leading unary minus sign as in 2 from a binary minus sign as in 2 a. The operator represents array access as in a i

The abstract syntax column species the grouping of operators. The assign ment operator is in a group by itself. The group \mathbf{cond} contains the conditional boolean operators and. The group \mathbf{rel} contains the relational comparison operators on the lines for and. The group \mathbf{op} contains the arithmetic operators like and. Unary minus boolean negation and array access are in groups by themselves

The mapping between concrete and abstract syntax in Fig 2 41 can be implemented by writing a translation scheme. The productions for nonterminals $expr\ rel\ add\ term$ and factor in Fig 2 39 specify the concrete syntax for a representative subset of the operators in Fig 2 41. The semantic actions in these productions create syntax tree nodes. For example, the rule

```
term \qquad term_1 \quad factor \quad \{ \ term \ n \quad \  \, \mathbf{new} \ \mathit{Op} \ ' \ ' \ term_1 \ n \ factor \ n \quad \}
```

creates a node of class Op which implements the operators grouped under **op** in Fig 2 41. The constructor Op has a parameter ' ' to identify the actual operator in addition to the nodes $term_1$ n and factor n for the subexpressions

283 Static Checking

Static checks are consistency checks that are done during compilation Not only do they assure that a program can be compiled successfully but they also have the potential for catching programming errors early before a program is run Static checking includes

Syntactic Checking There is more to syntax than grammars For ex ample constraints such as an identifier being declared at most once in a

scope or that a break statement must have an enclosing loop or switch statement are syntactic although they are not encoded in or enforced by a grammar used for parsing

Type Checking The type rules of a language assure that an operator or function is applied to the right number and type of operands If conversion between types is necessary e.g. when an integer is added to a oat then the type checker can insert an operator into the syntax tree to represent that conversion We discuss type conversion using the common term coercion below

L values and R values

We now consider some simple static checks that can be done during the construction of a syntax tree for a source program. In general complex static checks may need to be done by rst constructing an intermediate representation and then analyzing it

There is a distinction between the meaning of identi ers on the left and right sides of an assignment In each of the assignments

i 5 i 1

the right side speci es an integer value while the left side speci es where the value is to be stored. The terms l value and r value refer to values that are appropriate on the left and right sides of an assignment respectively. That is r values are what we usually think of as values while l values are locations

Static checking must assure that the left side of an assignment denotes an l value. An identi er like i has an l value as does an array access like a 2. But a constant like 2 is not appropriate on the left side of an assignment since it has an r value but not an l value.

Type Checking

Type checking assures that the type of a construct matches that expected by its context. For example, in the if statement

the expression expr is expected to have type **boolean**

Type checking rules follow the operator operand structure of the abstract syntax. Assume the operator \mathbf{rel} represents relational operators such as The type rule for the operator group \mathbf{rel} is that its two operands must have the same type and the result has type boolean. Using attribute type for the type of an expression let E consist of \mathbf{rel} applied to E_1 and E_2 . The type of E can be checked when its node is constructed by executing code like the following

2.8 INTERMEDIATE CODE GENERATION

if E_1 type E_2 type E type boolean else error

The idea of matching actual with expected types continues to apply even in the following situations

Coercions A coercion occurs if the type of an operand is automatically converted to the type expected by the operator. In an expression like $2\ 3\ 14$ the usual transformation is to convert the integer 2 into an equivalent oating point number $2\ 0$ and then perform a oating point operation on the resulting pair of oating point operands. The language de nition speci es the allowable coercions. For example, the actual rule for rel discussed above might be that E_1 type and E_2 type are convertible to the same type. In that case, it would be legal to compare say an integer with a oat

Overloading The operator in Java represents addition when applied to integers it means concatenation when applied to strings A symbol is said to be overloaded if it has different meanings depending on its context. Thus is overloaded in Java. The meaning of an overloaded operator is determined by considering the known types of its operands and results. For example, we know that the $[n \ z \ x \ y]$ is concatenation if we know that any of $[x \ y]$ or $[z \ is]$ of type string. However, if we also know that another one of these is of type integer, then we have a type error and there is no meaning to this use of

284 Three Address Code

Once syntax trees are constructed further analysis and synthesis can be done by evaluating attributes and executing code fragments at nodes in the tree We illustrate the possibilities by walking syntax trees to generate three address code Speci cally we show how to write functions that process the syntax tree and as a side e ect emit the necessary three address code

Three Address Instructions

Three address code is a sequence of instructions of the form

$$x \quad y \text{ op } z$$

where $x \ y$ and z are names constants or compiler generated temporaries and **op** stands for an operator

Arrays will be handled by using the following two variants of instructions

The rst puts the value of z in the location x y and the second puts the value of y z in the location x

Three address instructions are executed in numerical sequence unless forced to do otherwise by a conditional or unconditional jump We choose the following instructions for control ow

A label L can be attached to any instruction by prepending a pre x L An instruction can have more than one label

Finally we need instructions that copy a value $\,$ The following three address instruction copies the value of y into x

x - y

Translation of Statements

Statements are translated into three address code by using jump instructions to implement the ow of control through the statement. The layout in Fig. 2-42 illustrates the translation of **if** expr **then** $stmt_1$. The jump instruction in the layout

```
if False x goto after
```

jumps over the translation of $stmt_1$ if expr evaluates to **false** Other statement constructs are similarly translated using appropriate jumps around the code for their components

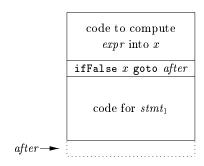

Figure 2 42 Code layout for if statements

For concreteness we show the pseudocode for class If in Fig 2 43 Class If is a subclass of Stmt as are the classes for the other statement constructs Each subclass of Stmt has a constructor If in this case and a function gen that is called to generate three address code for this kind of statement

```
class If extends Stmt {
    Expr E Stmt S
    public If Expr x Stmt y { E x S y after newlabel }
    public void gen {
        Expr n E rvalue
        emit ifFalse n toString goto after
        S gen
        emit after
    }
}
```

Figure 2 43 Function gen in class If generates three address code

The constructor If in Fig. 2.43 creates syntax tree nodes for if statements It is called with two parameters an expression node x and a statement node y which it saves as attributes E and S. The constructor also assigns attribute after a unique new label—by calling function newlabel—The label will be used according to the layout in Fig. 2.42

Once the entire syntax tree for a source program is constructed the function gen is called at the root of the syntax tree. Since a program is a block in our simple language the root of the syntax tree represents the sequence of statements in the block. All statement classes contain a function gen

The pseudocode for function gen of class If in Fig. 2.43 is representative. It calls E rvalue to translate the expression E the boolean valued expression that is part of the if statements and saves the result node returned by E Translation of expressions will be discussed shortly. Function gen then emits a conditional jump and calls S gen to translate the substatement S

Translation of Expressions

We now illustrate the translation of expressions by considering expressions containing binary operators **op** array accesses and assignments in addition to constants and identifiers. For simplicity in an array access y z we require that y be an identifier z For a detailed discussion of intermediate code generation for expressions see Section 6.4

We shall take the simple approach of generating one three address instruction for each operator node in the syntax tree for an expression. No code is generated for identifiers and constants since they can appear as addresses in instructions. If a node x of class Expr has operator \mathbf{op} , then an instruction is emitted to compute the value at node x into a compiler generated temporary name say t. Thus, in judicial key translates into two instructions

 $^{^{13}}$ This simple language supports a an but not a m n Note that a an has the form a E where E is a n

t1 i j t2 t1 k

With array accesses and assignments comes the need to distinguish between l values and r values. For example 2 a i can be translated by computing the r value of a i into a temporary as in

t1 a i t2 2 t1

But we cannot simply use a temporary in place of a i if a i appears on the left side of an assignment

The simple approach uses the two functions lvalue and rvalue which appear in Fig 2 44 and 2 45 respectively. When function rvalue is applied to a nonleaf node x it generates instructions to compute x into a temporary and returns a new node representing the temporary. When function lvalue is applied to a nonleaf it also generates instructions to compute the subtrees below x and returns a node representing the address for x

We describe function lvalue rst since it has fewer cases. When applied to a node x function lvalue simply returns x if it is the node for an identifier i.e. if x is of class Id. In our simple language, the only other case where an expression has an l value occurs when x represents an array access such as a i. In this case, x will have the form Access y z where class Access is a subclass of Expr y represents the name of the accessed array and z represents the object set index of the chosen element in that array. From the pseudo code in Fig. 2.44 function lvalue calls rvalue z to generate instructions if needed to compute the r value of z. It then constructs and returns a new Access node with children for the array name y and the r value of z

```
Expr lvalue x Expr {
    if x is an Id node return x
    else if x is an Access y z node and y is an Id node {
        return new Access y rvalue z
    }
    else error
}
```

Figure 2 44 Pseudocode for function lvalue

Example 2 19 When node x represents the array access a 2 k the call lvalue x generates an instruction

t 2 k

and returns a new node x' representing the l value a t where t is a new temporary name

In detail the code fragment

return new Access y rvalue z

is reached with y being the node for a and z being the node for expression 2 k. The call $rvalue\ z$ generates code for the expression 2 k i.e. the three address statement t 2 k and returns the new node z' representing the temporary name t. That node z' becomes the value of the second eld in the new Access node x' that is created \Box

```
Expr rvalue x Expr  {
      \mathbf{if} \quad x \text{ is an } \mathit{Id} \text{ or a } \mathit{Constant} \text{ node} \quad \mathbf{return} \ x
       else if x is an Op op y z or a Rel op y z node \{
             t new temporary
              emit string for t rvalue y op rvalue z
              return a new node for t
       else if x is an Access y z node \{
              t new temporary
              call lvalue x which returns Access y z'
              emit string for t Access y z'
              return a new node for t
       else if x is an Assign y z node {
              z' rvalue z
              emit string for lvalue y
              return z'
       }
}
```

Figure 2 45 Pseudocode for function rvalue

Function rvalue in Fig. 2.45 generates instructions and returns a possibly new node. When x represents an identity or a constant rvalue returns x itself. In all other cases, it returns an Id node for a new temporary t. The cases are as follows

When x represents y op z the code rst computes y' rvalue y and z' rvalue z. It creates a new temporary t and generates an instruction t y' op z' more precisely an instruction formed from the string representations of t y' op and z'. It returns a node for identi er t

When x represents an array access y z we can reuse function lvalue The call lvalue x returns an access y z' where z' represents an identifier holding the obset for the array access. The code creates a new temporary t generates an instruction based on t y z' and returns a node for t

CHAPTER 2 A SIMPLE SYNTAX DIRECTED TRANSLATOR

When x represents y = z then the code rst computes z' = rvalue z It generates an instruction based on lvalue y = z' and returns the node z'

Example 2 20 When applied to the syntax tree for

function rvalue generates

That is the root is an Assign node with rst argument a i and second ar gument 2 a j k. Thus the third case applies and function rvalue recursively evaluates 2 a j k. The root of this subtree is the Op node for which causes a new temporary t1 to be created before the left operand 2 is evaluated and then the right operand. The constant 2 generates no three address code and its r value is returned as a Constant node with value 2

The right operand a j k is an Access node which causes a new temporary t2 to be created before function lvalue is called on this node Recursively rvalue is called on the expression j k As a side e ect of this call the three address statement t3 j k is generated after the new temporary t3 is created. Then returning to the call of lvalue on a j k the temporary t2 is assigned the r value of the entire access expression that is t2 a t3

Now we return to the call of rvalue on the Op node 2 a j k which earlier created temporary t1 A three address statement t1 2 t2 is generated as a side e ect to evaluate this multiplication expression. Last the call to rvalue on the whole expression completes by calling lvalue on the left side a i and then generating a three address instruction a i t1 in which the right side of the assignment is assigned to the left side.

Better Code for Expressions

We can improve on function rvalue in Fig. 2.45 and generate fewer three address instructions in several ways

Reduce the number of copy instructions in a subsequent optimization phase For example the pair of instructions t i 1 and i t can be combined into i i 1 if there are no subsequent uses of t

Generate fewer instructions in the $\,$ rst place by taking context into ac count. For example, if the left side of a three address assignment is an array access a to then the right side must be a name a constant or a temporary all of which use just one address. But if the left side is a name $\,$ x then the right side can be an operation $\,$ y $\,$ op $\,$ z that uses two addresses

29 SUMMARY OF CHAPTER 2

We can avoid some copy instructions by modifying the translation functions to generate a partial instruction that computes say j k but does not commit to where the result is to be placed signi ed by a **null** address for the result

The null result address is later replaced by either an identifier or a temporary as appropriate. It is replaced by an identifier if j k is on the right side of an assignment as in i j k in which case 2.8 becomes

But if j k is a subexpression as in j k 1 then the null result address in 28 is replaced by a new temporary t and a new partial instruction is generated

Many compilers make every e ort to generate code that is as good as or bet ter than hand written assembly code produced by experts. If code optimization techniques such as the ones in Chapter 9 are used then an e ective strategy may well be to use a simple approach for intermediate code generation, and rely on the code optimizer to eliminate unnecessary instructions

285 Exercises for Section 28

Exercise 2 8 1 For statements in C and Java have the form

$$\quad \text{for} \quad expr_1 \quad expr_2 \quad expr_3 \quad stmt$$

The rst expression is executed before the loop it is typically used for initializing the loop index. The second expression is a test made before each iteration of the loop the loop is exited if the expression becomes 0. The loop itself can be thought of as the statement $stmt\ expr_3$. The third expression is executed at the end of each iteration it is typically used to increment the loop index. The meaning of the for statement is similar to

$$expr_1$$
 while $expr_2$ $stmt$ $expr_3$

2 9 Summary of Chapter 2

The syntax directed techniques in this chapter can be used to construct compiler front ends such as those illustrated in Fig 2 46

CHAPTER 2 A SIMPLE SYNTAX DIRECTED TRANSLATOR

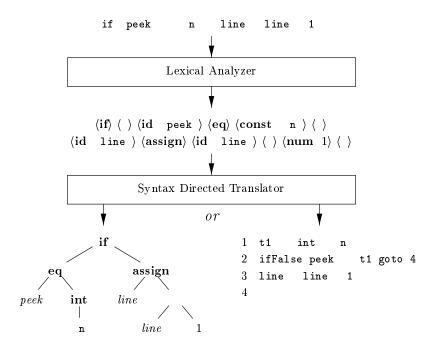

Figure 2 46 Two possible translations of a statement

- ◆ The starting point for a syntax directed translator is a grammar for the source language A grammar describes the hierarchical structure of programs It is de ned in terms of elementary symbols called terminals and variable symbols called nonterminals These symbols represent language constructs The rules or productions of a grammar consist of a nonterminal called the head or left side of a production and a sequence of terminals and nonterminals called the body or right side of the production One nonterminal is designated as the start symbol
- ◆ In specifying a translator it is helpful to attach attributes to programming construct where an attribute is any quantity associated with a construct Since constructs are represented by grammar symbols the concept of attributes extends to grammar symbols Examples of attributes include an integer value associated with a terminal num representing numbers and a string associated with a terminal id representing identi ers
- ♦ A lexical analyzer reads the input one character at a time and produces as output a stream of tokens where a token consists of a terminal symbol along with additional information in the form of attribute values. In Fig 2 46 tokens are written as tuples enclosed between ⟨⟩ The token ⟨id peek⟩ consists of the terminal id and a pointer to the symbol table entry containing the string peek. The translator uses the table to keep

29 SUMMARY OF CHAPTER 2

track of reserved words and identi ers that have already been seen

- ◆ Parsing is the problem of guring out how a string of terminals can be derived from the start symbol of the grammar by repeatedly replacing a nonterminal by the body of one of its productions Conceptually a parser builds a parse tree in which the root is labeled with the start symbol each nonleaf corresponds to a production and each leaf is labeled with a terminal or the empty string The parse tree derives the string of terminals at the leaves read from left to right
- ◆ E cient parsers can be built by hand using a top down from the root to the leaves of a parse tree method called predictive parsing A predictive parser has a procedure for each nonterminal procedure bodies mimic the productions for nonterminals and the ow of control through the procedure bodies can be determined unambiguously by looking one symbol ahead in the input stream See Chapter 4 for other approaches to parsing
- ◆ Syntax directed translation is done by attaching either rules or program fragments to productions in a grammar In this chapter we have consid ered only synthesized attributes—the value of a synthesized attribute at any node x can depend only on attributes at the children of x if any A syntax directed de nition attaches rules to productions the rules compute attribute values—A translation scheme embeds program fragments called semantic actions in production bodies—The actions are executed in the order that productions are used during syntax analysis
- ◆ The result of syntax analysis is a representation of the source program called *intermediate code* Two primary forms of intermediate code are il lustrated in Fig 2 46 An *abstract syntax tree* has nodes for programming constructs the children of a node give the meaningful subconstructs Al ternatively *three address code* is a sequence of instructions in which each instruction carries out a single operation
- ◆ Symbol tables are data structures that hold information about identi ers Information is put into the symbol table when the declaration of an iden ti er is analyzed A semantic action gets information from the symbol table when the identi er is subsequently used for example as a factor in an expression

Chapter 3

Lexical Analysis

In this chapter we show how to construct a lexical analyzer To implement a lexical analyzer by hand it helps to start with a diagram or other description for the lexemes of each token. We can then write code to identify each occurrence of each lexeme on the input and to return information about the token identified.

We can also produce a lexical analyzer automatically by specifying the lex eme patterns to a lexical analyzer generator and compiling those patterns into code that functions as a lexical analyzer. This approach makes it easier to mod ify a lexical analyzer since we have only to rewrite the a ected patterns not the entire program. It also speeds up the process of implementing the lexical analyzer since the programmer speci es the software at the very high level of patterns and relies on the generator to produce the detailed code. We shall introduce in Section 3.5 a lexical analyzer generator called Lex or Flex in a more recent embodiment

We begin the study of lexical analyzer generators by introducing regular expressions a convenient notation for specifying lexeme patterns. We show how this notation can be transformed—rst into nondeterministic automata and then into deterministic automata. The latter two notations can be used as input to a driver—that is code which simulates these automata and uses them as a guide to determining the next token—This driver and the speci—cation of the automaton form the nucleus of the lexical analyzer

3 1 The Role of the Lexical Analyzer

As the rst phase of a compiler the main task of the lexical analyzer is to read the input characters of the source program group them into lexemes and produce as output a sequence of tokens for each lexeme in the source program. The stream of tokens is sent to the parser for syntax analysis. It is common for the lexical analyzer to interact with the symbol table as well. When the lexical analyzer discovers a lexeme constituting an identifier it needs to enter that lexeme into the symbol table. In some cases, information regarding the

kind of identi er may be read from the symbol table by the lexical analyzer to assist it in determining the proper token it must pass to the parser

These interactions are suggested in Fig. 3.1. Commonly the interaction is implemented by having the parser call the lexical analyzer. The call suggested by the *getNextToken* command causes the lexical analyzer to read characters from its input until it can identify the next lexeme and produce for it the next token which it returns to the parser

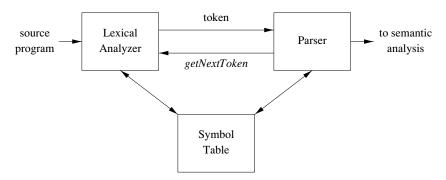

Figure 3.1 Interactions between the lexical analyzer and the parser

Since the lexical analyzer is the part of the compiler that reads the source text it may perform certain other tasks besides identication of lexemes. One such task is stripping out comments and whitespace blank newline tab and perhaps other characters that are used to separate tokens in the input. Another task is correlating error messages generated by the compiler with the source program. For instance, the lexical analyzer may keep track of the number of newline characters seen so it can associate a line number with each error message. In some compilers, the lexical analyzer makes a copy of the source program with the error messages inserted at the appropriate positions. If the source program uses a macro preprocessor, the expansion of macros may also be performed by the lexical analyzer.

Sometimes lexical analyzers are divided into a cascade of two processes

- a Scanning consists of the simple processes that do not require tokenization of the input such as deletion of comments and compaction of consecutive whitespace characters into one
- b Lexical analysis proper is the more complex portion which produces to kens from the output of the scanner

3 1 1 Lexical Analysis Versus Parsing

There are a number of reasons why the analysis portion of a compiler is normally separated into lexical analysis and parsing syntax analysis phases

3 1 THE ROLE OF THE LEXICAL ANALYZER

- 1 Simplicity of design is the most important consideration. The separation of lexical and syntactic analysis often allows us to simplify at least one of these tasks. For example, a parser that had to deal with comments and whitespace as syntactic units would be considerably more complex than one that can assume comments and whitespace have already been removed by the lexical analyzer. If we are designing a new language separating lexical and syntactic concerns can lead to a cleaner overall language design.
- 2 Compiler e ciency is improved A separate lexical analyzer allows us to apply specialized techniques that serve only the lexical task not the job of parsing In addition specialized bu ering techniques for reading input characters can speed up the compiler signi cantly
- 3 Compiler portability is enhanced Input device special c peculiarities can be restricted to the lexical analyzer

3 1 2 Tokens Patterns and Lexemes

When discussing lexical analysis we use three related but distinct terms

A token is a pair consisting of a token name and an optional attribute value. The token name is an abstract symbol representing a kind of lexical unit e.g. a particular keyword or a sequence of input characters denoting an identi er. The token names are the input symbols that the parser processes. In what follows we shall generally write the name of a token in boldface. We will often refer to a token by its token name

A pattern is a description of the form that the lexemes of a token may take In the case of a keyword as a token the pattern is just the sequence of characters that form the keyword For identi ers and some other tokens the pattern is a more complex structure that is matched by many strings

A *lexeme* is a sequence of characters in the source program that matches the pattern for a token and is identi ed by the lexical analyzer as an instance of that token

Example 3 1 Figure 3 2 gives some typical tokens their informally described patterns and some sample lexemes To see how these concepts are used in practice in the C statement

printf Total d n score

both printf and score are lexemes matching the pattern for token id and Total d n is a lexeme matching literal \Box

In many programming languages the following classes cover most or all of the tokens

TOKEN	Informal Description	Sample Lexemes		
if	characters i f	if		
${f else}$	characters e l s e	else		
${f comparison}$	or or or or			
id	letter followed by letters and digits	pi score D2		
${f number}$	any numeric constant	3 14159 0 6 02e23		
${f literal}$	anything but surrounded by s	core dumped		

Figure 3 2 Examples of tokens

- 1 One token for each keyword. The pattern for a keyword is the same as the keyword itself
- 2 Tokens for the operators either individually or in classes such as the token comparison mentioned in Fig 3 2
- 3 One token representing all identi ers
- 4 One or more tokens representing constants—such as numbers and literal strings
- 5 Tokens for each punctuation symbol such as left and right parentheses comma and semicolon

3 1 3 Attributes for Tokens

When more than one lexeme can match a pattern the lexical analyzer must provide the subsequent compiler phases additional information about the particular lexeme that matched. For example, the pattern for token **number** matches both 0 and 1 but it is extremely important for the code generator to know which lexeme was found in the source program. Thus, in many cases the lexical analyzer returns to the parser not only a token name, but an attribute value that describes the lexeme represented by the token, the token name in uences parsing decisions while the attribute value in uences translation of tokens after the parse.

We shall assume that tokens have at most one associated attribute although this attribute may have a structure that combines several pieces of information. The most important example is the token id where we need to associate with the token a great deal of information. Normally information about an identification of e.g., its lexeme its type and the location at which it is rest found in case an error message about that identifier must be issued is kept in the symbol table. Thus, the appropriate attribute value for an identifier is a pointer to the symbol table entry for that identifier.

Tricky Problems When Recognizing Tokens

Usually given the pattern describing the lexemes of a token it is relatively simple to recognize matching lexemes when they occur on the input How ever in some languages it is not immediately apparent when we have seen an instance of a lexeme corresponding to a token The following example is taken from Fortran in the xed format still allowed in Fortran 90 In the statement

DO 5 I 1 25

it is not apparent that the <code>rst</code> lexeme is <code>D05I</code> an instance of the identi er token until we see the dot following the 1 Note that blanks in <code>xed</code> format Fortran are ignored an archaic convention. Had we seen a comma instead of the dot we would have had a do statement

DO 5 I 1 25

in which the srst lexeme is the keyword DO

Example 3 2 The token names and associated attribute values for the For tran statement

E M C 2

are written below as a sequence of pairs

id pointer to symbol table entry for E
assign_op
id pointer to symbol table entry for M
mult_op
id pointer to symbol table entry for C
exp_op
number integer value 2

Note that in certain pairs especially operators punctuation and keywords there is no need for an attribute value. In this example, the token **number** has been given an integer valued attribute. In practice, a typical compiler would instead store a character string representing the constant and use as an attribute value for **number** a pointer to that string \Box

3 1 4 Lexical Errors

It is hard for a lexical analyzer to tell without the aid of other components that there is a source code error For instance if the string fi is encountered for the rst time in a C program in the context

fi a fx

a lexical analyzer cannot tell whether fi is a misspelling of the keyword if or an undeclared function identi er Since fi is a valid lexeme for the token id the lexical analyzer must return the token id to the parser and let some other phase of the compiler probably the parser in this case handle an error due to transposition of the letters

However suppose a situation arises in which the lexical analyzer is unable to proceed because none of the patterns for tokens matches any pre x of the remaining input. The simplest recovery strategy is panic mode recovery. We delete successive characters from the remaining input until the lexical analyzer can and a well formed token at the beginning of what input is left. This recovery technique may confuse the parser but in an interactive computing environment it may be quite adequate.

Other possible error recovery actions are

- 1 Delete one character from the remaining input
- 2 Insert a missing character into the remaining input
- 3 Replace a character by another character
- 4 Transpose two adjacent characters

Transformations like these may be tried in an attempt to repair the input The simplest such strategy is to see whether a pre x of the remaining input can be transformed into a valid lexeme by a single transformation. This strategy makes sense since in practice most lexical errors involve a single character. A more general correction strategy is to indicate the smallest number of transformations needed to convert the source program into one that consists only of valid lexemes but this approach is considered too expensive in practice to be worth the e ort

3 1 5 Exercises for Section 3 1

Exercise 3 1 1 Divide the following C program

```
float limitedSquare x float x
    returns x squared but never more than 100
    return x 10 0 x 10 0 100 x x
```

into appropriate lexemes using the discussion of Section 3 1 2 as a guide Which lexemes should get associated lexical values What should those values be

Exercise 3 1 2 Tagged languages like HTML or XML are different from conventional programming languages in that the punctuation tags are either very numerous as in HTML or a user denable set as in XML. Further tags can often have parameters. Suggest how to divide the following HTML document.

3.2 INPUT BUFFERING

```

```

into appropriate lexemes Which lexemes should get associated lexical values and what should those values be

3 2 Input Bu ering

Before discussing the problem of recognizing lexemes in the input let us examine some ways that the simple but important task of reading the source program can be speeded. This task is made discult by the fact that we often have to look one or more characters beyond the next lexeme before we can be sure we have the right lexeme The box on Tricky Problems When Recognizing Tokens in Section 3.1 gave an extreme example but there are many situations where we need to look at least one additional character ahead For instance we cannot be sure we ve seen the end of an identi er until we see a character that is not a letter or digit and therefore is not part of the lexeme for id In C single character operators like could also be the beginning of a or two character operator like Thus we shall introduce a two bu er or scheme that handles large lookaheads safely. We then consider an improvement involving sentinels that saves time checking for the ends of bu ers

3 2 1 Bu er Pairs

Because of the amount of time taken to process characters and the large number of characters that must be processed during the compilation of a large source program specialized bu ering techniques have been developed to reduce the amount of overhead required to process a single input character. An important scheme involves two bu ers that are alternately reloaded as suggested in Fig. 3.3

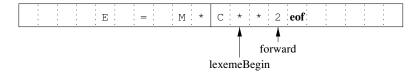

Figure 3.3 Using a pair of input bu ers

Each bu er is of the same size N and N is usually the size of a disk block e.g. 4096 bytes. Using one system read command we can read N characters into a bu er rather than using one system call per character. If fewer than N characters remain in the input—le then a special character represented by **eof**

marks the end of the source le and is di erent from any possible character of the source program

Two pointers to the input are maintained

- 1 Pointer lexemeBegin marks the beginning of the current lexeme whose extent we are attempting to determine
- 2 Pointer forward scans ahead until a pattern match is found the exact strategy whereby this determination is made will be covered in the balance of this chapter

Once the next lexeme is determined forward is set to the character at its right end. Then after the lexeme is recorded as an attribute value of a token returned to the parser lexemeBegin is set to the character immediately after the lexeme just found. In Fig. 3.3 we see forward has passed the end of the next lexeme

the Fortran exponentiation operator—and must be retracted one position to its left

Advancing forward requires that we set test whether we have reached the end of one of the busers and if so we must reload the other buser from the input and move forward to the beginning of the newly loaded buser. As long as we never need to look so far ahead of the actual lexeme that the sum of the lexemes length plus the distance we look ahead is greater than N we shall never overwrite the lexeme in its buser before determining it

3 2 2 Sentinels

If we use the scheme of Section 3 2 1 as described we must check each time we advance forward that we have not moved o one of the bu ers if we do then we must also reload the other bu er. Thus for each character read we make two tests one for the end of the bu er and one to determine what character is read the latter may be a multiway branch. We can combine the bu er end test with the test for the current character if we extend each bu er to hold a sentinel character at the end. The sentinel is a special character that cannot be part of the source program and a natural choice is the character eof

Figure 3 4 shows the same arrangement as Fig 3 3 but with the sentinels added Note that **eof** retains its use as a marker for the end of the entire input Any **eof** that appears other than at the end of a bu er means that the input is at an end Figure 3 5 summarizes the algorithm for advancing **forward** Notice how the rst test which can be part of a multiway branch based on the character pointed to by **forward** is the only test we make except in the case where we actually are at the end of a bu er or the end of the input

3 3 Speci cation of Tokens

Regular expressions are an important notation for specifying lexeme patterns While they cannot express all possible patterns they are very e ective in spec

Can We Run Out of Bu er Space

In most modern languages lexemes are short and one or two characters of lookahead is su-cient. Thus a bu-er size N in the thousands is ample and the double bu-er scheme of Section 3.2.1 works without problem. However there are some risks. For example, if character strings can be very long extending over many lines, then we could face the possibility that a lexeme is longer than N. To avoid problems with long character strings, we can treat them as a concatenation of components one from each line over which the string is written. For instance, in Java it is conventional to represent long strings by writing a piece on each line and concatenating pieces with a operator at the end of each piece.

A more di cult problem occurs when arbitrarily long lookahead may be needed. For example, some languages like PL I do not treat key words as reserved, that is you can use identi ers with the same name as a keyword like DECLARE. If the lexical analyzer is presented with text of a PL I program that begins DECLARE. ARG1. ARG2—it cannot be sure whether DECLARE is a keyword and ARG1 and so on are variables being declared or whether DECLARE is a procedure name with its arguments. For this reason modern languages tend to reserve their keywords. However, if not one can treat a keyword like DECLARE as an ambiguous identier and let the parser resolve the issue perhaps in conjunction with symbol table lookup.

ifying those types of patterns that we actually need for tokens. In this section we shall study the formal notation for regular expressions and in Section 3.5 we shall see how these expressions are used in a lexical analyzer generator. Then Section 3.7 shows how to build the lexical analyzer by converting regular expressions to automata that perform the recognition of the specified tokens.

3 3 1 Strings and Languages

An alphabet is any nite set of symbols Typical examples of symbols are let ters digits and punctuation The set $\{0\ 1\}$ is the binary alphabet ASCII is an important example of an alphabet it is used in many software systems. Uni

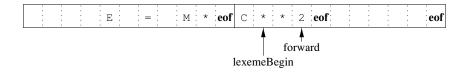

Figure 3 4 Sentinels at the end of each bu er

```
switch
          forward
      case eof
            if forward is at end of rst bu er {
                   reload second bu er
                   forward
                            beginning of second bu er
            else if forward is at end of second bu er {
                   reload rst bu er
                   forward
                            beginning of rst bu er
            else
                    eof within a bu er marks the end of input
                   terminate lexical analysis
            break
      Cases for the other characters
}
```

Figure 3 5 Lookahead code with sentinels

Implementing Multiway Branches

We might imagine that the switch in Fig 3.5 requires many steps to execute and that placing the case **eof** rst is not a wise choice. Actually it doesn't matter in what order we list the cases for each character. In practice, a multiway branch depending on the input character is made in one step by jumping to an address found in an array of addresses indexed by characters.

code which includes approximately 100 000 characters from alphabets around the world is another important example of an alphabet

A string over an alphabet is a nite sequence of symbols drawn from that alphabet In language theory the terms—sentence—and—word are often used as synonyms for string—The length of a string s—usually written |s|—is the number of occurrences of symbols in s—For example—banana is a string of length six—The empty string—denoted—is the string of length zero

A language is any countable set of strings over some xed alphabet. This de nition is very broad. Abstract languages like—the empty set or {} the set containing only the empty string are languages under this de nition. So too are the set of all syntactically well formed C programs and the set of all grammatically correct English sentences although the latter two languages are discult to specify exactly. Note that the de nition of language does not require that any meaning be ascribed to the strings in the language. Methods for defining the meaning of strings are discussed in Chapter 5

Terms for Parts of Strings

The following string related terms are commonly used

- 1 A pre x of string s is any string obtained by removing zero or more symbols from the end of s. For example, ban banana and are pre xes of banana
- 2 A su x of string s is any string obtained by removing zero or more symbols from the beginning of s For example nana banana and are su xes of banana
- 3 A *substring* of s is obtained by deleting any pre x and any su x from s For instance banana nan and are substrings of banana
- 4 The *proper* pre xes su xes and substrings of a string s are those pre xes su xes and substrings respectively of s that are not or not equal to s itself
- 5 A *subsequence* of s is any string formed by deleting zero or more not necessarily consecutive positions of s. For example baan is a subsequence of banana

If x and y are strings then the *concatenation* of x and y denoted xy is the string formed by appending y to x. For example, if x dog and y house then xy doghouse. The empty string is the identity under concatenation that is for any string s s s s

If we think of concatenation as a product we can de ne the exponentiation of strings as follows De ne s^0 to be and for all i 0 de ne s^i to be $s^{i-1}s$ Since s s it follows that s^1 s Then s^2 ss s^3 sss and so on

3 3 2 Operations on Languages

In lexical analysis the most important operations on languages are union concatenation and closure which are defined formally in Fig. 3.6. Union is the familiar operation on sets. The concatenation of languages is all strings formed by taking a string from the first language and a string from the second language in all possible ways and concatenating them. The Kleene closure of a language L denoted L is the set of strings you get by concatenating L zero or more times. Note that L^0 the concatenation of L zero times is defined to be $\{\ \}$ and inductively L^i is $L^{i-1}L$. Finally, the positive closure denoted L is the same as the Kleene closure, but without the term L^0 . That is will not be in L unless it is in L itself

OPERATION	DEFINITION AND NOTATION
$Union ext{ of } L ext{ and } M$	$L M \{s \mid s \text{ is in } L \text{ or } s \text{ is in } M\}$
Concatenation of L and M	$LM \{st \mid s \text{ is in } L \text{ and } t \text{ is in } M\}$
$Kleene\ closure\ of\ L$	$L = egin{array}{ccc} \infty & L^i \end{array}$
$Positive\ closure\ of\ L$	$L \qquad {\displaystyle \mathop{\sim}_{i=1}^{\infty}} \ L^{i}$

Figure 3.6 De nitions of operations on languages

Example 3 3 Let L be the set of letters {A B Z a b z} and let D be the set of digits {0 1 9} We may think of L and D in two essentially equivalent ways. One way is that L and D are respectively the alphabets of uppercase and lowercase letters and of digits. The second way is that L and D are languages all of whose strings happen to be of length one. Here are some other languages that can be constructed from languages L and D using the operators of Fig. 3.6

- $1\ L\ D$ is the set of letters and digits—strictly speaking the language with 62 strings of length one—each of which strings is either one letter or one digit
- 2 LD is the set of 520 strings of length two each consisting of one letter followed by one digit
- 3 L^4 is the set of all 4 letter strings
- 4~L~ is the set of all strings of letters including ~ the empty string
- 5 $\ L \ L \ D$ is the set of all strings of letters and digits beginning with a letter
- 6 D is the set of all strings of one or more digits

3 3 3 Regular Expressions

Suppose we wanted to describe the set of valid C identi ers. It is almost ex actly the language described in item. 5 above the only di erence is that the underscore is included among the letters

In Example 3 3 we were able to describe identi ers by giving names to sets of letters and digits and using the language operators union concatenation and closure. This process is so useful that a notation called regular expressions has come into common use for describing all the languages that can be built from these operators applied to the symbols of some alphabet. In this notation if letter_ is established to stand for any letter or the underscore and digit is

3.3 SPECIFICATION OF TOKENS

established to stand for any digit then we could describe the language of C identi ers by

The vertical bar above means union the parentheses are used to group subex pressions the star means zero or more occurrences of and the juxtaposition of *letter*_ with the remainder of the expression signi es concatenation

The regular expressions are built recursively out of smaller regular expressions using the rules described below. Each regular expression r denotes a language L r which is also defined recursively from the languages denoted by r s subexpressions. Here are the rules that defined ne the regular expressions over some alphabet and the languages that those expressions denote

BASIS There are two rules that form the basis

- 1 is a regular expression and L is $\{\ \}$ that is the language whose sole member is the empty string
- 2 If a is a symbol in then \mathbf{a} is a regular expression and L \mathbf{a} $\{a\}$ that is the language with one string of length one with a in its one position Note that by convention we use italics for symbols and boldface for their corresponding regular expression 1

INDUCTION There are four parts to the induction whereby larger regular expressions are built from smaller ones Suppose r and s are regular expressions denoting languages L r and L s respectively

- 1 $r \mid s$ is a regular expression denoting the language L r = L s
- 2 r s is a regular expression denoting the language L + r L s
- 3 r is a regular expression denoting L r
- 4 r is a regular expression denoting L r This last rule says that we can add additional pairs of parentheses around expressions without changing the language they denote

As de ned regular expressions often contain unnecessary pairs of paren theses We may drop certain pairs of parentheses if we adopt the conventions that

- a The unary operator has highest precedence and is left associative
- b Concatenation has second highest precedence and is left associative

¹However when talking about speci c characters from the ASCII character set we shall generally use teletype font for both the character and its regular expression

c | has lowest precedence and is left associative

Under these conventions for example we may replace the regular expression $\mathbf{a} \mid \mathbf{b} \quad \mathbf{c} \quad \text{by } \mathbf{a} \mid \mathbf{b} \quad \mathbf{c} \quad \text{Both expressions denote the set of strings that are either a single } a \text{ or are zero or more } b \text{ s followed by one } c$

Example 3 4 Let $\{a \ b\}$

- 1 The regular expression $\mathbf{a}|\mathbf{b}$ denotes the language $\{a\ b\}$
- 2 $\mathbf{a}|\mathbf{b} \ \mathbf{a}|\mathbf{b} \ \text{denotes} \{aa \ ab \ ba \ bb\}$ the language of all strings of length two over the alphabet Another regular expression for the same language is $\mathbf{aa}|\mathbf{ab}|\mathbf{ba}|\mathbf{bb}$
- 3 **a** denotes the language consisting of all strings of zero or more a s that is $\{aaaaaaa\}$
- 4 $\mathbf{a}|\mathbf{b}$ denotes the set of all strings consisting of zero or more instances of a or b that is all strings of a s and b s $\{ab aa ab ba bb aaa \}$ Another regular expression for the same language is $\mathbf{a} \mathbf{b}$
- 5 $\mathbf{a}|\mathbf{a}$ \mathbf{b} denotes the language $\{a\ b\ ab\ aab\ aaab\ \}$ that is the string a and all strings consisting of zero or more a s and ending in b

A language that can be de ned by a regular expression is called a regular set If two regular expressions r and s denote the same regular set we say they are equivalent and write r s For instance $\mathbf{a}|\mathbf{b}$ $\mathbf{b}|\mathbf{a}$ There are a number of algebraic laws for regular expressions each law asserts that expressions of two di erent forms are equivalent. Figure 3.7 shows some of the algebraic laws that hold for arbitrary regular expressions r s and t

LAW	DESCRIPTION		
r s-s r	is commutative		
r s t $r s t$	is associative		
$r \ st \ rs \ t$	Concatenation is associative		
$r \ s t \ rs rt \ s t \ r \ sr tr$	Concatenation distributes over		
$egin{array}{cccccccccccccccccccccccccccccccccccc$	is the identity for concatenation		
r r	is guaranteed in a closure		
r r	is idempotent		

Figure 3 7 Algebraic laws for regular expressions

3 3 4 Regular De nitions

For notational convenience we may wish to give names to certain regular ex pressions and use those names in subsequent expressions as if the names were themselves symbols If is an alphabet of basic symbols then a regular de nition is a sequence of de nitions of the form

$$egin{array}{lll} d_1 & & r_1 \\ d_2 & & r_2 \\ \end{array}$$

where

- 1 Each d_i is a new symbol not in and not the same as any other of the d s and
- 2 Each r_i is a regular expression over the alphabet $\{d_1 \ d_2 \ d_{i-1}\}$

By restricting r_i to — and the previously de ned d s we avoid recursive de ni tions and we can construct a regular expression over — alone for each r_i We do so by —rst replacing uses of d_1 in r_2 —which cannot use any of the d s except for d_1 —then replacing uses of d_1 and d_2 in r_3 by r_1 and the substituted r_2 and so on —Finally in r_n we replace each d_i for i —1 —2 — n —1 by the substituted version of r_i —each of which has only symbols of

Example 3 5 C identi ers are strings of letters digits and underscores Here is a regular de nition for the language of C identi ers. We shall conventionally use italics for the symbols de ned in regular de nitions

Example 3 6 Unsigned numbers integer or oating point are strings such as 5280 0 01234 6 336E4 or 1 89E 4 The regular de nition

is a precise speci cation for this set of strings. That is an optional Fraction is either a decimal point dot followed by one or more digits or it is missing the empty string. An optional Exponent if not missing is the letter E followed by an optional or sign followed by one or more digits. Note that at least one digit must follow the dot so number does not match 1 but does match 1 0 \Box

3 3 5 Extensions of Regular Expressions

Since Kleene introduced regular expressions with the basic operators for union concatenation and Kleene closure in the 1950s many extensions have been added to regular expressions to enhance their ability to specify string patterns. Here we mention a few notational extensions that were rst incorporated into Unix utilities such as Lex that are particularly useful in the specification lexical analyzers. The references to this chapter contain a discussion of some regular expression variants in use today.

- 1 One or more instances The unary post x operator represents the positive closure of a regular expression and its language That is if r is a regular expression then r denotes the language L r The operator has the same precedence and associativity as the operator Two useful algebraic laws r r | and r rr r relate the Kleene closure and positive closure
- 2 Zero or one instance The unary post x operator means zero or one occurrence That is r is equivalent to r| or put another way L r L r $\{$ $\}$ The operator has the same precedence and associativity as and
- 3 Character classes A regular expression $a_1|a_2| = |a_n|$ where the a_i s are each symbols of the alphabet can be replaced by the shorthand $a_1a_2 = a_n$ More importantly when $a_1 = a_2 = a_n$ form a logical se quence e.g. consecutive uppercase letters lowercase letters or digits we can replace them by $a_1 = a_n$ that is just the rst and last separated by a hyphen. Thus \mathbf{abc} is shorthand for $\mathbf{a}|\mathbf{b}|\mathbf{c}$ and \mathbf{a} \mathbf{z} is shorthand for $\mathbf{a}|\mathbf{b}| = |\mathbf{z}|$

Example 3 7 Using these shorthands we can rewrite the regular de nition of Example 3.5 as

The regular de nition of Example 3 6 can also be simpli ed

 $egin{array}{lll} digit & 0 & 9 \\ digits & digit \\ number & digits & digits & {\tt E} & digits \\ \end{array}$

3 3 6 Exercises for Section 3 3

Exercise 3 3 1 Consult the language reference manuals to determine i the sets of characters that form the input alphabet excluding those that may only appear in character strings or comments ii the lexical form of numerical constants and iii the lexical form of identi ers for each of the following languages a C b C c C d Fortran e Java f Lisp g SQL

Exercise 3 3 2 Describe the languages denoted by the following regular ex pressions

```
a a a|b a
b |a b
c a|b a a|b a|b
d a ba ba ba
```

Exercise 3 3 3 In a string of length n how many of the following are there

ab|ba aa|bb ab|ba aa|bb

a Pre xes

aa|bb

- b Su xes
- c Proper pre xes
- d Substrings
- e Subsequences

Exercise 3 3 4 Most languages are case sensitive so keywords can be written only one way and the regular expressions describing their lexemes are very simple However some languages like SQL are case insensitive so a keyword can be written either in lowercase or in uppercase or in any mixture of cases. Thus the SQL keyword SELECT can also be written select Select or select for instance. Show how to write a regular expression for a keyword in a case insensitive language. Illustrate the idea by writing the expression for select in SQL.

Exercise 3 3 5 Write regular de nitions for the following languages

- a All strings of lowercase letters that contain the ve vowels in order
- b All strings of lowercase letters in which the letters are in ascending lexi cographic order
- c Comments consisting of a string surrounded by and without an intervening unless it is inside double quotes

CHAPTER 3 LEXICAL ANALYSIS

- d All strings of digits with no repeated digits *Hint* Try this problem rst with a few digits such as {0 1 2}
- e All strings of digits with at most one repeated digit
- f All strings of a s and b s with an even number of a s and an odd number of b s
- g The set of Chess moves in the informal notation such as p k4 or kbp qn
- h All strings of a s and b s that do not contain the substring abb
- i All strings of a s and b s that do not contain the subsequence abb

Exercise 3 3 6 Write character classes for the following sets of characters

- a The rst ten letters up to j in either upper or lower case
- b The lowercase consonants
- c The digits in a hexadecimal number choose either upper or lower case for the digits above 9
- d The characters that can appear at the end of a legitimate English sentence e g exclamation point

The following exercises up to and including Exercise 3 3 10 discuss the extended regular expression notation from Lex the lexical analyzer generator that we shall discuss extensively in Section 3 5 The extended notation is listed in Fig. 3 8

Exercise 3 3 7 Note that these regular expressions give all of the following symbols operator characters a special meaning

Their special meaning must be turned o if they are needed to represent them selves in a character string We can do so by quoting the character within a string of length one or more e g the regular expression matches the string

We can also get the literal meaning of an operator character by preceding it by a backslash. Thus, the regular expression—also matches the string Write a regular expression that matches the string

Exercise 3 3 8 In Lex a complemented character class represents any character except the ones listed in the character class. We denote a complemented class by using as the rst character this symbol caret is not itself part of the class being complemented unless it is listed within the class itself. Thus A Za z matches any character that is not an uppercase or lowercase letter

and represents any character that is not an uppercase or lowercase letter and represents any character but the caret or newline since newline cannot be in any character class. Show that for every regular expression with complemented character classes there is an equivalent regular expression with out complemented character classes.

3 3 SPECIFICATION OF TOKENS

EXPRESSION	MATCHES	EXAMPLE	
\overline{c}	the one non operator character c	a	
$\setminus c$	character c literally		
s	string s literally		
	any character but newline	a b	
	beginning of a line	abc	
	end of a line	abc	
s	any one of the characters in string s	abc	
s	any one character not in string s	abc	
r	zero or more strings matching r	a	
r	one or more strings matching r	a	
r	zero or one r	a	
$r\{m \mid n\}$	between m and n occurrences of r	a{1 5}	
$r_1 r_2$	an r_1 followed by an r_2	ab	
$r_1 \mid r_2$	an r_1 or an r_2	a b	
r	same as r	a b	
r_1 r_2	r_1 when followed by r_2	abc 123	

Figure 38 Lex regular expressions

Exercise 3 3 9 The regular expression $r\{m \ n\}$ matches from m to n occur rences of the pattern r For example $a\{1 \ 5\}$ matches a string of one to $ve \ a \ s$ Show that for every regular expression containing repetition operators of this form there is an equivalent regular expression without repetition operators

Exercise 3 3 10 The operator matches the left end of a line and matches the right end of a line. The operator is also used to introduce complemented character classes but the context always makes it clear which meaning is in tended. For example aeiou matches any complete line that does not contain a lowercase yowel.

- a How do you tell which meaning of is intended
- b Can you always replace a regular expression using the and operators by an equivalent expression that does not use either of these operators

Exercise 3 3 11 The UNIX shell command sh uses the operators in Fig 3 9 in lename expressions to describe sets of le names For example the lename expression o matches all le names ending in o sort1 matches all le names of the form sort1 c where c is any character. Show how sh lename

Expression	MATCHES	Example			
's'	string s literally				
$\setminus c$	character c literally				
	any string	0			
	any character	sort1			
s	any character in s	sort1 cso			

Figure 3 9 Filename expressions used by the shell command sh

expressions can be replaced by equivalent regular expressions using only the basic union concatenation and closure operators

Exercise 3 3 12 SQL allows a rudimentary form of patterns in which two characters have special meaning underscore _ stands for any one character and percent sign stands for any string of 0 or more characters. In addition the programmer may de ne any character say e to be the escape character so an e preceding _ or another e gives the character that follows its literal meaning. Show how to express any SQL pattern as a regular expression given that we know which character is the escape character.

3 4 Recognition of Tokens

In the previous section we learned how to express patterns using regular expressions. Now we must study how to take the patterns for all the needed tokens and build a piece of code that examines the input string and indicate it has a lexeme matching one of the patterns. Our discussion will make use of the following running example

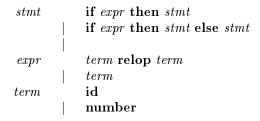

Figure 3 10 A grammar for branching statements

Example 3 8 The grammar fragment of Fig 3 10 describes a simple form of branching statements and conditional expressions. This syntax is similar to that of the language Pascal in that **then** appears explicitly after conditions

3.4 RECOGNITION OF TOKENS

For **relop** we use the comparison operators of languages like Pascal or SQL where is equals and is not equals because it presents an interesting structure of lexemes

The terminals of the grammar which are **if then else relop id** and **number** are the names of tokens as far as the lexical analyzer is concerned. The patterns for these tokens are described using regular de nitions as in Fig. 3.11. The patterns for *id* and *number* are similar to what we saw in Example 3.7.

```
digit
                 0 9
  digits
                 digit
number
                digits
                           digits
                                               digits
  letter
                 A Za z
     id
                letter
                         letter | digit
      if
                if
   then
                then
    else
                else
  relop
```

Figure 3 11 Patterns for tokens of Example 3 8

For this language the lexical analyzer will recognize the keywords if then and else as well as lexemes that match the patterns for relop id and number. To simplify matters we make the common assumption that keywords are also reserved words—that is they are not identifiers—even though their lexemes match the pattern for identifiers

In addition we assign the lexical analyzer the job of stripping out white space by recognizing the token ws de ned by

$$ws$$
 blank | tab | newline

Here **blank tab** and **newline** are abstract symbols that we use to express the ASCII characters of the same names. Token ws is different from the other tokens in that when we recognize it we do not return it to the parser but rather restart the lexical analysis from the character that follows the whitespace. It is the following token that gets returned to the parser

Our goal for the lexical analyzer is summarized in Fig 3 12. That table shows for each lexeme or family of lexemes which token name is returned to the parser and what attribute value as discussed in Section 3 1 3 is returned. Note that for the six relational operators symbolic constants LT LE and so on are used as the attribute value in order to indicate which instance of the token ${\bf relop}$ we have found. The particular operator found will in uence the code that is output from the compiler.

LEXEMES	TOKEN NAME	ATTRIBUTE VALUE		
Any ws				
if	if			
then	${f then}$			
else	${f else}$			
$\mathrm{Any}\ id$	id	Pointer to table entry		
Any $number$	number	Pointer to table entry		
	${f relop}$	LT		
	${f relop}$	LE		
	${f relop}$	EQ		
	${f relop}$	NE		
	${f relop}$	GT		
	${f relop}$	GE		

Figure 3 12 Tokens their patterns and attribute values

3 4 1 Transition Diagrams

As an intermediate step in the construction of a lexical analyzer we rst convert patterns into stylized owcharts called transition diagrams. In this section we perform the conversion from regular expression patterns to transition diagrams by hand but in Section 3.6 we shall see that there is a mechanical way to construct these diagrams from collections of regular expressions

Transition diagrams have a collection of nodes or circles called states Each state represents a condition that could occur during the process of scanning the input looking for a lexeme that matches one of several patterns. We may think of a state as summarizing all we need to know about what characters we have seen between the lexemeBegin pointer and the forward pointer as in the situation of Fig. 3.3

Edges are directed from one state of the transition diagram to another Each edge is labeled by a symbol or set of symbols. If we are in some state s and the next input symbol is a we look for an edge out of state s labeled by a and perhaps by other symbols as well. If we ind such an edge we advance the forward pointer and enter the state of the transition diagram to which that edge leads. We shall assume that all our transition diagrams are deterministic meaning that there is never more than one edge out of a given state with a given symbol among its labels. Starting in Section 3.5 we shall relax the condition of determinism making life much easier for the designer of a lexical analyzer although trickier for the implementer. Some important conventions about transition diagrams are

1 Certain states are said to be accepting or nal These states indicate that a lexeme has been found although the actual lexeme may not consist of all positions between the lexemeBegin and forward pointers We always

3.4 RECOGNITION OF TOKENS

indicate an accepting state by a double circle and if there is an action to be taken—typically returning a token and an attribute value to the parser—we shall attach that action to the accepting state

- 2 In addition if it is necessary to retract the *forward* pointer one position i e the lexeme does not include the symbol that got us to the accepting state then we shall additionally place a near that accepting state In our example it is never necessary to retract *forward* by more than one position but if it were we could attach any number of s to the accepting state
- 3 One state is designated the *start state* or *initial state* it is indicated by an edge labeled start entering from nowhere The transition diagram always begins in the start state before any input symbols have been read

Example 3 9 Figure 3 13 is a transition diagram that recognizes the lexemes matching the token **relop** We begin in state 0 the start state. If we see as the rst input symbol then among the lexemes that match the pattern for relop we can only be looking at We therefore go to state 1 and look at or the next character If it is then we recognize lexeme enter state 2 and return the token **relop** with attribute LE the symbolic constant representing this particular comparison operator If in state 1 the next character is and enter state 3 to return an indication that the instead we have lexeme not equals operator has been found. On any other character, the lexeme is and we enter state 4 to return that information Note however that state 4 has a to indicate that we must retract the input one position

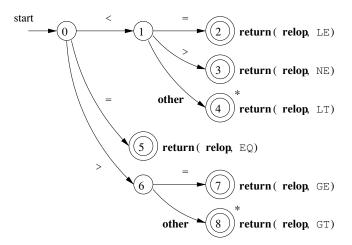

Figure 3 13 Transition diagram for **relop**

On the other hand if in state 0 the rst character we see is then this one character must be the lexeme. We immediately return that fact from state 5

The remaining possibility is that the rst character is Then we must enter state 6 and decide on the basis of the next character whether the lexeme is if we next see the sign or just on any other character. Note that if in state 0 we see any character besides or we can not possibly be seeing a relop lexeme so this transition diagram will not be used \Box

3 4 2 Recognition of Reserved Words and Identi ers

Recognizing keywords and identi ers presents a problem Usually keywords like if or then are reserved as they are in our running example so they are not identi ers even though they look like identi ers. Thus although we typically use a transition diagram like that of Fig. 3.14 to search for identi er lexemes this diagram will also recognize the keywords if then and else of our running example

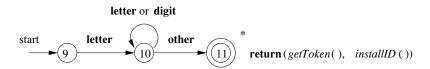

Figure 3 14 A transition diagram for id s and keywords

There are two ways that we can handle reserved words that look like iden ti ers

- 1 Install the reserved words in the symbol table initially A eld of the symbol table entry indicates that these strings are never ordinary identi ers and tells which token they represent We have supposed that this method is in use in Fig 3 14 When we nd an identi er a call to installID places it in the symbol table if it is not already there and returns a pointer to the symbol table entry for the lexeme found. Of course any identi er not in the symbol table during lexical analysis cannot be a reserved word so its token is id. The function getToken examines the symbol table entry for the lexeme found and returns whatever token name the symbol table says this lexeme represents either id or one of the keyword tokens that was initially installed in the table
- 2 Create separate transition diagrams for each keyword an example for the keyword then is shown in Fig 3.15. Note that such a transition diagram consists of states representing the situation after each successive letter of the keyword is seen followed by a test for a nonletter or digit i.e. any character that cannot be the continuation of an identi er. It is necessary to check that the identi er has ended or else we would return token then in situations where the correct token was id with a lexeme like thenextvalue that has then as a proper pre x. If we adopt this approach then we must prioritize the tokens so that the reserved word

3 4 RECOGNITION OF TOKENS

tokens are recognized in preference to **id** when the lexeme matches both patterns We *do not* use this approach in our example which is why the states in Fig. 3.15 are unnumbered

Figure 3 15 Hypothetical transition diagram for the keyword then

3 4 3 Completion of the Running Example

The transition diagram for **id** s that we saw in Fig 3 14 has a simple structure Starting in state 9 it checks that the lexeme begins with a letter and goes to state 10 if so We stay in state 10 as long as the input contains letters and digits. When we rst encounter anything but a letter or digit we go to state 11 and accept the lexeme found. Since the last character is not part of the identifier we must retract the input one position and as discussed in Section 3 4 2 we enter what we have found in the symbol table and determine whether we have a keyword or a true identifier.

The transition diagram for token **number** is shown in Fig 3 16 and is so far the most complex diagram we have seen Beginning in state 12 if we see a digit we go to state 13 In that state we can read any number of additional digits. However if we see anything but a digit dot or E we have seen a number in the form of an integer 123 is an example. That case is handled by entering state 20 where we return token **number** and a pointer to a table of constants where the found lexeme is entered. These mechanics are not shown on the diagram but are analogous to the way we handled identifiers.

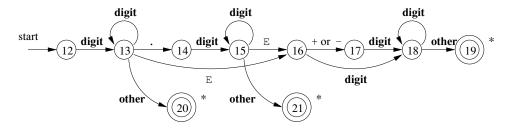

Figure 3 16 A transition diagram for unsigned numbers

If we instead see a dot in state 13 then we have an optional fraction State 14 is entered and we look for one or more additional digits—state 15 is used for that purpose—If we see an E—then we have an optional exponent whose recognition is the job of states 16 through 19—Should we in state 15 instead see anything but E or a digit—then we have come to the end of the fraction—there is no exponent—and we return the lexeme found—via state 21

The nal transition diagram shown in Fig 3 17 is for whitespace In that diagram we look for one or more whitespace characters represented by **delim** in that diagram—typically these characters would be blank tab newline and perhaps other characters that are not considered by the language design to be part of any token

Figure 3 17 A transition diagram for whitespace

Note that in state 24 we have found a block of consecutive whitespace characters followed by a nonwhitespace character. We retract the input to begin at the nonwhitespace but we do not return to the parser. Rather we must restart the process of lexical analysis after the whitespace.

3 4 4 Architecture of a Transition Diagram Based Lexical Analyzer

There are several ways that a collection of transition diagrams can be used to build a lexical analyzer Regardless of the overall strategy each state is represented by a piece of code We may imagine a variable state holding the number of the current state for a transition diagram A switch based on the value of state takes us to code for each of the possible states where we not the action of that state Often the code for a state is itself a switch statement or multiway branch that determines the next state by reading and examining the next input character

Example 3 10 In Fig 3 18 we see a sketch of getRelop a C function whose job is to simulate the transition diagram of Fig 3 13 and return an object of type TOKEN that is a pair consisting of the token name which must be relop in this case and an attribute value the code for one of the six comparison operators in this case getRelop rst creates a new object retToken and initializes its rst component to RELOP the symbolic code for token relop

We see the typical behavior of a state in case 0 the case where the current state is 0. A function nextChar obtains the next character from the input and assigns it to local variable c. We then check c for the three characters we expect to nd making the state transition dictated by the transition diagram of Fig. 3.13 in each case. For example, if the next input character is nd we go to state 5.

If the next input character is not one that can begin a comparison operator then a function fail is called What fail does depends on the global error recovery strategy of the lexical analyzer. It should reset the forward pointer to lexemeBegin in order to allow another transition diagram to be applied to

3 4 RECOGNITION OF TOKENS

TOKEN getRelop

```
TOKEN retToken
                 new RELOP
while 1
              repeat character processing until a return
              or failure occurs
    switch state
        case 0 c
                    nextChar
                if
                     С
                                 state
                                         1
                else if
                                      state
                else if
                                      state
                else fail
                                 lexeme is not a relop
                break
        case 1
        case 8
                retract
                retToken attribute
                                      GT
                return retToken
```

Figure 3 18 Sketch of implementation of **relop** transition diagram

the true beginning of the unprocessed input—It might then change the value of state to be the start state for another transition diagram—which will search for another token—Alternatively if there is no other transition diagram—that remains unused fail—could initiate an error correction phase that will try to repair the input and—nd a lexeme—as discussed in Section 3.1.4

We also show the action for state 8 in Fig. 3.18. Because state 8 bears a we must retract the input pointer one position i.e. put c back on the input stream. That task is accomplished by the function retract. Since state 8 represents the recognition of lexeme. we set the second component of the returned object which we suppose is named attribute to GT the code for this operator. \Box

To place the simulation of one transition diagram in perspective let us consider the ways code like Fig. 3 18 could t into the entire lexical analyzer

1 We could arrange for the transition diagrams for each token to be tried se quentially Then the function fail of Example 3 10 resets the pointer forward and starts the next transition diagram each time it is called This method allows us to use transition diagrams for the individual key words like the one suggested in Fig 3 15 We have only to use these before we use the diagram for id in order for the keywords to be reserved words

- 2 We could run the various transition diagrams in parallel feeding the next input character to all of them and allowing each one to make what ever transitions it required. If we use this strategy we must be careful to resolve the case where one diagram and a lexeme that matches its pattern while one or more other diagrams are still able to process input. The normal strategy is to take the longest pre-x of the input that matches any pattern. That rule allows us to prefer identifier thenext to keyword then or the operator to for example.
- 3 The preferred approach and the one we shall take up in the following sections is to combine all the transition diagrams into one. We allow the transition diagram to read input until there is no possible next state and then take the longest lexeme that matched any pattern as we discussed in item 2 above. In our running example, this combination is easy because no two tokens can start with the same character if each rest character immediately tells us which token we are looking for. Thus we could simply combine states 0. 9. 12 and 22 into one start state leaving other transitions intact. However, in general, the problem of combining transition diagrams for several tokens is more complex, as we shall see shortly

3 4 5 Exercises for Section 3 4

Exercise 3 4 1 Provide transition diagrams to recognize the same languages as each of the regular expressions in Exercise 3 3 2

Exercise 3 4 2 Provide transition diagrams to recognize the same languages as each of the regular expressions in Exercise 3 3 5

The following exercises up to Exercise 3 4 12 introduce the Aho Corasick algorithm for recognizing a collection of keywords in a text string in time proportional to the length of the text and the sum of the length of the keywords. This algorithm uses a special form of transition diagram called a *trie*. A trie is a tree structured transition diagram with distinct labels on the edges leading from a node to its children. Leaves of the trie represent recognized keywords.

Knuth Morris and Pratt presented an algorithm for recognizing a single keyword b_1b_2 b_n in a text string. Here the trie is a transition diagram with n-1 states 0 through n. State 0 is the initial state and state n represents acceptance that is discovery of the keyword. From each state s from 0 through n-1 there is a transition to state s-1 labeled by symbol b_{s-1} . For example the trie for the keyword ababaa is

$$0 \xrightarrow{a} 1 \xrightarrow{b} 2 \xrightarrow{a} 3 \xrightarrow{b} 4 \xrightarrow{a} 5 \xrightarrow{a} 6$$

In order to process text strings rapidly and search those strings for a key word it is useful to de ne for keyword b_1b_2 — b_n and position s in that keyword corresponding to state s of its trie—a failure function—f s—computed as in

3.4 RECOGNITION OF TOKENS

Fig 3 19 The objective is that b_1b_2 b_f s is the longest proper pre x of b_1b_2 b_s that is also a su x of b_1b_2 b_s The reason f s is important is that if we are trying to match a text string for b_1b_2 b_n and we have matched the rst s positions but we then fail i e the next position of the text string does not hold b_{s-1} then f s is the longest pre x of b_1b_2 b_n that could possibly match the text string up to the point we are at Of course the next character of the text string must be b_f s 1 or else we still have problems and must consider a yet shorter pre x which will be b_f s 1

Figure 3 19 Algorithm to compute the failure function for keyword b_1b_2 b_n

As an example $\,$ the failure function for the trie constructed above for ababaa is

s	1	2	3	4	5	6
f s	0	0	1	2	3	1

For instance states 3 and 1 represent pre xes aba and a respectively f 3 1 because a is the longest proper pre x of aba that is also a su x of aba Also f 2 0 because the longest proper pre x of ab that is also a su x is the empty string

Exercise 3 4 3 Construct the failure function for the strings

- a abababaab
- b aaaaaa
- c abbaabb

Exercise 3 4 4 Prove by induction on s that the algorithm of Fig. 3 19 correctly computes the failure function

Exercise 3 4 5 Show that the assignment t-f t in line 4 of Fig 3 19 is executed at most n times. Show that therefore the entire algorithm takes only O(n) time on a keyword of length n

Having computed the failure function for a keyword b_1b_2 b_n we can scan a string a_1a_2 a_m in time O m to tell whether the keyword occurs in the string. The algorithm shown in Fig. 3.20 slides the keyword along the string trying to make progress by matching the next character of the keyword with the next character of the string. If it cannot do so after matching s characters then it slides the keyword right s f s positions so only the rst f s characters of the keyword are considered matched with the string

Figure 3 20 The KMP algorithm tests whether string a_1a_2 a_m contains a single keyword b_1b_2 b_n as a substring in O(m) n time

Exercise 3 4 6 Apply Algorithm KMP to test whether keyword ababaa is a substring of

- a abababaab
- b abababbaa

Exercise 3 4 7 Show that the algorithm of Fig 3 20 correctly tells whether the keyword is a substring of the given string Hint proceed by induction on i Show that for all i the value of s after line 4 is the length of the longest pre x of the keyword that is a su x of a_1a_2 a_i

Exercise 3 4 8 Show that the algorithm of Fig 3 20 runs in time O m n assuming that function f is already computed and its values stored in an array indexed by s

Exercise 3 4 9 The Fibonacci strings are de ned as follows

For example s_3 ab s_4 aba and s_5 abaab

a What is the length of s_n

3 4 RECOGNITION OF TOKENS

- b Construct the failure function for s_6
- c Construct the failure function for s_7
- d Show that the failure function for any s_n can be expressed by f 1 f 2 0 and for 2 j $|s_n|$ f j is j $|s_{k-1}|$ where k is the largest integer such that $|s_k|$ j 1
- e In the KMP algorithm what is the largest number of consecutive applications of the failure function when we try to determine whether keyword s_k appears in text string s_{k-1}

Aho and Corasick generalized the KMP algorithm to recognize any of a set of keywords in a text string. In this case the trie is a true tree with branching from the root. There is one state for every string that is a pre-x not necessarily proper of any keyword. The parent of a state corresponding to string b_1b_2 b_k is the state that corresponds to b_1b_2 b_k 1. A state is accepting if it corresponds to a complete keyword. For example, Fig. 3.21 shows the trie for the keywords he she his and hers

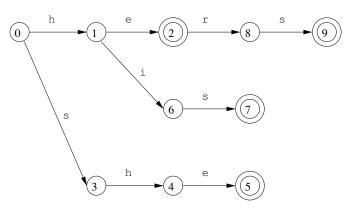

Figure 3 21 Trie for keywords he she his hers

The failure function for the general trie is defined as follows. Suppose s is the state that corresponds to string b_1b_2 b_n . Then f s is the state that corresponds to the longest proper su x of b_1b_2 b_n that is also a pre x of some keyword. For example, the failure function for the trie of Fig. 3.21 is

s	1	2	3	4	5	6	7	8	9
f s	0	0	0	1	2	0	3	0	3

Exercise 3 4 10 Modify the algorithm of Fig 3 19 to compute the failure function for general tries Hint The major difference is that we cannot simply test for equality or inequality of b_{s-1} and b_{t-1} in lines 4 and 5 of Fig 3 19 Rather from any state there may be several transitions out on several characters as there are transitions on both e and i from state 1 in Fig 3 21 Any of

those transitions could lead to a state that represents the longest su $\,$ x that is also a pre $\,$ x

Exercise 3 4 11 Construct the tries and compute the failure function for the following sets of keywords

- a aaa abaaa and ababaaa
- b all fall fatal llama and lame
- c pipe pet item temper and perpetual

Exercise 3 4 12 Show that your algorithm from Exercise 3 4 10 still runs in time that is linear in the sum of the lengths of the keywords

3 5 The Lexical Analyzer Generator Lex

In this section we introduce a tool called Lex or in a more recent implementation Flex that allows one to specify a lexical analyzer by specifying regular expressions to describe patterns for tokens. The input notation for the Lex tool is referred to as the Lex language and the tool itself is the Lex compiler. Behind the scenes the Lex compiler transforms the input patterns into a transition diagram and generates code in a lecalled lex yy c that simulates this transition diagram. The mechanics of how this translation from regular expressions to transition diagrams occurs is the subject of the next sections here we only learn the Lex language.

351 Use of Lex

Figure 3 22 suggests how Lex is used An input le which we call lex 1 is written in the Lex language and describes the lexical analyzer to be generated. The Lex compiler transforms lex 1 to a C program in a le that is always named lex yy c. The latter le is compiled by the C compiler into a le called a out as always. The C compiler output is a working lexical analyzer that can take a stream of input characters and produce a stream of tokens.

The normal use of the compiled C program referred to as a out in Fig 3 22 is as a subroutine of the parser. It is a C function that returns an integer which is a code for one of the possible token names. The attribute value whether it be another numeric code a pointer to the symbol table or nothing is placed in a global variable yylval ² which is shared between the lexical analyzer and parser thereby making it simple to return both the name and an attribute value of a token

²Incidentally the yy that appears in yylval and lex yy c refers to the Yacc parser generator which we shall describe in Section 4.9 and which is commonly used in conjunction with Lex

35 THE LEXICAL ANALYZER GENERATOR LEX

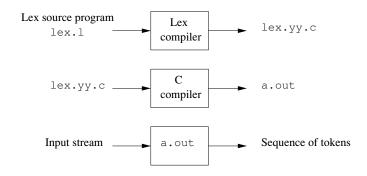

Figure 3 22 Creating a lexical analyzer with Lex

3 5 2 Structure of Lex Programs

A Lex program has the following form

declarations

translation rules

auxiliary functions

The declarations section includes declarations of variables $manifest\ constants$ identi ers declared to stand for a constant e.g. the name of a token and regular de nitions in the style of Section 3 3 4

The translation rules each have the form

Each pattern is a regular expression which may use the regular de nitions of the declaration section. The actions are fragments of code typically written in C although many variants of Lex using other languages have been created

The third section holds whatever additional functions are used in the actions Alternatively these functions can be compiled separately and loaded with the lexical analyzer

The lexical analyzer created by Lex behaves in concert with the parser as follows. When called by the parser the lexical analyzer begins reading its remaining input one character at a time until it ands the longest pre x of the input that matches one of the patterns P_i . It then executes the associated action A_i . Typically A_i will return to the parser but if it does not e.g. because P_i describes whitespace or comments—then the lexical analyzer proceeds to—nd additional lexemes—until one of the corresponding actions causes a return to the parser—The lexical analyzer returns a single value—the token name—to the parser—but uses the shared—integer variable yylval to pass additional information about the lexeme found—if needed

Example 3 11 Figure 3 23 is a Lex program that recognizes the tokens of Fig 3 12 and returns the token found. A few observations about this code will introduce us to many of the important features of Lex

In the declarations section we see a pair of special brackets and Anything within these brackets is copied directly to the lelex yy c and is not treated as a regular denition. It is common to place there the denitions of the manifest constants using C define statements to associate unique integer codes with each of the manifest constants. In our example, we have listed in a comment the names of the manifest constants LT IF and so on but have not shown them dened to be particular integers 3

Also in the declarations section is a sequence of regular de nitions. These use the extended notation for regular expressions described in Section 3.3.5. Regular de nitions that are used in later de nitions or in the patterns of the translation rules are surrounded by curly braces. Thus, for instance delim is de ned to be a shorthand for the character class consisting of the blank, the tab and the newline, the latter two are represented as in all UNIX commands by backslash followed by t or n respectively. Then ws is de ned to be one or more delimiters by the regular expression delim

Notice that in the de nition of id and number parentheses are used as grouping metasymbols and do not stand for themselves. In contrast E in the de nition of number stands for itself. If we wish to use one of the Lex meta symbols such as any of the parentheses or to stand for themselves we may precede them with a backslash. For instance, we see — in the definition of number to represent the dot since that character is a metasymbol representing any character— as usual in UNIX regular expressions

In the auxiliary function section we see two such functions installID and installNum
Like the portion of the declaration section that appears between everything in the auxiliary section is copied directly to le lex yy c but may be used in the actions

Finally let us examine some of the patterns and rules in the middle section of Fig 3 23 First ws an identi er declared in the rst section has an associated empty action. If we ind whitespace we do not return to the parser but look for another lexeme. The second token has the simple regular expression pattern if Should we see the two letters if on the input and they are not followed by another letter or digit, which would cause the lexical analyzer to ind a longer preximal of the input matching the pattern for id then the lexical analyzer consumes these two letters from the input and returns the token name IF that is the integer for which the manifest constant IF stands. Keywords then and else are treated similarly

The fth token has the pattern de ned by id Note that although keywords like if match this pattern as well as an earlier pattern. Lex chooses whichever

 $^{^3}$ If Lex is used along with Yacc then it would be normal to de ne the manifest constants in the Yacc program and use them without de nition in the Lex program. Since lex yy c is compiled with the Yacc output the constants thus will be available to the actions in the Lex program

similar to installID but puts numer ical constants into a separate table

int installNum

pattern is listed $\,$ rst in situations where the longest matching pre $\,$ x matches two or more patterns $\,$ The action taken when id is matched is threefold

- 1 Function installID is called to place the lexeme found in the symbol table
- 2 This function returns a pointer to the symbol table which is placed in global variable yylval where it can be used by the parser or a later component of the compiler Note that installID has available to it two variables that are set automatically by the lexical analyzer that Lex generates
 - a yytext is a pointer to the beginning of the lexeme analogous to lexemeBegin in Fig 33
 - b yyleng is the length of the lexeme found
- 3 The token name ID is returned to the parser

The action taken when a lexeme matching the pattern number is similar using the auxiliary function installNum

3 5 3 Con ict Resolution in Lex

We have alluded to the two rules that Lex uses to decide on the proper lexeme to select when several pre xes of the input match one or more patterns

- 1 Always prefer a longer pre x to a shorter pre x
- 2 If the longest possible pre x matches two or more patterns prefer the pattern listed rst in the Lex program

Example 3 12 The rst rule tells us to continue reading letters and digits to nd the longest pre x of these characters to group as an identi er. It also tells us to treat—as a single lexeme—rather than selecting—as one lexeme and as the next lexeme—The second rule makes keywords reserved—if we list the keywords before id in the program—For instance—if then is determined to be the longest pre x of the input that matches any pattern—and the pattern then precedes—id—as it does in Fig. 3 23—then the token THEN is returned—rather than ID—

3 5 4 The Lookahead Operator

Lex automatically reads one character ahead of the last character that forms the selected lexeme and then retracts the input so only the lexeme itself is consumed from the input However sometimes we want a certain pattern to be matched to the input only when it is followed by a certain other characters If so we may use the slash in a pattern to indicate the end of the part of the

35 THE LEXICAL ANALYZER GENERATOR LEX

pattern that matches the lexeme What follows is additional pattern that must be matched before we can decide that the token in question was seen but what matches this second pattern is not part of the lexeme

Example 3 13 In Fortran and some other languages keywords are not reserved. That situation creates problems such as a statement

IF I J 3

where IF is the name of an array not a keyword. This statement contrasts with statements of the form

IF condition THEN

where IF is a keyword Fortunately we can be sure that the keyword IF is always followed by a left parenthesis some text—the condition—that may contain parentheses a right parenthesis and a letter—Thus—we could write a Lex rule for the keyword IF like

IF letter

This rule says that the pattern the lexeme matches is just the two letters IF The slash says that additional pattern follows but does not match the lexeme In this pattern the rst character is the left parentheses. Since that character is a Lex metasymbol it must be preceded by a backslash to indicate that it has its literal meaning. The dot and star match, any string without a newline. Note that the dot is a Lex metasymbol meaning, any character except newline. It is followed by a right parenthesis again with a backslash to give that character its literal meaning. The additional pattern is followed by the symbol letter which is a regular definition representing the character class of all letters.

Note that in order for this pattern to be foolproof we must preprocess the input to delete whitespace We have in the pattern neither provision for whitespace nor can we deal with the possibility that the condition extends over lines since the dot will not match a newline character

For instance suppose this pattern is asked to match a pre x of input

IF A B C D THEN

the rst two characters match IF the next character matches — the next nine characters match — and the next two match — and letter Note the fact that the rst right parenthesis after C is not followed by a letter is irrelevant we only need to —nd some way of matching the input to the pattern. We conclude that the letters IF constitute the lexeme —and they are an instance of token if —

3 5 5 Exercises for Section 3 5

Exercise 3 5 1 Describe how to make the following modi cations to the Lex program of Fig 3 23

- a Add the keyword while
- b Change the comparison operators to be the C operators of that kind
- c Allow the underscore _ as an additional letter
- d Add a new pattern with token STRING The pattern consists of a double quote any string of characters and a nal double quote However if a double quote appears in the string it must be escaped by preceding it with a backslash and therefore a backslash in the string must be represented by two backslashes. The lexical value which is the string without the surrounding double quotes and with backslashes used to escape a character removed. Strings are to be installed in a table of strings

Exercise 3 5 2 Write a Lex program that copies a le replacing each non empty sequence of white space by a single blank

Exercise 3 5 3 Write a Lex program that copies a C program replacing each instance of the keyword float by double

Exercise 3 5 4 Write a Lex program that converts a le to Pig latin Speci cally assume the le is a sequence of words groups of letters separated by whitespace Every time you encounter a word

- 1 If the rst letter is a consonant move it to the end of the word and then add ay
- 2 If the rst letter is a vowel just add ay to the end of the word

All nonletters are copied intact to the output

Exercise 3 5 5 In SQL keywords and identi ers are case insensitive Write a Lex program that recognizes the keywords SELECT FROM and WHERE in any combination of capital and lower case letters—and token ID which for the purposes of this exercise you may take to be any sequence of letters and digits beginning with a letter. You need not install identifiers in a symbol table but tell how the install function would differ from that described for case sensitive identifiers as in Fig. 3 23.

3.6 Finite Automata

We shall now discover how Lex turns its input program into a lexical analyzer At the heart of the transition is the formalism known as *nite automata* These are essentially graphs like transition diagrams with a few di erences

- 1 Finite automata are *recognizers* they simply say yes or no about each possible input string
- 2 Finite automata come in two avors
 - a Nondeterministic nite automata NFA have no restrictions on the labels of their edges. A symbol can label several edges out of the same state and the empty string is a possible label
 - b Deterministic nite automata DFA have for each state and for each symbol of its input alphabet exactly one edge with that symbol leaving that state

Both deterministic and nondeterministic nite automata are capable of recognizing the same languages. In fact these languages are exactly the same languages called the *regular languages* that regular expressions can describe ⁴

3 6 1 Nondeterministic Finite Automata

A nondeterministic nite automaton NFA consists of

- 1 A nite set of states S
- 2 A set of input symbols the *input alphabet* We assume that which stands for the empty string is never a member of
- 3 A transition function that gives for each state and for each symbol in $\{\ \}$ a set of next states
- 4 A state s_0 from S that is distinguished as the start state or initial state
- 5 A set of states F a subset of S that is distinguished as the accepting states or nal states

We can represent either an NFA or DFA by a transition graph where the nodes are states and the labeled edges represent the transition function. There is an edge labeled a from state s to state t if and only if t is one of the next states for state s and input a. This graph is very much like a transition diagram except

 $^{^4}$ There is a small lacuna as we de ned them regular expressions cannot describe the empty language since we would never want to use this pattern in practice. However nite automata can de ne the empty language. In the theory—is treated as an additional regular expression for the sole purpose of de ning the empty language.

- a The same symbol can label edges from one state to several di erent states and
- b An edge may be labeled by the empty string instead of or in addition to symbols from the input alphabet

Example 3 14 The transition graph for an NFA recognizing the language of regular expression $\mathbf{a}|\mathbf{b}$ $\mathbf{a}\mathbf{b}\mathbf{b}$ is shown in Fig 3 24. This abstract example describing all strings of a s and b s ending in the particular string abb will be used throughout this section. It is similar to regular expressions that describe languages of real interest however. For instance, an expression describing all les whose name ends in \mathbf{o} is \mathbf{any} \mathbf{o} where \mathbf{any} stands for any printable character.

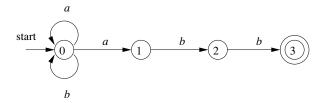

Figure 3 24 A nondeterministic nite automaton

Following our convention for transition diagrams the double circle around state 3 indicates that this state is accepting. Notice that the only ways to get from the start state 0 to the accepting state is to follow some path that stays in state 0 for a while then goes to states 1–2 and 3 by reading abb from the input. Thus, the only strings getting to the accepting state are those that end in abb.

3 6 2 Transition Tables

We can also represent an NFA by a transition table whose rows correspond to states and whose columns correspond to the input symbols and — The entry for a given state and input is the value of the transition function applied to those arguments—If the transition function has no information about that state input pair—we put—in the table for the pair

Example 3 15 The transition table for the NFA of Fig 3 24 is shown in Fig 3 25 \square

The transition table has the advantage that we can easily not the transitions on a given state and input. Its disadvantage is that it takes a lot of space when the input alphabet is large yet most states do not have any moves on most of the input symbols.

STATE	a	b	
0	{0 1}	{0}	
1		$\{2\}$	
2		$\{3\}$	
3			

Figure 3 25 Transition table for the NFA of Fig 3 24

3 6 3 Acceptance of Input Strings by Automata

An NFA accepts input string x if and only if there is some path in the transition graph from the start state to one of the accepting states such that the symbols along the path spell out x Note that labels along the path are e ectively ignored since the empty string does not contribute to the string constructed along the path

Example 3 16 The string *aabb* is accepted by the NFA of Fig. 3 24. The path labeled by aabb from state 0 to state 3 demonstrating this fact is $0 \xrightarrow{a} 0 \xrightarrow{a} 1 \xrightarrow{b} 2 \xrightarrow{b} 3$

$$0 \xrightarrow{a} 0 \xrightarrow{a} 1 \xrightarrow{b} 2 \xrightarrow{b} 3$$

Note that several paths labeled by the same string may lead to dierent states For instance path

$$0 \xrightarrow{a} 0 \xrightarrow{a} 0 \xrightarrow{b} 0 \xrightarrow{b} 0$$

is another path from state 0 labeled by the string aabb. This path leads to state 0 which is not accepting However remember that an NFA accepts a string as long as some path labeled by that string leads from the start state to an accepting state The existence of other paths leading to a nonaccepting state is irrelevant

The language de ned or accepted by an NFA is the set of strings labeling some path from the start to an accepting state. As was mentioned the NFA of Fig 3 24 de nes the same language as does the regular expression a|b abb that is all strings from the alphabet $\{a \ b\}$ that end in abb. We may use $L \ A$ to stand for the language accepted by automaton A

Example 3 17 Figure 3 26 is an NFA accepting L aa |bb| String aaa is accepted because of the path

$$0 \xrightarrow{\varepsilon} 1 \xrightarrow{a} 2 \xrightarrow{a} 2 \xrightarrow{a} 2$$

Note that s disappear in a concatenation so the label of the path is aaa

3 6 4 Deterministic Finite Automata

A deterministic nite automaton DFA is a special case of an NFA where

CHAPTER 3 LEXICAL ANALYSIS

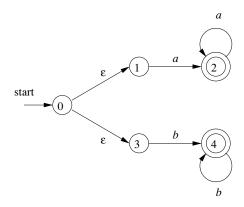

Figure 3 26 NFA accepting aa |bb

- 1 There are no moves on input and
- 2 For each state s and input symbol a there is exactly one edge out of s labeled a

If we are using a transition table to represent a DFA then each entry is a single state. We may therefore represent this state without the curly braces that we use to form sets

While the NFA is an abstract representation of an algorithm to recognize the strings of a certain language the DFA is a simple concrete algorithm for recognizing strings. It is fortunate indeed that every regular expression and every NFA can be converted to a DFA accepting the same language because it is the DFA that we really implement or simulate when building lexical analyzers. The following algorithm shows how to apply a DFA to a string

Algorithm 3 18 Simulating a DFA

INPUT An input string x terminated by an end of le character **eof** A DFA D with start state s_0 accepting states F and transition function move

OUTPUT Answer yes if D accepts x no otherwise

METHOD Apply the algorithm in Fig. 3.27 to the input string x. The function $move\ s\ c$ gives the state to which there is an edge from state s on input c. The function nextChar returns the next character of the input string x. \Box

Example 3 19 In Fig 3 28 we see the transition graph of a DFA accepting the language $\mathbf{a}|\mathbf{b}$ $\mathbf{a}\mathbf{b}\mathbf{b}$ the same as that accepted by the NFA of Fig 3 24 Given the input string ababb this DFA enters the sequence of states 0 1 2 1 2 3 and returns yes

3 7 From Regular Expressions to Automata

The regular expression is the notation of choice for describing lexical analyzers and other pattern processing software as was re ected in Section 3.5. How ever implementation of that software requires the simulation of a DFA as in Algorithm 3.18 or perhaps simulation of an NFA Because an NFA often has a choice of move on an input symbol as Fig. 3.24 does on input a from state 0 or on as Fig. 3.26 does from state 0 or even a choice of making a transition on or on a real input symbol its simulation is less straightforward than for a DFA. Thus often it is important to convert an NFA to a DFA that accepts the same language

In this section we shall section we shall section to convert NFA is to DFA is. Then we use this technique known as the subset construction to give a useful algorithm for simulating NFA is directly in situations other than lexical analysis where the NFA to DFA conversion takes more time than the direct simulation Next we show how to convert regular expressions to NFA is from which a DFA can be constructed if desired. We conclude with a discussion of the time space tradeo inherent in the various methods for implementing regular expressions and see how to choose the appropriate method for your application.

3 7 1 Conversion of an NFA to a DFA

The general idea behind the subset construction is that each state of the constructed DFA corresponds to a set of NFA states. After reading input

3 7 FROM REGULAR EXPRESSIONS TO AUTOMATA

 a_1a_2 a_n the DFA is in that state which corresponds to the set of states that the NFA can reach from its start state following paths labeled a_1a_2 a_n

It is possible that the number of DFA states is exponential in the number of NFA states which could lead to disculties when we try to implement this DFA However part of the power of the automaton based approach to lexical analysis is that for real languages the NFA and DFA have approximately the same number of states and the exponential behavior is not seen

Algorithm 3 20 The subset construction of a DFA from an NFA

INPUT An NFA N

OUTPUT A DFA D accepting the same language as N

METHOD Our algorithm constructs a transition table Dtran for D Each state of D is a set of NFA states and we construct Dtran so D will simulate in parallel all possible moves N can make on a given input string Our rst problem is to deal with transitions of N properly. In Fig. 3.31 we see the definitions of several functions that describe basic computations on the states of N that are needed in the algorithm. Note that s is a single state of N while T is a set of states of N.

OPERATION	DESCRIPTION
closure s	Set of NFA states reachable from NFA state s
	on transitions alone
$closure \ T$	Set of NFA states reachable from some NFA state s
	in set T on transitions alone s in T closure s
$move \ T \ a$	Set of NFA states to which there is a transition on
	input symbol a from some state s in T

Figure 3 31 Operations on NFA states

We must explore those sets of states that N can be in after seeing some input string. As a basis before reading the rst input symbol N can be in any of the states of $closure\ s_0$ where s_0 is its start state. For the induction suppose that N can be in set of states T after reading input string x. If it next reads input a then N can immediately go to any of the states in $move\ T$ a. However after reading a it may also make several transitions thus N could be in any state of $closure\ move\ T$ a after reading input xa. Following these ideas the construction of the set of D s states Dstates and its transition function Dtran is shown in Fig. 3.32

The start state of D is closure s_0 and the accepting states of D are all those sets of N s states that include at least one accepting state of N. To complete our description of the subset construction we need only to show how

```
initially closure \ s_0 is the only state in Dstates and it is unmarked while there is an unmarked state T in Dstates {

mark T

for each input symbol a {

U closure \ move \ T a

if U is not in Dstates

add U as an unmarked state to Dstates

Dtran \ T \ a \ U

}
```

Figure 3 32 The subset construction

closure T is computed for any set of NFA states T This process shown in Fig 3.33 is a straightforward search in a graph from a set of states. In this case imagine that only the labeled edges are available in the graph.

```
push all states of T onto stack
initialize closure\ T to T

while stack is not empty {
	pop t the top element o stack
	for each state u with an edge from t to u labeled 	if u is not in closure\ T {
	add u to closure\ T
	push u onto stack
}
```

Figure 3 33 Computing closure T

Example 3 21 Figure 3 34 shows another NFA accepting **a**|**b abb** it hap pens to be the one we shall construct directly from this regular expression in Section 3 7 Let us apply Algorithm 3 20 to Fig. 3 34

The start state A of the equivalent DFA is $\ closure\ 0$ or A {0 1 2 4 7} since these are exactly the states reachable from state 0 via a path all of whose edges have label Note that a path can have zero edges so state 0 is reachable from itself by an labeled path

The input alphabet is $\{a\ b\}$ Thus our set step is to mark A and compute $Dtran\ A\ a$ closure move $A\ a$ and $Dtran\ A\ b$ closure move $A\ b$ Among the states $0\ 1\ 2\ 4$ and 7 only 2 and 7 have transitions on a to 3 and 8 respectively. Thus move $A\ a$ $\{3\ 8\}$ Also closure $\{3\ 8\}$ $\{1\ 2\ 3\ 4\ 6\ 7\ 8\}$ so we conclude

3 7 FROM REGULAR EXPRESSIONS TO AUTOMATA

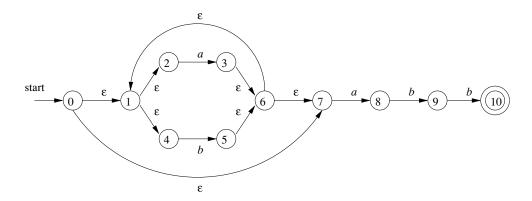

Figure 3 34 NFA N for $\mathbf{a}|\mathbf{b}$ \mathbf{abb}

 $Dtran A a \qquad closure \ move \ A \ a \qquad closure \ \{3\ 8\} \qquad \{1\ 2\ 3\ 4\ 6\ 7\ 8\}$

Let us call this set B so Dtran A a B

Now we must compute Dtran A b Among the states in A only 4 has a transition on b and it goes to 5 Thus

 $Dtran A b \qquad closure \{5\} \qquad \{1 \ 2 \ 4 \ 5 \ 6 \ 7\}$

Let us call the above set C so Dtran A b

NFA STATE	DFA STATE	a	b
{0 1 2 4 7}	A	B	C
$\{1\ 2\ 3\ 4\ 6\ 7\ 8\}$	B	B	D
$\{1\ 2\ 4\ 5\ 6\ 7\}$	C	B	C
$\{1\ 2\ 4\ 5\ 6\ 7\ 9\}$	D	B	E
$\{1\ 2\ 4\ 5\ 6\ 7\ 10\}$	E	B	C

Figure 3 35 Transition table Dtran for DFA D

If we continue this process with the unmarked sets B and C we eventually reach a point where all the states of the DFA are marked. This conclusion is guaranteed since there are only 2^{11} di erent subsets of a set of eleven NFA states. The ve di erent DFA states we actually construct their corresponding sets of NFA states and the transition table for the DFA D are shown in Fig. 3.35 and the transition graph for D is in Fig. 3.36. State A is the start state and state E which contains state 10 of the NFA is the only accepting state

Note that D has one more state than the DFA of Fig. 3 28 for the same language. States A and C have the same move function, and so can be merged. We discuss the matter of minimizing the number of states of a DFA in Section 3 9 6.

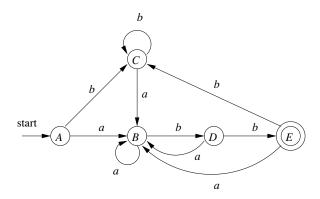

Figure 3 36 Result of applying the subset construction to Fig 3 34

3 7 2 Simulation of an NFA

A strategy that has been used in a number of text editing programs is to construct an NFA from a regular expression and then simulate the NFA using something like an on the y subset construction. The simulation is outlined below

Algorithm 3 22 Simulating an NFA

INPUT An input string x terminated by an end of le character **eof** An NFA N with start state s_0 accepting states F and transition function move

OUTPUT Answer yes if N accepts x no otherwise

METHOD The algorithm keeps a set of current states S those that are reached from s_0 following a path labeled by the inputs read so far If c is the next input character read by the function nextChar then we rst compute $move\ S\ c$ and then close that set using closure The algorithm is sketched in Fig. 3 37 \Box

```
1
          closure \ s_0
2
        nextChar
3
    while
           c
                 eof
          S
4
                 closure move S c
5
              nextChar
6
7
    if S
            F
                     return yes
    else return no
```

Figure 3 37 Simulating an NFA

3 7 3 E ciency of NFA Simulation

If carefully implemented Algorithm 3 22 can be quite e cient. As the ideas involved are useful in a number of similar algorithms involving search of graphs we shall look at this implementation in additional detail. The data structures we need are

- 1 Two stacks each of which holds a set of NFA states. One of these stacks oldStates holds the current set of states i.e. the value of S on the right side of line 4 in Fig 3 37. The second newStates holds the next set of states. S on the left side of line 4. Unseen is a step where as we go around the loop of lines 3. through 6. newStates is transferred to oldStates.
- 2 A boolean array already On indexed by the NFA states to indicate which states are in newStates While the array and stack hold the same information it is much faster to interrogate already Ons than to search for state s on the stack newStates It is for this e ciency that we maintain both representations
- 3 A two dimensional array $moves\ a$ holding the transition table of the NFA. The entries in this table which are sets of states are represented by linked lists

To implement line 1 of Fig 3 37 we need to set each entry in array al readyOn to FALSE then for each state s in $closure s_0$ push s onto oldStates and set alreadyOn s to TRUE This operation on state s and the implementation of line 4 as well are facilitated by a function we shall call addState s. This function pushes state s onto newStates sets alreadyOn s to TRUE and calls itself recursively on the states in move s in order to further the computation of closure s. However to avoid duplicating work we must be careful never to call addState on a state that is already on the stack newStates. Figure 3 38 sketches this function

Figure 3 38 Adding a new state s which is known not to be on newStates

We implement line 4 of Fig 3 37 by looking at each state s on oldStates We rst nd the set of states $move\ s\ c$ where c is the next input and for each

of those states that is not already on newStates we apply addState to it Note that addState has the e ect of computing the closure and adding all those states to newStates as well if they were not already on This sequence of steps is summarized in Fig 3 39

```
s 	ext{ on } oldStates  {
17
             for
                  t on moves c
18
                   if
                        alreadyOn t
19
                           addState t
20
             pop s from oldStates
      }
21
22
            s on newStates
23
             pop s from newStates
24
             push s onto oldStates
25
             alreadyOn s
                             FALSE
      }
26
```

Figure 3 39 Implementation of step 4 of Fig 3 37

Now suppose that the NFA N has n states and m transitions i.e. m is the sum over all states of the number of symbols or on which the state has a transition out. Not counting the call to addState at line 19 of Fig. 3.39 the time spent in the loop of lines 16 through 21 is O(n). That is we can go around the loop at most n times and each step of the loop requires constant work except for the time spent in addState. The same is true of the loop of lines 22 through 26

During one execution of Fig 3 39 i.e. of step 4 of Fig 3 37 it is only possible to call addState on a given state once. The reason is that whenever we call addState s we set alreadyOn s to TRUE at line 11 of Fig 3 38. Once alreadyOn s is TRUE the tests at line 13 of Fig 3 38 and line 18 of Fig 3 39 prevent another call

The time spent in one call to addState exclusive of the time spent in recursive calls at line 14 is O 1 for lines 10 and 11. For lines 12 and 13 the time depends on how many transitions there are out of state s. We do not know this number for a given state but we know that there are at most m transitions in total out of all states. As a result, the aggregate time spent in lines 12 and 13 over all calls to addState during one execution of the code of Fig. 3.39 is O m. The aggregate for the rest of the steps of addState is O n since it is a constant per call, and there are at most n calls

We conclude that implemented properly the time to execute line 4 of Fig 3 37 is O n m The rest of the while loop of lines 3 through 6 takes O 1 time per iteration. If the input x is of length k then the total work in that loop is O k n m Line 1 of Fig 3 37 can be executed in O n m time since it is essentially the steps of Fig 3 39 with oldStates containing only

Big Oh Notation

An expression like O n is a shorthand for at most some constant times n Technically we say a function f n perhaps the running time of some step of an algorithm is O g n if there are constants c and n_0 such that whenever n n_0 it is true that f n cg n A useful idiom is O 1 which means some constant. The use of this big oh notation enables us to avoid getting too far into the details of what we count as a unit of execution time yet lets us express the rate at which the running time of an algorithm grows

the state s_0 Lines 2 7 and 8 each take O 1 time. Thus the running time of Algorithm 3 22 properly implemented is O k n m. That is the time taken is proportional to the length of the input times the size nodes plus edges of the transition graph

3 7 4 Construction of an NFA from a Regular Expression

We now give an algorithm for converting any regular expression to an NFA that de nes the same language. The algorithm is syntax directed in the sense that it works recursively up the parse tree for the regular expression. For each subexpression the algorithm constructs an NFA with a single accepting state

Algorithm 3 23 The McNaughton Yamada Thompson algorithm to convert a regular expression to an NFA

INPUT A regular expression r over alphabet

OUTPUT An NFA N accepting L r

METHOD Begin by parsing r into its constituent subexpressions. The rules for constructing an NFA consist of basis rules for handling subexpressions with no operators and inductive rules for constructing larger NFA s from the NFA s for the immediate subexpressions of a given expression

BASIS For expression construct the NFA

$$\frac{\epsilon}{}$$

Here i is a new state the start state of this NFA and f is another new state the accepting state for the NFA

For any subexpression a in — construct the NFA

where again i and f are new states the start and accepting states respectively Note that in both of the basis constructions we construct a distinct NFA with new states for every occurrence of or some a as a subexpression of r

INDUCTION Suppose N s and N t are NFA s for regular expressions s and t respectively

a Suppose r s|t Then N r the NFA for r is constructed as in Fig. 3.40. Here i and f are new states the start and accepting states of N r respectively. There are transitions from i to the start states of N s and N t and each of their accepting states have transitions to the accepting state f. Note that the accepting states of N s and N t are not accepting in N r. Since any path from i to f must pass through either N s or N t exclusively and since the label of that path is not changed by the s leaving i or entering f we conclude that N r accepts L s L t which is the same as L r. That is Fig. 3.40 is a correct construction for the union operator

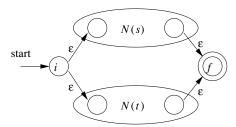

Figure 3 40 NFA for the union of two regular expressions

b Suppose r st Then construct N r as in Fig. 3.41 The start state of N s becomes the start state of N r and the accepting state of N t is the only accepting state of N t The accepting state of N t and the start state of N t are merged into a single state with all the transitions in or out of either state. A path from i to f in Fig. 3.41 must go rst through N s and therefore its label will begin with some string in L s. The path then continues through N t so the path s label in hishes with a string in L t. As we shall soon argue accepting states never have edges out and start states never have edges in so it is not possible for a path to refere t t after leaving it. Thus t t accepts exactly t t t and is a correct NFA for t t

Figure 3 41 NFA for the concatenation of two regular expressions

3 7 FROM REGULAR EXPRESSIONS TO AUTOMATA

Suppose r-s Then for r we construct the NFA N-r shown in Fig. 3.42. Here i and f are new states the start state and lone accepting state of N-r To get from i to f we can either follow the introduced path labeled which takes care of the one string in $L-s^{-0}$ or we can go to the start state of N-s through that NFA then from its accepting state back to its start state zero or more times. These options allow N-r to accept all the strings in $L-s^{-1}$ and so on so the entire set of strings accepted by N-r is L-s

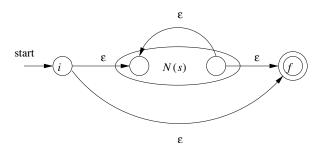

Figure 3 42 NFA for the closure of a regular expression

d Finally suppose r s Then L r L s and we can use the NFA N s as N r

The method description in Algorithm 3 23 contains hints as to why the inductive construction works as it should. We shall not give a formal correctness proof but we shall list several properties of the constructed NFA s. in addition to the all important fact that $N\ r$ accepts language $L\ r$. These properties are interesting in their own right, and helpful in making a formal proof

- $1 \ N \ r$ has at most twice as many states as there are operators and operands in r. This bound follows from the fact that each step of the algorithm creates at most two new states
- 2 N r has one start state and one accepting state. The accepting state has no outgoing transitions and the start state has no incoming transitions
- 3 Each state of N r other than the accepting state has either one outgoing transition on a symbol in N or two outgoing transitions both on

Example 3 24 Let us use Algorithm 3 23 to construct an NFA for r $\mathbf{a}|\mathbf{b}$ \mathbf{abb} Figure 3 43 shows a parse tree for r that is analogous to the parse trees constructed for arithmetic expressions in Section 2 2 3 For subexpression r_1 the rst \mathbf{a} we construct the NFA

CHAPTER 3 LEXICAL ANALYSIS

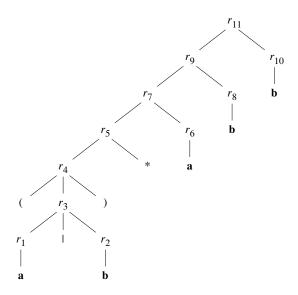

Figure 3 43 Parse tree for **a**|**b abb**

State numbers have been chosen for consistency with what follows For r_2 we construct

$$\frac{b}{4}$$

We can now combine N r_1 and N r_2 using the construction of Fig. 3.40 to obtain the NFA for r_3 $r_1|r_2$ this NFA is shown in Fig. 3.44

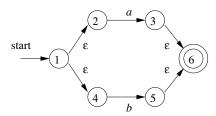

Figure 3 44 NFA for r_3

The NFA for r_4 r_3 is the same as that for r_3 The NFA for r_5 r_3 is then as shown in Fig. 3.45. We have used the construction in Fig. 3.42 to build this NFA from the NFA in Fig. 3.44.

Now consider subexpression r_6 which is another **a** We use the basis construction for a again but we must use new states It is not permissible to reuse

3 7 FROM REGULAR EXPRESSIONS TO AUTOMATA

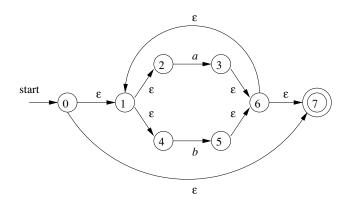

Figure 3 45 NFA for r_5

the NFA we constructed for r_1 even though r_1 and r_6 are the same expression. The NFA for r_6 is

To obtain the NFA for r_7 r_5r_6 we apply the construction of Fig 3 41 We merge states 7 and 7' yielding the NFA of Fig 3 46 Continuing in this fashion with new NFA s for the two subexpressions **b** called r_8 and r_{10} we eventually construct the NFA for $\mathbf{a}|\mathbf{b}$ $\mathbf{a}\mathbf{b}\mathbf{b}$ that we rst met in Fig 3 34 \square

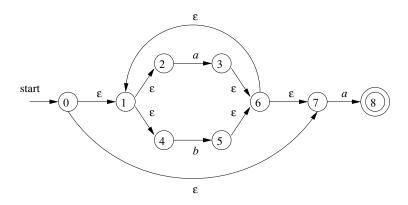

Figure 3 46 $\,$ NFA for r_7

3 7 5 E ciency of String Processing Algorithms

We observed that Algorithm 3 18 processes a string x in time O|x| while in Section 3 7 3 we concluded that we could simulate an NFA in time proportional to the product of |x| and the size of the NFA s transition graph. Obviously it

is faster to have a DFA to simulate than an NFA so we might wonder whether it ever makes sense to simulate an NFA

One issue that may favor an NFA is that the subset construction can in the worst case exponentiate the number of states While in principle the number of DFA states does not in uence the running time of Algorithm 3 18 should the number of states become so large that the transition table does not t in main memory then the true running time would have to include disk I O and therefore rise noticeably

Example 3 25 Consider the family of languages described by regular expres sions of the form L_n a | b a a | b $^{n-1}$ that is each language L_n consists of strings of a s and b s such that the nth character to the left of the right end holds a An n 1 state NFA is easy to construct. It stays in its initial state under any input but also has the option on input a of going to state 1. From state 1 it goes to state 2 on any input and so on until in state n it accepts Figure 3.47 suggests this NFA

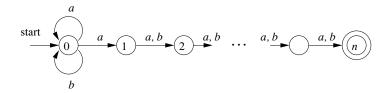

Figure 3 47 An NFA that has many fewer states than the smallest equivalent DFA

However any DFA for the language L_n must have at least 2^n states. We shall not prove this fact but the idea is that if two strings of length n can get the DFA to the same state, then we can exploit the last position where the strings dier and therefore one must have a the other b to continue the strings identically until they are the same in the last n-1 positions. The DFA will then be in a state where it must both accept and not accept. Fortunately as we mentioned it is rare for lexical analysis to involve patterns of this type and we do not expect to encounter DFA s with outlandish numbers of states in practice.

However lexical analyzer generators and other string processing systems often start with a regular expression. We are faced with a choice of converting the regular expression to an NFA or DFA. The additional cost of going to a DFA is thus the cost of executing Algorithm 3 20 on the NFA one could go directly from a regular expression to a DFA but the work is essentially the same. If the string processor is one that will be executed many times as is the case for lexical analysis then any cost of converting to a DFA is worthwhile. However in other string processing applications such as grep where the user species one regular expression and one or several less to be searched for the pattern

3 7 FROM REGULAR EXPRESSIONS TO AUTOMATA

of that expression it may be more e cient to skip the step of constructing a DFA and simulate the NFA directly

Let us consider the cost of converting a regular expression r to an NFA by Algorithm 3 23. A key step is constructing the parse tree for r. In Chapter 4 we shall see several methods that are capable of constructing this parse tree in linear time that is in time O|r| where |r| stands for the size of r—the sum of the number of operators and operands in r. It is also easy to check that each of the basis and inductive constructions of Algorithm 3 23 takes constant time so the entire time spent by the conversion to an NFA is O|r|

Moreover as we observed in Section 3.7.4 the NFA we construct has at most 2|r| states and at most 4|r| transitions. That is in terms of the analysis in Section 3.7.3 we have n-2|r| and m-4|r|. Thus simulating this NFA on an input string x takes time O|r|-|x|. This time dominates the time taken by the NFA construction which is O|r| and therefore we conclude that it is possible to take a regular expression r and string x and tell whether x is in L r in time O |r|-|x|

The time taken by the subset construction is highly dependent on the number of states the resulting DFA has. To begin notice that in the subset construction of Fig. 3.32, the key step the construction of a set of states U from a set of states T and an input symbol a is very much like the construction of a new set of states from the old set of states in the NFA simulation of Algorithm 3.22. We already concluded that properly implemented this step takes time at most proportional to the number of states and transitions of the NFA

Suppose we start with a regular expression r and convert it to an NFA. This NFA has at most 2|r| states and at most 4|r| transitions. Moreover, there are at most |r| input symbols. Thus, for every DFA state constructed, we must construct at most |r| new states, and each one takes at most O |r| time. The time to construct a DFA of s states is thus O $|r|^2s$

In the common case where s is about |r| the subset construction takes time $O|r|^3$. However in the worst case as in Example 3.25 this time is $O|r|^2 2^{|r|}$. Figure 3.48 summarizes the options when one is given a regular expression r and wants to produce a recognizer that will tell whether one or more strings x are in L r

AUTOMATON	Initial	PER STRING
NFA	O r	O r x
DFA typical case	$O r ^3$	O x
DFA worst case	$O r ^2 2^{ r }$	O x

Figure 3 48 Initial cost and per string cost of various methods of recognizing the language of a regular expression

If the per string cost dominates as it does when we build a lexical analyzer

we clearly prefer the DFA. However in commands like grep where we run the automaton on only one string we generally prefer the NFA. It is not until |x| approaches $|r|^3$ that we would even think about converting to a DFA.

There is however a mixed strategy that is about as good as the better of the NFA and the DFA strategy for each expression r and string x. Start o simulating the NFA but remember the sets of NFA states i.e. the DFA states and their transitions as we compute them. Before processing the current set of NFA states and the current input symbol check to see whether we have already computed this transition and use the information if so

3 8 Design of a Lexical Analyzer Generator

In this section we shall apply the techniques presented in Section 3.7 to see how a lexical analyzer generator such as Lex is architected. We discuss two approaches based on NFAs and DFAs the latter is essentially the implementation of Lex

3 8 1 The Structure of the Generated Analyzer

Figure 3 49 overviews the architecture of a lexical analyzer generated by Lex The program that serves as the lexical analyzer includes a xed program that simulates an automaton at this point we leave open whether that automaton is deterministic or nondeterministic. The rest of the lexical analyzer consists of components that are created from the Lex program by Lex itself

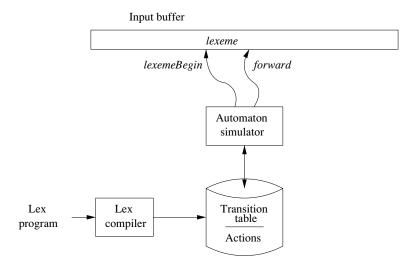

Figure 3 49 A Lex program is turned into a transition table and actions which are used by a nite automaton simulator

These components are

- 1 A transition table for the automaton
- 2 Those functions that are passed directly through Lex to the output see Section 3 5 2
- 3 The actions from the input program which appear as fragments of code to be invoked at the appropriate time by the automaton simulator

To construct the automaton we begin by taking each regular expression pattern in the Lex program and converting it using Algorithm 3 23 to an NFA We need a single automaton that will recognize lexemes matching any of the patterns in the program so we combine all the NFAs into one by introducing a new start state with transitions to each of the start states of the NFAs N_i for pattern p_i . This construction is shown in Fig. 3 50

Example 3 26 We shall illustrate the ideas of this section with the following simple abstract example

CHAPTER 3 LEXICAL ANALYSIS

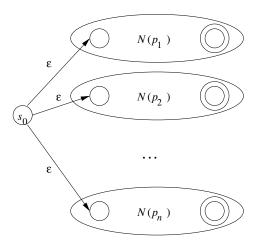

Figure 3 50 An NFA constructed from a Lex program

```
a { action A_1 for pattern p_1 }

abb { action A_2 for pattern p_2 }

a b { action A_3 for pattern p_3 }
```

Note that these three patterns present some con icts of the type discussed in Section 3 5 3 In particular string abb matches both the second and third patterns but we shall consider it a lexeme for pattern p_2 since that pattern is listed rst in the above Lex program. Then input strings such as aabbb have many pre xes that match the third pattern. The Lex rule is to take the longest so we continue reading b s until another a is met whereupon we report the lexeme to be the initial a s followed by as many b s as there are

Figure 3 51 shows three NFA s that recognize the three patterns. The third is a simplification of what would come out of Algorithm 3 23. Then Fig. 3 52 shows these three NFA s combined into a single NFA by the addition of start state 0 and three transitions \Box

3 8 2 Pattern Matching Based on NFA s

If the lexical analyzer simulates an NFA such as that of Fig 3 52 then it must read input beginning at the point on its input which we have referred to as lexemeBegin As it moves the pointer called forward ahead in the input it calculates the set of states it is in at each point following Algorithm 3 22

Eventually the NFA simulation reaches a point on the input where there are no next states At that point there is no hope that any longer pre x of the input would ever get the NFA to an accepting state rather the set of states will always be empty Thus we are ready to decide on the longest pre x that is a lexeme matching some pattern

38 DESIGN OF A LEXICAL ANALYZER GENERATOR

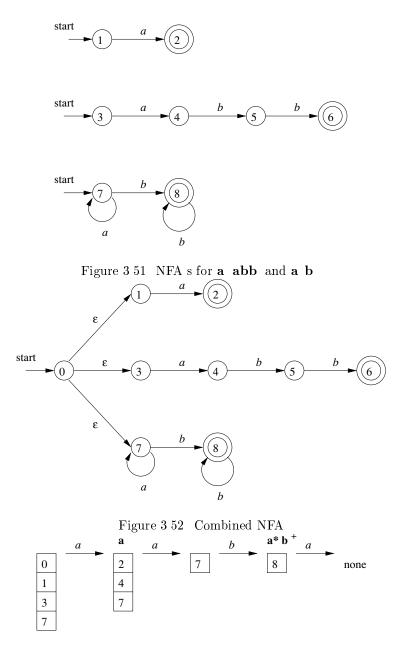

Figure 3 53 Sequence of sets of states entered when processing input aaba

We look backwards in the sequence of sets of states until we nd a set that includes one or more accepting states. If there are several accepting states in that set pick the one associated with the earliest pattern p_i in the list from the Lex program. Move the *forward* pointer back to the end of the lexeme and perform the action A_i associated with pattern p_i

Example 3 27 Suppose we have the patterns of Example 3 26 and the input begins aaba Figure 3 53 shows the sets of states of the NFA of Fig 3 52 that we enter starting with closure of the initial state 0 which is $\{0\ 1\ 3\ 7\}$ and proceeding from there After reading the fourth input symbol we are in an empty set of states since in Fig 3 52 there are no transitions out of state 8 on input a

Thus we need to back up looking for a set of states that includes an ac cepting state. Notice that as indicated in Fig. 3.53 after reading a we are in a set that includes state 2 and therefore indicates that the pattern \mathbf{a} has been matched. However after reading aab we are in state 8 which indicates that \mathbf{a} \mathbf{b} has been matched pre x aab is the longest pre x that gets us to an accepting state. We therefore select aab as the lexeme and execute action A_3 which should include a return to the parser indicating that the token whose pattern is p_3 a \mathbf{b} has been found.

3 8 3 DFA s for Lexical Analyzers

Another architecture resembling the output of Lex is to convert the NFA for all the patterns into an equivalent DFA using the subset construction of Algorithm 3 20 Within each DFA state if there are one or more accepting NFA states determine the rst pattern whose accepting state is represented and make that pattern the output of the DFA state

Example 3 28 Figure 3 54 shows a transition diagram based on the DFA that is constructed by the subset construction from the NFA in Fig 3 52. The accepting states are labeled by the pattern that is identified by that state. For instance, the state {6 8} has two accepting states corresponding to patterns **abb** and **a b** Since the former is listed are that is the pattern associated with state {6 8} □

We use the DFA in a lexical analyzer much as we did the NFA. We simulate the DFA until at some point there is no next state or strictly speaking the next state is—the *dead state* corresponding to the empty set of NFA states. At that point we back up through the sequence of states we entered and as soon as we meet an accepting DFA state—we perform the action associated with the pattern for that state

Example 3 29 Suppose the DFA of Fig 3 54 is given input abba The se quence of states entered is 0137 247 58 68 and at the nal a there is no tran sition out of state 68 Thus we consider the sequence from the end and in this case 68 itself is an accepting state that reports pattern p_2 **abb** \Box

38 DESIGN OF A LEXICAL ANALYZER GENERATOR

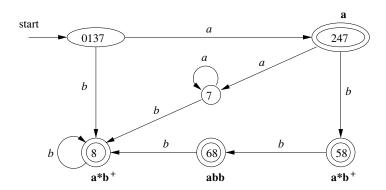

Figure 3 54 Transition graph for DFA handling the patterns **a abb** and **a b**

3 8 4 Implementing the Lookahead Operator

Recall from Section 3 5 4 that the Lex lookahead operator—in a Lex pattern r_1 — r_2 is sometimes necessary because the pattern r_1 for a particular token may need to describe some trailing context r_2 in order to correctly identify the actual lexeme—When converting the pattern r_1 — r_2 to an NFA—we treat the—as if it were—so we do not actually look for a—on the input—However—if the NFA recognizes a pre—x xy of the input bu—er as matching this regular expression the end of the lexeme—is not where the NFA entered its accepting state—Rather the end occurs when the NFA enters a state s such that

- $1 ext{ } s ext{ has an } transition on the imaginary$
- 2 There is a path from the start state of the NFA to state s that spells out x
- 3 There is a path from state s to the accepting state that spells out y
- 4 x is as long as possible for any xy satisfying conditions 1 3

If there is only one transition state on the imaginary in the NFA then the end of the lexeme occurs when this state is entered for the last time as the following example illustrates If the NFA has more than one transition state on the imaginary then the general problem of nding the correct state s is much more discult

Example 3 30 An NFA for the pattern for the Fortran IF with lookahead from Example 3 13 is shown in Fig 3 55 Notice that the transition from state 2 to state 3 represents the lookahead operator State 6 indicates the presence of the keyword IF However we nd the lexeme IF by scanning backwards to the last occurrence of state 2 whenever state 6 is entered \Box

Dead States in DFA s

Technically the automaton in Fig 3 54 is not quite a DFA. The reason is that a DFA has a transition from every state on every input symbol in its input alphabet. Here we have omitted transitions to the dead state and we have therefore omitted the transitions from the dead state to itself on every input. Previous NFA to DFA examples did not have a way to get from the start state to but the NFA of Fig 3 52 does

However when we construct a DFA for use in a lexical analyzer it is important that we treat the dead state di erently since we must know when there is no longer any possibility of recognizing a longer lexeme Thus we suggest always omitting transitions to the dead state and eliminating the dead state itself. In fact, the problem is harder than it appears since an NFA to DFA construction may yield several states that cannot reach any accepting state and we must know when any of these states have been reached. Section 3.9.6 discusses how to combine all these states into one dead state so their identication becomes easy. It is also interesting to note that if we construct a DFA from a regular expression using Algorithms 3.20 and 3.23, then the DFA will not have any states besides that cannot lead to an accepting state.

Exercise 3 8 3 Suppose we were to revise the de nition of a DFA to allow zero or one transition out of each state on each input symbol rather than exactly one such transition as in the standard DFA de nition Some regular

3 9 OPTIMIZATION OF DFA BASED PATTERN MATCHERS

expressions would then have smaller DFA s than they do under the standard de nition of a DFA Give an example of one such regular expression

Exercise 3 8 4 Design an algorithm to recognize Lex lookahead patterns of the form r_1 r_2 where r_1 and r_2 are regular expressions. Show how your algorithm works on the following inputs

- a abcd|abc d
- b aab ba
- c **aa a**

3 9 Optimization of DFA Based Pattern Matchers

In this section we present three algorithms that have been used to implement and optimize pattern matchers constructed from regular expressions

- 1 The rst algorithm is useful in a Lex compiler because it constructs a DFA directly from a regular expression without constructing an interme diate NFA The resulting DFA also may have fewer states than the DFA constructed via an NFA
- 2 The second algorithm minimizes the number of states of any DFA by combining states that have the same future behavior. The algorithm itself is quite excient running in time $O(n \log n)$ where n is the number of states of the DFA.
- 3 The third algorithm produces more compact representations of transition tables than the standard two dimensional table

3 9 1 Important States of an NFA

To begin our discussion of how to go directly from a regular expression to a DFA we must—rst dissect the NFA construction of Algorithm 3 23 and consider the roles played by various states—We call a state of an NFA important if it has a non—out transition—Notice that the subset construction—Algorithm 3 20—uses only the important states in a set T when it computes— $closure\ move\ T\ a$ —the set of states reachable from T on input a—That is the set of states $move\ s\ a$ —is nonempty only if state s is important—During the subset construction—two sets of NFA states can be identified—treated as if they were the same set—if they

- 1 Have the same important states and
- 2 Either both have accepting states or neither does

When the NFA is constructed from a regular expression by Algorithm 3 23 we can say more about the important states. The only important states are those introduced as initial states in the basis part for a particular symbol position in the regular expression. That is each important state corresponds to a particular operand in the regular expression.

The constructed NFA has only one accepting state but this state having no out transitions is not an important state By concatenating a unique right endmarker—to a regular expression r—we give the accepting state for r a transition on—making it an important state of the NFA for r—In other words—by using the augmented regular expression r—we can forget about accepting states as the subset construction proceeds—when the construction is complete—any state with a transition on—must be an accepting state

The important states of the NFA correspond directly to the positions in the regular expression that hold symbols of the alphabet. It is useful as we shall see to present the regular expression by its $syntax\ tree$ where the leaves correspond to operands and the interior nodes correspond to operators. An interior node is called a $cat\ node$ or node or $star\ node$ if it is labeled by the concatenation operator dot union operator | or star operator | respectively. We can construct a syntax tree for a regular expression just as we did for arithmetic expressions in Section 2.5.1

Example 3 31 Figure 3 56 shows the syntax tree for the regular expression of our running example Cat nodes are represented by circles \Box

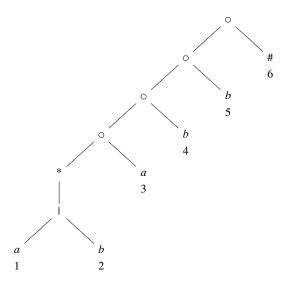

Figure 3 56 Syntax tree for a|b abb

Leaves in a syntax tree are labeled by or by an alphabet symbol To each leaf not labeled we attach a unique integer. We refer to this integer as the

OPTIMIZATION OF DFA BASED PATTERN MATCHERS

position of the leaf and also as a position of its symbol Note that a symbol can have several positions for instance a has positions 1 and 3 in Fig 3.56. The positions in the syntax tree correspond to the important states of the constructed NFA

Example 3 32 Figure 3 57 shows the NFA for the same regular expression as Fig 3 56 with the important states numbered and other states represented by letters. The numbered states in the NFA and the positions in the syntax tree correspond in a way we shall soon see \Box

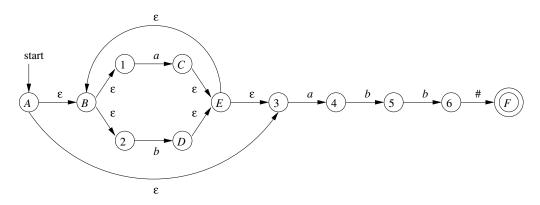

Figure 3 57 NFA constructed by Algorithm 3 23 for **a|b abb**

3 9 2 Functions Computed From the Syntax Tree

To construct a DFA directly from a regular expression we construct its syntax tree and then compute four functions nullable rstpos lastpos and followpos de ned as follows. Each de nition refers to the syntax tree for a particular augmented regular expression r

- 1 $nullable\ n$ is true for a syntax tree node n if and only if the subexpression represented by n has in its language. That is the subexpression can be made null or the empty string even though there may be other strings it can represent as well
- 2 rstpos n is the set of positions in the subtree rooted at n that correspond to the rst symbol of at least one string in the language of the subexpression rooted at n
- 3 $lastpos\ n$ is the set of positions in the subtree rooted at n that correspond to the last symbol of at least one string in the language of the subexpression rooted at n

4 followpos p for a position p is the set of positions q in the entire syntax tree such that there is some string x a_1a_2 a_n in L r such that for some i there is a way to explain the membership of x in L r by matching a_i to position p of the syntax tree and a_{i-1} to position q

Example 3 33 Consider the cat node n in Fig. 3 56 that corresponds to the expression $\mathbf{a}|\mathbf{b}$ \mathbf{a} We claim nullable~n is false since this node generates all strings of a s and b s ending in an a it does not generate. On the other hand the star node below it is nullable it generates—along with all other strings of a s and b s

rstpos $n = \{1 \ 2 \ 3\}$ In a typical generated string like aa the rst position of the string corresponds to position 1 of the tree and in a string like ba the rst position of the string comes from position 2 of the tree However when the string generated by the expression of node n is just a then this a comes from position 3

lastpos n {3} That is no matter what string is generated from the expression of node n the last position is the a from position 3 of the tree

followpos is trickier to compute but we shall see the rules for doing so shortly. Here is an example of the reasoning followpos 1 $\{1\ 2\ 3\}$ Consider a string ac where the c is either a or b and the a comes from position 1. That is this a is one of those generated by the \mathbf{a} in expression $\mathbf{a}|\mathbf{b}$. This a could be followed by another a or b coming from the same subexpression in which case c comes from position 1 or 2. It is also possible that this a is the last in the string generated by $\mathbf{a}|\mathbf{b}$ in which case the symbol c must be the a that comes from position 3. Thus 1.2 and 3 are exactly the positions that can follow position 1.

3 9 3 Computing nullable rstpos and lastpos

We can compute nullable rstpos and lastpos by a straightforward recursion on the height of the tree. The basis and inductive rules for nullable and rstpos are summarized in Fig. 3.58. The rules for lastpos are essentially the same as for rstpos but the roles of children c_1 and c_2 must be swapped in the rule for a cat node

Example 3 34 Of all the nodes in Fig 3 56 only the star node is nullable We note from the table of Fig 3 58 that none of the leaves are nullable because they each correspond to non operands. The or node is not nullable because neither of its children is. The star node is nullable because every star node is nullable. Finally, each of the cat nodes having at least one nonnullable child is not nullable.

The computation of rstpos and lastpos for each of the nodes is shown in Fig 3 59 with rstpos n to the left of node n and lastpos n to its right Each of the leaves has only itself for rstpos and lastpos as required by the rule for non—leaves in Fig 3 58. For the or node we take the union of rstpos at the

OPTIMIZATION OF DFA BASED PATTERN MATCHERS

Node n	$nullable \ n$	$rstpos \ n$		
A leaf labeled	true			
A leaf with position i	false	$\{i\}$		
An or node $n = c_1 c_2$	$nullable \ c_1 \mathbf{or}$	$rstpos \ c_1 \qquad rstpos \ c_2$		
	$nullable \ c_2$			
A cat node $n = c_1 c_2$	$nullable \ c_1$ and	$\mathbf{if} nullable c_1$		
	$nullable \ c_2$	$rstpos \ c_1 \qquad rstpos \ c_2$		
		else $rstpos c_1$		
A star node $n = c_1$	true	$rstpos \ c_1$		

Figure 3 58 Rules for computing nullable and rstpos

children and do the same for *lastpos* The rule for the star node says that we take the value of *rstpos* or *lastpos* at the one child of that node

Now consider the lowest cat node which we shall call n. To compute $rstpos\ n$ we rst consider whether the left operand is nullable which it is in this case. Therefore rstpos for n is the union of rstpos for each of its children that is $\{1\ 2\}$ $\{3\}$ $\{1\ 2\ 3\}$. The rule for lastpos does not appear explicitly in Fig. 3.58 but as we mentioned the rules are the same as for rstpos with the children interchanged. That is to compute $lastpos\ n$ we must ask whether its right child the leaf with position 3 is nullable which it is not. Therefore $lastpos\ n$ is the same as lastpos of the right child or $\{3\}$

3 9 4 Computing followpos

Finally we need to see how to compute *followpos* There are only two ways that a position of a regular expression can be made to follow another

- 1 If n is a cat node with left child c_1 and right child c_2 then for every position i in $lastpos\ c_1$ all positions in $rstpos\ c_2$ are in $followpos\ i$
- 2 If n is a star node and i is a position in $lastpos\ n$ then all positions in $rstpos\ n$ are in $followpos\ i$

Example 3.35 Let us continue with our running example recall that *rstpos* and *lastpos* were computed in Fig. 3.59 Rule 1 for *followpos* requires that we look at each cat node and put each position in *rstpos* of its right child in *followpos* for each position in *lastpos* of its left child. For the lowest cat node in Fig. 3.59 that rule says position 3 is in *followpos* 1 and *followpos* 2. The next cat node above says that 4 is in *followpos* 3 and the remaining two cat nodes give us 5 in *followpos* 4 and 6 in *followpos* 5

CHAPTER 3 LEXICAL ANALYSIS

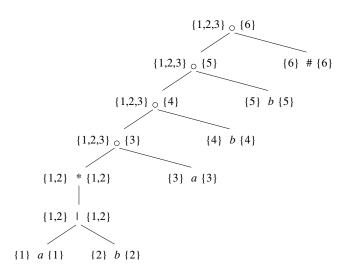

Figure 3 59 rstpos and lastpos for nodes in the syntax tree for $\mathbf{a}|\mathbf{b}$ \mathbf{abb}

We must also apply rule 2 to the star node. That rule tells us positions 1 and 2 are in both followpos 1 and followpos 2 since both rstpos and lastpos for this node are $\{1\ 2\}$. The complete sets followpos are summarized in Fig. 3.60 \Box

followpos n
$\{1\ 2\ 3\}$ $\{1\ 2\ 3\}$
{1 2 3} {4}
$\{5\}$
{6}

Figure 3 60 The function followpos

We can represent the function followpos by creating a directed graph with a node for each position and an arc from position i to position j if and only if j is in followpos i Figure 3 61 shows this graph for the function of Fig. 3 60

It should come as no surprise that the graph for *followpos* is almost an NFA without—transitions for the underlying regular expression—and would become one if we

- 1 Make all positions in *rstpos* of the root be initial states
- 2 Label each arc from i to j by the symbol at position i and

OPTIMIZATION OF DFA BASED PATTERN MATCHERS

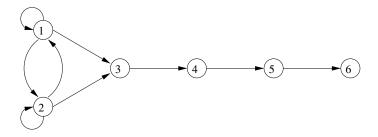

Figure 3 61 Directed graph for the function followpos

3 Make the position associated with endmarker be the only accepting state

3 9 5 Converting a Regular Expression Directly to a DFA

Algorithm 3 36 Construction of a DFA from a regular expression r

INPUT A regular expression r

OUTPUT A DFA D that recognizes L r

METHOD

- 1 Construct a syntax tree T from the augmented regular expression r
- 2 Compute nullable rstpos lastpos and followpos for T using the methods of Sections 3 9 3 and 3 9 4
- 3 Construct Dstates the set of states of DFA D and Dtran the transition function for D by the procedure of Fig. 3.62. The states of D are sets of positions in T. Initially each state is unmarked and a state becomes marked just before we consider its out transitions. The start state of D is $rstpos\ n_0$ —where node n_0 is the root of T—The accepting states are those containing the position for the endmarker symbol

Example 3 37 We can now put together the steps of our running example to construct a DFA for the regular expression r a $|\mathbf{b}|$ abb. The syntax tree for r appeared in Fig 3 56. We observed that for this tree nullable is true only for the star node and we exhibited rstpos and lastpos in Fig 3 59. The values of followpos appear in Fig. 3 60.

The value of rstpos for the root of the tree is $\{1\ 2\ 3\}$ so this set is the start state of D Call this set of states A We must compute $Dtran\ A\ a$ and $Dtran\ A\ b$ Among the positions of $A\ 1$ and B corresponds to B Thus $Dtran\ A\ a$ followpos B followpos B and B followpos B followp

```
initialize Dstates to contain only the unmarked state totallow{rstpos}\ n_0 where totallow{rstpos}\ n_0 while there is an unmarked state totallow{rstpos}\ n_0 while there is an unmarked state totallow{rstpos}\ n_0 while there is an unmarked state totallow{rstpos}\ n_0 while there is an unmarked totallow{rstpos}\ n_0 while there is an unmarked totallow{rstpos}\ n_0 and total
```

Figure 3 62 Construction of a DFA directly from a regular expression

and $Dtran\ A\ b$ followpos 2 {1 2 3} The latter is state A and so does not have to be added to Dstates but the former B {1 2 3 4} is new so we add it to Dstates and proceed to compute its transitions The complete DFA is shown in Fig. 3 63 \Box

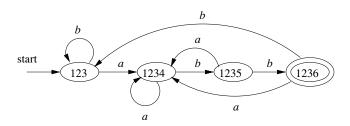

Figure 3 63 DFA constructed from Fig 3 57

3 9 6 Minimizing the Number of States of a DFA

There can be many DFA s that recognize the same language. For instance note that the DFA s of Figs. 3.36 and 3.63 both recognize language L $\mathbf{a}|\mathbf{b}$ $\mathbf{a}\mathbf{b}\mathbf{b}$. Not only do these automata have states with di erent names but they don t even have the same number of states. If we implement a lexical analyzer as a DFA, we would generally prefer a DFA with as few states as possible since each state requires entries in the table that describes the lexical analyzer.

The matter of the names of states is minor We shall say that two automata are the same up to state names if one can be transformed into the other by doing nothing more than changing the names of states Figures 3 36 and 3 63 are not the same up to state names However there is a close relationship between the

OPTIMIZATION OF DFA BASED PATTERN MATCHERS

states of each States A and C of Fig 3 36 are actually equivalent in the sense that neither is an accepting state and on any input they transfer to the same state — to B on input a and to C on input b — Moreover both states A and C behave like state 123 of Fig 3 63 — Likewise state B of Fig 3 36 behaves like state 1234 of Fig 3 63 — state D behaves like state 1235 — and state E behaves like state 1236

It turns out that there is always a unique up to state names minimum state DFA for any regular language Moreover this minimum state DFA can be constructed from any DFA for the same language by grouping sets of equivalent states In the case of L $\mathbf{a}|\mathbf{b}$ \mathbf{abb} Fig 3 63 is the minimum state DFA and it can be constructed by partitioning the states of Fig 3 36 as $\{A \ C\}\{B\}\{D\}\{E\}$

In order to understand the algorithm for creating the partition of states that converts any DFA into its minimum state equivalent DFA we need to see how input strings distinguish states from one another. We say that string x distinguishes state s from state t if exactly one of the states reached from s and t by following the path with label x is an accepting state. State s is distinguishable from state t if there is some string that distinguishes them

Example 3 38 The empty string distinguishes any accepting state from any nonaccepting state. In Fig. 3 36, the string bb distinguishes state A from state B since bb takes A to a nonaccepting state C but takes B to accepting state E. \Box

The state minimization algorithm works by partitioning the states of a DFA into groups of states that cannot be distinguished. Each group of states is then merged into a single state of the minimum state DFA. The algorithm works by maintaining a partition whose groups are sets of states that have not yet been distinguished while any two states from dierent groups are known to be distinguishable. When the partition cannot be remed further by breaking any group into smaller groups, we have the minimum state DFA.

Initially the partition consists of two groups the accepting states and the nonaccepting states. The fundamental step is to take some group of the current partition say $A = \{s_1 \ s_2 = s_k\}$ and some input symbol a and see whether a can be used to distinguish between any states in group A. We examine the transitions from each of $s_1 \ s_2 = s_k$ on input a and if the states reached fall into two or more groups of the current partition, we split A into a collection of groups so that s_i and s_j are in the same group if and only if they go to the same group on input a. We repeat this process of splitting groups until for no group, and for no input symbol can the group be split further. The idea is formalized in the next algorithm

Algorithm 3 39 Minimizing the number of states of a DFA

INPUT A DFA D with set of states S input alphabet — start state s_0 and set of accepting states F

OUTPUT A DFA D' accepting the same language as D and having as few states as possible

Why the State Minimization Algorithm Works

We need to prove two things that states remaining in the same group in $_{\rm nal}$ are indistinguishable by any string and that states winding up in di erent groups are distinguishable. The rst is an induction on i that if after the ith iteration of step 2 of Algorithm 3 39 s and t are in the same group, then there is no string of length i or less that distinguishes them. We shall leave the details of the induction to you

The second is an induction on i that if states s and t are placed in di erent groups at the ith iteration of step 2—then there is a string that distinguishes them. The basis when s and t are placed in di erent groups of the initial partition—is easy—one must be accepting and the other not so—distinguishes them. For the induction—there must be an input a and states p and q such that s and t go to states p and q respectively—on input a—Moreover—p—and q—must already have been placed in di—erent groups. Then by the inductive hypothesis—there is some string x—that distinguishes p—from q—Therefore—ax—distinguishes s—from t

METHOD

- 1 Start with an initial partition with two groups F and S F the accepting and nonaccepting states of D
- 2 Apply the procedure of Fig. 3 64 to construct a new partition $_{\mathrm{new}}$

Figure 3 64 Construction of new

- 3 If $_{\rm new}$ let $_{\rm nal}$ and continue with step 4 Otherwise repeat step 2 with $_{\rm new}$ in place of
- 4 Choose one state in each group of $_{\rm nal}$ as the representative for that group. The representatives will be the states of the minimum state DFA D'. The other components of D' are constructed as follows

Eliminating the Dead State

The minimization algorithm sometimes produces a DFA with one dead state—one that is not accepting and transfers to itself on each input symbol—This state is technically needed—because a DFA must have a transition from every state on every symbol—However as discussed in Section 3 8 3 we often want to know when there is no longer any possibility of acceptance—so we can establish that the proper lexeme has already been seen—Thus—we may wish to eliminate the dead state and use an automaton that is missing some transitions—This automaton has one fewer state than the minimum state DFA—but is strictly speaking not a DFA—because of the missing transitions to the dead state

- a The start state of D' is the representative of the group containing the start state of D
- b The accepting states of D' are the representatives of those groups that contain an accepting state of D Note that each group contains either only accepting states or only nonaccepting states because we started by separating those two classes of states and the procedure of Fig 3 64 always forms new groups that are subgroups of previously constructed groups
- c Let s be the representative of some group G of $_{\rm nal}$ and let the transition of D from s on input a be to state t Let r be the representative of t s group H. Then in D' there is a transition from s to r on input a. Note that in D every state in group G must go to some state of group H on input a or else group G would have been split according to Fig. 3.64

Example 3 40 Let us reconsider the DFA of Fig 3 36 The initial partition consists of the two groups $\{A \ B \ C \ D\}\{E\}$ which are respectively the nonac cepting states and the accepting states To construct new the procedure of Fig 3 64 considers both groups and inputs a and b The group $\{E\}$ cannot be split because it has only one state so $\{E\}$ will remain intact in new

The other group $\{A\ B\ C\ D\}$ can be split so we must consider the e ect of each input symbol. On input a each of these states goes to state B so there is no way to distinguish these states using strings that begin with a. On input b states A B and C go to members of group $\{A\ B\ C\ D\}$ while state D goes to E a member of another group. Thus, in $_{\text{new}}$ group $\{A\ B\ C\ D\}$ is split into $\{A\ B\ C\}\{D\}$ and $_{\text{new}}$ for this round is $\{A\ B\ C\}\{D\}\{E\}$

In the next round we can split $\{A \ B \ C\}$ into $\{A \ C\}\{B\}$ since A and C each go to a member of $\{A \ B \ C\}$ on input b while B goes to a member of another group $\{D\}$. Thus after the second round $_{\text{new}}$ $_{\text{new}}$ $_{\text{new}}$ $_{\text{new}}$ $_{\text{new}}$ $_{\text{new}}$ for the third round we cannot split the one remaining group with more than one state since A and C each go to the same state and therefore to the same group on each input. We conclude that $_{\text{nal}}$ $_{\text{new}}$ $_{\text{new}}$

Now we shall construct the minimum state DFA It has four states corresponding to the four groups of $_{\rm nal}$ and let us pick A B D and E as the representatives of these groups. The initial state is A and the only accepting state is E. Figure 3 65 shows the transition function for the DFA. For instance the transition from state E on input b is to A since in the original DFA. E goes to C on input b and A is the representative of C s group. For the same reason the transition on b from state A is to A itself, while all other transitions are as in Fig. 3.36. \Box

STATE	a	b
A	B	A
B	B	D
D	B	E
E	B	A

Figure 3 65 Transition table of minimum state DFA

3 9 7 State Minimization in Lexical Analyzers

To apply the state minimization procedure to the DFAs generated in Section 3 8 3 we must begin Algorithm 3 39 with the partition that groups to gether all states that recognize a particular token and also places in one group all those states that do not indicate any token. An example should make the extension clear

Example 3 41 For the DFA of Fig 3 54 the initial partition is

That is states 0137 and 7 belong together because neither announces any token States 8 and 58 belong together because they both announce token \mathbf{a} \mathbf{b} Note that we have added a dead state—which we suppose has transitions to itself on inputs a and b The dead state is also the target of missing transitions on a from states 8–58 and 68

We must split 0137 from 7 because they go to di erent groups on input a We also split 8 from 58 because they go to di erent groups on b Thus all states are in groups by themselves and Fig 3.54 is the minimum state DFA

OPTIMIZATION OF DFA BASED PATTERN MATCHERS

recognizing its three tokens Recall that a DFA serving as a lexical analyzer will normally drop the dead state while we treat missing transitions as a signal to end token recognition \Box

3 9 8 Trading Time for Space in DFA Simulation

The simplest and fastest way to represent the transition function of a DFA is a two dimensional table indexed by states and characters. Given a state and next input character, we access the array to and the next state and any special action we must take e.g. returning a token to the parser. Since a typical lexical analyzer has several hundred states in its DFA and involves the ASCII alphabet of 128 input characters, the array consumes less than a megabyte.

However compilers are also appearing in very small devices where even a megabyte of storage may be too much. For such situations, there are many methods that can be used to compact the transition table. For instance, we can represent each state by a list of transitions—that is character state pairs ended by a default state that is to be chosen for any input character not on the list. If we choose as the default the most frequently occurring next state, we can often reduce the amount of storage needed by a large factor.

There is a more subtle data structure that allows us to combine the speed of array access with the compression of lists with defaults. We may think of this structure as four arrays as suggested in Fig. 3.66 5 . The base array is used to determine the base location of the entries for state s which are located in the next and check arrays. The default array is used to determine an alternative base location if the check array tells us the one given by base s is invalid

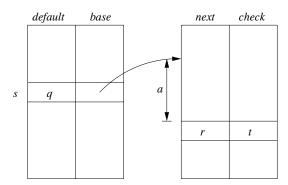

Figure 3 66 Data structure for representing transition tables

To compute $nextState\ s\ a$ the transition for state s on input a we examine the next and check entries in location l base s a where character a is treated as an integer presumably in the range 0 to 127 If $check\ l$ s then this entry

⁵In practice there would be another array indexed by states to give the action associated with that state if any

is valid and the next state for state s on input a is $next \, l$ If $check \, l$ / s then we determine another state t default s and repeat the process as if t were the current state More formally the function nextState is de ned as follows

While we may not be able to choose base values so that no next check entries remain unused experience has shown that the simple strategy of assigning base values to states in turn and assigning each $base\,s$ value the lowest integer so that the special entries for state s are not previously occupied utilizes little more space than the minimum possible

3 9 9 Exercises for Section 3 9

Exercise 3 9 1 Extend the table of Fig 3 58 to include the operators a and b

Exercise 3 9 2 Use Algorithm 3 36 to convert the regular expressions of Exercise 3 7 3 directly to deterministic nite automata

Exercise 3 9 3 We can prove that two regular expressions are equivalent by showing that their minimum state DFA s are the same up to renaming of states. Show in this way that the following regular expressions $\mathbf{a}|\mathbf{b}$ \mathbf{a} $|\mathbf{b}$ and $|\mathbf{a}$ \mathbf{b} are all equivalent *Note*. You may have constructed the DFA s for these expressions in response to Exercise 3 7 3

Exercise 3 9 4 Construct the minimum state DFA s for the following regular expressions

3 10 SUMMARY OF CHAPTER 3

Do you see a pattern

Exercise 3 9 5 To make formal the informal claim of Example 3 25 show that any deterministic nite automaton for the regular expression

where $\mathbf{a}|\mathbf{b}$ appears n-1 times at the end-must have at least 2^n states Hint Observe the pattern in Exercise 3 9 4. What condition regarding the history of inputs does each state represent

3 10 Summary of Chapter 3

- ◆ Tokens The lexical analyzer scans the source program and produces as output a sequence of tokens which are normally passed one at a time to the parser Some tokens may consist only of a token name while others may also have an associated lexical value that gives information about the particular instance of the token that has been found on the input
- ◆ Lexemes Each time the lexical analyzer returns a token to the parser it has an associated lexeme — the sequence of input characters that the token represents
- → Bu ering Because it is often necessary to scan ahead on the input in order to see where the next lexeme ends it is usually necessary for the lexical analyzer to bu er its input Using a pair of bu ers cyclicly and ending each bu ers contents with a sentinel that warns of its end are two techniques that accelerate the process of scanning the input
- ♦ Patterns Each token has a pattern that describes which sequences of characters can form the lexemes corresponding to that token. The set of words or strings of characters that match a given pattern is called a language
- ◆ Regular Expressions These expressions are commonly used to describe patterns Regular expressions are built from single characters using union concatenation and the Kleene closure or any number of oper ator
- → Regular De nitions Complex collections of languages such as the pat terns that describe the tokens of a programming language are often de ned by a regular de nition which is a sequence of statements that each de ne one variable to stand for some regular expression. The regular expression for one variable can use previously de ned variables in its regular expression.

CHAPTER 3 LEXICAL ANALYSIS

- ◆ Extended Regular Expression Notation A number of additional operators may appear as shorthands in regular expressions to make it easier to express patterns Examples include the operator one or more of zero or one of and character classes the union of the strings each consisting of one of the characters
- ◆ Transition Diagrams The behavior of a lexical analyzer can often be described by a transition diagram These diagrams have states each of which represents something about the history of the characters seen during the current search for a lexeme that matches one of the possible patterns There are arrows or transitions from one state to another each of which indicates the possible next input characters that cause the lexical analyzer to make that change of state
- ◆ Finite Automata These are a formalization of transition diagrams that include a designation of a start state and one or more accepting states as well as the set of states input characters and transitions among states Accepting states indicate that the lexeme for some token has been found Unlike transition diagrams nite automata can make transitions on empty input as well as on input characters
- ◆ Deterministic Finite Automata A DFA is a special kind of nite au tomaton that has exactly one transition out of each state for each input symbol Also transitions on empty input are disallowed The DFA is easily simulated and makes a good implementation of a lexical analyzer similar to a transition diagram
- ♦ Nondeterministic Finite Automata Automata that are not DFAs are called nondeterministic NFAs often are easier to design than are DFAs Another possible architecture for a lexical analyzer is to tabulate all the states that NFAs for each of the possible patterns can be in as we scan the input characters
- ♦ Conversion Among Pattern Representations It is possible to convert any regular expression into an NFA of about the same size recognizing the same language as the regular expression de nes Further any NFA can be converted to a DFA for the same pattern although in the worst case never encountered in common programming languages the size of the automaton can grow exponentially It is also possible to convert any non deterministic or deterministic nite automaton into a regular expression that de nes the same language recognized by the nite automaton
- ◆ Lex There is a family of software systems including Lex and Flex that are lexical analyzer generators. The user specifies the patterns for tokens using an extended regular expression notation. Lex converts these expressions into a lexical analyzer that is essentially a deterministic in nite automator that recognizes any of the patterns.

3 11 REFERENCES FOR CHAPTER 3

♦ Minimization of Finite Automata For every DFA there is a minimum state DFA accepting the same language Moreover the minimum state DFA for a given language is unique except for the names given to the various states

3 11 References for Chapter 3

Regular expressions were rst developed by Kleene in the 1950 s 9 Kleene was interested in describing the events that could be represented by McCullough and Pitts 12 nite automaton model of neural activity. Since that time regular expressions and nite automata have become widely used in computer science

Regular expressions in various forms were used from the outset in many popular Unix utilities such as awk ed egrep grep lex sed sh and vi The IEEE 1003 and ISO IEC 9945 standards documents for the Portable Operating System Interface POSIX de ne the POSIX extended regular expressions which are similar to the original Unix regular expressions with a few exceptions such as mnemonic representations for character classes Many scripting languages such as Perl Python and Tcl have adopted regular expressions but often with incompatible extensions

The familiar nite automaton model and the minimization of nite automata as in Algorithm 3 39 come from Hu man 6 and Moore 14 Non deterministic nite automata were rst proposed by Rabin and Scott 15 the subset construction of Algorithm 3 20 showing the equivalence of deterministic and nondeterministic nite automata is from there

McNaughton and Yamada 13 rst gave an algorithm to convert regular expressions directly to deterministic nite automata Algorithm 3 36 described in Section 3 9 was rst used by Aho in creating the Unix regular expression matching tool egrep. This algorithm was also used in the regular expression pattern matching routines in awk 3. The approach of using nondeterministic automata as an intermediary is due Thompson 17. The latter paper also contains the algorithm for the direct simulation of nondeterministic nite automata. Algorithm 3 22. which was used by Thompson in the text editor QED.

Lesk developed the rst version of Lex and then Lesk and Schmidt created a second version using Algorithm 3 36 10 Many variants of Lex have been subsequently implemented The GNU version Flex can be downloaded along with documentation at 4 Popular Java versions of Lex include JFlex 7 and JLex 8

The KMP algorithm discussed in the exercises to Section 3 4 just prior to Exercise 3 4 3 is from 11 Its generalization to many keywords appears in 2 and was used by Aho in the rst implementation of the Unix utility fgrep

The theory of __nite automata and regular expressions is covered in 5 _ A survey of string matching techniques is in 1

Chapter 4

Syntax Analysis

This chapter is devoted to parsing methods that are typically used in compilers We rst present the basic concepts then techniques suitable for hand implemen tation and nally algorithms that have been used in automated tools. Since programs may contain syntactic errors we discuss extensions of the parsing methods for recovery from common errors.

By design every programming language has precise rules that prescribe the syntactic structure of well formed programs. In C for example a program is made up of functions a function out of declarations and statements a statement out of expressions and so on. The syntax of programming language constructs can be specified by context free grammars or BNF. Backus Naur Form notation introduced in Section 2.2. Grammars of er significant benefits for both language designers and compiler writers.

A grammar gives a precise yet easy to understand syntactic speci cation of a programming language

From certain classes of grammars we can construct automatically an e cient parser that determines the syntactic structure of a source program As a side bene t the parser construction process can reveal syntactic ambiguities and trouble spots that might have slipped through the initial design phase of a language

The structure imparted to a language by a properly designed grammar is useful for translating source programs into correct object code and for detecting errors

A grammar allows a language to be evolved or developed iteratively by adding new constructs to perform new tasks. These new constructs can be integrated more easily into an implementation that follows the gram matical structure of the language.

4 1 Introduction

In this section we examine the way the parser—ts into a typical compiler—We then look at typical grammars for arithmetic expressions—Grammars for expressions su—ce for illustrating the essence of parsing—since parsing techniques for expressions carry over to most programming constructs—This section ends with a discussion of error handling—since the parser must respond gracefully to—nding that its input cannot be generated by its grammar

4 1 1 The Role of the Parser

In our compiler model the parser obtains a string of tokens from the lexical analyzer as shown in Fig 4.1 and veri es that the string of token names can be generated by the grammar for the source language. We expect the parser to report any syntax errors in an intelligible fashion and to recover from commonly occurring errors to continue processing the remainder of the program. Conceptually for well formed programs the parser constructs a parse tree and passes it to the rest of the compiler for further processing. In fact, the parse tree need not be constructed explicitly since checking and translation actions can be interspersed with parsing as we shall see. Thus, the parser and the rest of the front end could well be implemented by a single module

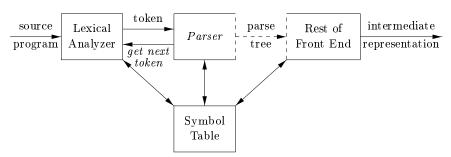

Figure 4.1 Position of parser in compiler model

There are three general types of parsers for grammars universal top down and bottom up Universal parsing methods such as the Cocke Younger Kasami algorithm and Earley's algorithm can parse any grammar see the bibliographic notes. These general methods are however too ine cient to use in production compilers

The methods commonly used in compilers can be classi ed as being either top down or bottom up. As implied by their names top down methods build parse trees from the top-root to the bottom-leaves—while bottom up methods start from the leaves and work their way up to the root. In either case, the input to the parser is scanned from left to right one symbol at a time

4.1 INTRODUCTION

The most e cient top down and bottom up methods work only for sub classes of grammars but several of these classes particularly LL and LR gram mars are expressive enough to describe most of the syntactic constructs in modern programming languages Parsers implemented by hand often use LL grammars for example the predictive parsing approach of Section 2 4 2 works for LL grammars Parsers for the larger class of LR grammars are usually constructed using automated tools

In this chapter we assume that the output of the parser is some represent ation of the parse tree for the stream of tokens that comes from the lexical analyzer. In practice, there are a number of tasks that might be conducted during parsing such as collecting information about various tokens into the symbol table performing type checking and other kinds of semantic analysis and generating intermediate code. We have lumped all of these activities into the rest of the front end box in Fig. 4.1. These activities will be covered in detail in subsequent chapters.

4 1 2 Representative Grammars

Some of the grammars that will be examined in this chapter are presented here for ease of reference. Constructs that begin with keywords like **while** or **int** are relatively easy to parse because the keyword guides the choice of the grammar production that must be applied to match the input. We therefore concentrate on expressions which present more of challenge because of the associativity and precedence of operators

Associativity and precedence are captured in the following grammar which is similar to ones used in Chapter 2 for describing expressions terms and factors E represents expressions consisting of terms separated by signs T represents terms consisting of factors separated by signs and F represents factors that can be either parenthesized expressions or identi ers

Expression grammar 4.1 belongs to the class of LR grammars that are suitable for bottom up parsing. This grammar can be adapted to handle additional operators and additional levels of precedence. However, it cannot be used for top down parsing because it is left recursive.

The following non left recursive variant of the expression grammar 4.1 will be used for top down parsing

The following grammar treats and alike so it is useful for illustrating techniques for handling ambiguities during parsing

Here E represents expressions of all types Grammar 4.3 permits more than one parse tree for expressions like a b c

4 1 3 Syntax Error Handling

The remainder of this section considers the nature of syntactic errors and gen eral strategies for error recovery. Two of these strategies called panic mode and phrase level recovery are discussed in more detail in connection with special parsing methods.

If a compiler had to process only correct programs its design and implemen tation would be simplified greatly. However, a compiler is expected to assist the programmer in locating and tracking down errors that inevitably creep into programs despite the programmer s best efforts. Strikingly few languages have been designed with error handling in mind even though errors are so common place. Our civilization would be radically different if spoken languages had the same requirements for syntactic accuracy as computer languages. Most programming language specifications do not describe how a compiler should respond to errors error handling is left to the compiler designer. Planning the error handling right from the start can both simplify the structure of a compiler and improve its handling of errors.

Common programming errors can occur at many di erent levels

Lexical errors include misspellings of identiers keywords or operators e.g. the use of an identier elipseSize instead of ellipseSize and missing quotes around text intended as a string

Syntactic errors include misplaced semicolons or extra or missing braces that is or As another example in C or Java the appearance of a case statement without an enclosing switch is a syntactic error however this situation is usually allowed by the parser and caught later in the processing as the compiler attempts to generate code

Semantic errors include type mismatches between operators and operands e.g. the return of a value in a Java method with result type void

Logical errors can be anything from incorrect reasoning on the part of the programmer to the use in a C program of the assignment operator instead of the comparison operator — The program containing — may be well formed however it may not re—ect the programmer s intent

The precision of parsing methods allows syntactic errors to be detected very e ciently Several parsing methods such as the LL and LR methods detect

4.1 INTRODUCTION

an error as soon as possible that is when the stream of tokens from the lexical analyzer cannot be parsed further according to the grammar for the language More precisely they have the *viable pre x property* meaning that they detect that an error has occurred as soon as they see a pre x of the input that cannot be completed to form a string in the language

Another reason for emphasizing error recovery during parsing is that many errors appear syntactic whatever their cause and are exposed when parsing cannot continue A few semantic errors such as type mismatches can also be detected e ciently however accurate detection of semantic and logical errors at compile time is in general a di-cult task

The error handler in a parser has goals that are simple to state but challenging to realize

Report the presence of errors clearly and accurately

Recover from each error quickly enough to detect subsequent errors

Add minimal overhead to the processing of correct programs

Fortunately common errors are simple ones and a relatively straightforward error handling mechanism often su—ces

How should an error handler report the presence of an error At the very least it must report the place in the source program where an error is detected because there is a good chance that the actual error occurred within the previous few tokens A common strategy is to print the o ending line with a pointer to the position at which an error is detected

4 1 4 Error Recovery Strategies

Once an error is detected how should the parser recover—Although no strategy has proven itself universally acceptable—a few methods have broad applicabil ity—The simplest approach is for the parser to quit with an informative error message when it detects the—rst error—Additional errors are often uncovered if the parser can restore itself to a state where processing of the input can continue with reasonable hopes that the further processing will provide meaningful diagnostic information—If errors pile up—it is better for the compiler to give up after exceeding some error limit than to produce an annoying avalanche of spurious—errors

The balance of this section is devoted to the following recovery strategies panic mode phrase level error productions and global correction

Panic Mode Recovery

With this method on discovering an error the parser discards input symbols one at a time until one of a designated set of *synchronizing tokens* is found. The synchronizing tokens are usually delimiters such as semicolon or whose role in the source program is clear and unambiguous. The compiler designer

must select the synchronizing tokens appropriate for the source language While panic mode correction often skips a considerable amount of input without check ing it for additional errors it has the advantage of simplicity and unlike some methods to be considered later is guaranteed not to go into an in nite loop

Phrase Level Recovery

On discovering an error a parser may perform local correction on the remaining input that is it may replace a pre x of the remaining input by some string that allows the parser to continue A typical local correction is to replace a comma by a semicolon delete an extraneous semicolon or insert a missing semicolon. The choice of the local correction is left to the compiler designer. Of course we must be careful to choose replacements that do not lead to in nite loops as would be the case for example if we always inserted something on the input ahead of the current input symbol.

Phrase level replacement has been used in several error repairing compilers as it can correct any input string. Its major drawback is the disculty it has in coping with situations in which the actual error has occurred before the point of detection.

Error Productions

By anticipating common errors that might be encountered we can augment the grammar for the language at hand with productions that generate the erroneous constructs. A parser constructed from a grammar augmented by these error productions detects the anticipated errors when an error production is used during parsing. The parser can then generate appropriate error diagnostics about the erroneous construct that has been recognized in the input

Global Correction

Ideally we would like a compiler to make as few changes as possible in processing an incorrect input string. There are algorithms for choosing a minimal sequence of changes to obtain a globally least cost correction. Given an incorrect input string x and grammar G, these algorithms will and a parse tree for a related string y such that the number of insertions deletions and changes of tokens required to transform x into y is as small as possible. Unfortunately, these methods are in general too costly to implement in terms of time and space so these techniques are currently only of theoretical interest

Do note that a closest correct program may not be what the programmer had in mind Nevertheless the notion of least cost correction provides a yardstick for evaluating error recovery techniques and has been used for nding optimal replacement strings for phrase level recovery

4.2 Context Free Grammars

Grammars were introduced in Section 2 2 to systematically describe the syntax of programming language constructs like expressions and statements. Using a syntactic variable stmt to denote statements and variable expr to denote expressions the production

$$stmt$$
 if $expr$ $stmt$ else $stmt$ 4 4

speci es the structure of this form of conditional statement. Other productions then de ne precisely what an expr is and what else a stmt can be

This section reviews the de nition of a context free grammar and introduces terminology for talking about parsing In particular the notion of derivations is very helpful for discussing the order in which productions are applied during parsing

4 2 1 The Formal De nition of a Context Free Grammar

From Section 2 2 a context free grammar grammar for short consists of ter minals nonterminals a start symbol and productions

- 1 Terminals are the basic symbols from which strings are formed. The term token name is a synonym for terminal and frequently we will use the word token for terminal when it is clear that we are talking about just the token name. We assume that the terminals are the rst components of the tokens output by the lexical analyzer. In 4.4 the terminals are the keywords if and else and the symbols.
- 2 Nonterminals are syntactic variables that denote sets of strings In 4.4 stmt and expr are nonterminals. The sets of strings denoted by nonterminals help de ne the language generated by the grammar. Nonterminals impose a hierarchical structure on the language that is key to syntax analysis and translation
- 3 In a grammar one nonterminal is distinguished as the *start symbol* and the set of strings it denotes is the language generated by the grammar Conventionally the productions for the start symbol are listed rst
- 4 The productions of a grammar specify the manner in which the termi nals and nonterminals can be combined to form strings Each *production* consists of
 - a A nonterminal called the *head* or *left side* of the production this production de nes some of the strings denoted by the head
 - b The symbol Sometimes has been used in place of the arrow
 - c A body or right side consisting of zero or more terminals and non terminals. The components of the body describe one way in which strings of the nonterminal at the head can be constructed.

CHAPTER 4 SYNTAX ANALYSIS

Example 4 5 The grammar in Fig 4 2 de nes simple arithmetic expressions In this grammar the terminal symbols are

id

The nonterminal symbols are $expression\ term$ and $factor\$ and expression is the start symbol $\ \ \Box$

    factor
                 id
```

Figure 4.2 Grammar for simple arithmetic expressions

4 2 2 Notational Conventions

To avoid always having to state that these are the terminals these are the nonterminals and so on the following notational conventions for grammars will be used throughout the remainder of this book

- 1 These symbols are terminals
 - a Lowercase letters early in the alphabet such as $a \ b \ c$
 - b Operator symbols such as and so on
 - c Punctuation symbols such as parentheses comma and so on
 - d The digits 0 1
 - e Boldface strings such as **id** or **if** each of which represents a single terminal symbol
- 2 These symbols are nonterminals
 - a Uppercase letters early in the alphabet such as A B C
 - b The letter S which when it appears is usually the start symbol
 - c Lowercase italic names such as expr or stmt
 - d When discussing programming constructs uppercase letters may be used to represent nonterminals for the constructs. For example, non terminals for expressions, terms, and factors are often represented by $E \setminus T$ and F respectively

4.2 CONTEXT FREE GRAMMARS

- 3 Uppercase letters late in the alphabet such as X Y Z represent grammar symbols that is either nonterminals or terminals
- 4 Lowercase letters late in the alphabet chie y u v z represent possibly empty strings of terminals
- 5 Lowercase Greek letters for example represent possibly empty strings of grammar symbols. Thus a generic production can be written as A where A is the head and the body
- 6 A set of productions A $_1$ A $_2$ A $_k$ with a common head A call them A productions may be written A $_1$ $_1$ $_2$ $_1$ $_k$ Call $_1$ $_2$ $_k$ the alternatives for A
- 7 Unless stated otherwise the head of the rst production is the start symbol

Example 4 6 Using these conventions the grammar of Example 4 5 can be rewritten concisely as

The notational conventions tell us that E T and F are nonterminals with E the start symbol. The remaining symbols are terminals. \square

4 2 3 Derivations

The construction of a parse tree can be made precise by taking a derivational view in which productions are treated as rewriting rules. Beginning with the start symbol each rewriting step replaces a nonterminal by the body of one of its productions. This derivational view corresponds to the top down construction of a parse tree, but the precision a orded by derivations will be especially helpful when bottom up parsing is discussed. As we shall see, bottom up parsing is related to a class of derivations known as rightmost derivations in which the rightmost nonterminal is rewritten at each step.

For example consider the following grammar with a single nonterminal E which adds a production E — E to the grammar 4 3

$$E$$
 E E $|$ E $|$ E $|$ E $|$ \mathbf{id} 47

The production E E signi es that if E denotes an expression then E must also denote an expression. The replacement of a single E by E will be described by writing

$$E$$
 E

CHAPTER 4 SYNTAX ANALYSIS

which is read E derives E The production E E can be applied to replace any instance of E in any string of grammar symbols by E e g E E E for E E E We can take a single E and repeatedly apply productions in any order to get a sequence of replacements. For example

E E id

We call such a sequence of replacements a derivation of id from E. This derivation provides a proof that the string id is one particular instance of an expression

For a general denition of derivation consider a nonterminal A in the middle of a sequence of grammar symbols as in A where and are arbitrary strings of grammar symbols Suppose A is a production. Then we write A. The symbol means derives in one step. When a sequence of derivation steps $\begin{pmatrix} 1 & 2 & n \end{pmatrix}$ rewrites $\begin{pmatrix} 1 & 1 & n \end{pmatrix}$ we say $\begin{pmatrix} 1 & derives \\ n \end{pmatrix}$ Often we wish to say derives in zero or more steps. For this purpose we can use the symbol. Thus

- 1 for any string and
- 2 If and then

Likewise means derives in one or more steps

If S — where S is the start symbol of a grammar G we say that — is a sentential form of G — Note that a sentential form may contain both terminals and nonterminals and may be empty A sentence of G is a sentential form with no nonterminals. The language generated by a grammar is its set of sentences. Thus a string of terminals w is in w — the language generated by w if and only if w is a sentence of w — A language that can be generated by a grammar is said to be a context free language. If two grammars generate the same language the grammars are said to be equivalent

The string **id id** is a sentence of grammar 4.7 because there is a derivation

E E E E E E E E E E

The strings E E E \mathbf{id} \mathbf{id} are all sentential forms of this gram mar We write E \mathbf{id} \mathbf{id} to indicate that \mathbf{id} \mathbf{id} can be derived from E

At each step in a derivation there are two choices to be made. We need to choose which nonterminal to replace and having made this choice we must pick a production with that nonterminal as head. For example, the following alternative derivation of **id id** di ers from derivation 4.8 in the last two steps

E E E E E **id id** 49

4.2 CONTEXT FREE GRAMMARS

Each nonterminal is replaced by the same body in the two derivations but the order of replacements is di erent

To understand how parsers work we shall consider derivations in which the nonterminal to be replaced at each step is chosen as follows

- 1 In *leftmost* derivations the leftmost nonterminal in each sentential is al ways chosen If is a step in which the leftmost nonterminal in is replaced we write
- 2 In rightmost derivations the rightmost nonterminal is always chosen we write in this case

Derivation 48 is leftmost so it can be rewritten as

Note that 49 is a rightmost derivation

Using our notational conventions every leftmost step can be written as wA w where w consists of terminals only A is the production applied and is a string of grammar symbols. To emphasize that derives by a leftmost derivation we write $ext{If }S$ then we say that is a left sentential form of the grammar at hand

Analogous de nitions hold for rightmost derivations Rightmost derivations are sometimes called *canonical* derivations

4 2 4 Parse Trees and Derivations

A parse tree is a graphical representation of a derivation that liters out the order in which productions are applied to replace nonterminals. Each interior node of a parse tree represents the application of a production. The interior node is labeled with the nonterminal A in the head of the production the children of the node are labeled from left to right by the symbols in the body of the production by which this A was replaced during the derivation

For example the parse tree for **id id** in Fig 4.3 results from the derivation 4.8 as well as derivation 4.9

The leaves of a parse tree are labeled by nonterminals or terminals and read from left to right constitute a sentential form called the *yield* or *frontier* of the tree

To see the relationship between derivations and parse trees consider any derivation $_1$ $_2$ $_n$ where $_1$ is a single nonterminal A. For each sentential form $_i$ in the derivation we can construct a parse tree whose yield is $_i$. The process is an induction on i

BASIS The tree for $_1$ A is a single node labeled A

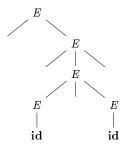

Figure 4.3 Parse tree for id id

INDUCTION Suppose we already have constructed a parse tree with yield $_{i\ 1}\ X_1X_2\ X_k$ note that according to our notational conventions each grammar symbol X_i is either a nonterminal or a terminal Suppose $_i$ is derived from $_{i\ 1}$ by replacing X_j a nonterminal by $Y_1Y_2\ Y_m$ That is at the ith step of the derivation production X_j is applied to $_{i\ 1}$ to derive $_{i\ 1}\ X_1X_2\ X_{j\ 1}\ X_{j\ 1}\ X_k$

To model this step of the derivation nd the jth non leaf from the left in the current parse tree. This leaf is labeled X_j . Give this leaf m children labeled Y_1 Y_2 . Y_m from the left. As a special case if m=0, then and we give the jth leaf one child labeled

Example 4 10 The sequence of parse trees constructed from the derivation $4\ 8$ is shown in Fig $4\ 4$ In the rst step of the derivation E E To model this step add two children labeled and E to the root E of the initial tree. The result is the second tree

In the second step of the derivation E E Consequently add three children labeled E and to the leaf labeled E of the second tree to obtain the third tree with yield E Continuing in this fashion we obtain the complete parse tree as the sixth tree \Box

Since a parse tree ignores variations in the order in which symbols in senten tial forms are replaced there is a many to one relationship between derivations and parse trees. For example, both derivations, 4,8, and 4,9, are associated with the same, and parse tree of Fig. 4,4.

In what follows we shall frequently parse by producing a leftmost or a rightmost derivation since there is a one to one relationship between parse trees and either leftmost or rightmost derivations Both leftmost and rightmost derivations pick a particular order for replacing symbols in sentential forms so they too lter out variations in the order. It is not hard to show that every parse tree has associated with it a unique leftmost and a unique rightmost derivation

4.2 CONTEXT FREE GRAMMARS

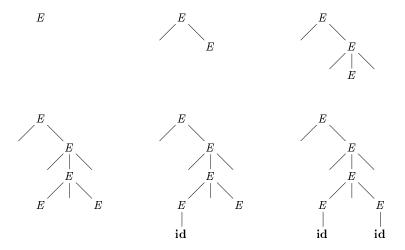

Figure 4.4 Sequence of parse trees for derivation 4.8

4 2 5 Ambiguity

From Section 2 2 4 a grammar that produces more than one parse tree for some sentence is said to be *ambiguous* Put another way an ambiguous grammar is one that produces more than one leftmost derivation or more than one rightmost derivation for the same sentence

Example 4 11 The arithmetic expression grammar 4 3 permits two distinct leftmost derivations for the sentence **id id id**

E	E	E		E	E	E	
	id	E			E	E	E
	id	E	E		id	E	E
	id	id	E		id	id	E
	id	id	id		id	id	id

The corresponding parse trees appear in Fig. 4.5

Note that the parse tree of Fig. 4.5 a rejects the commonly assumed precedence of and while the tree of Fig. 4.5 b does not. That is it is customary to treat operator—as having higher precedence than—corresponding to the fact that we would normally evaluate an expression like a b c as a b c rather than as a b c

For most parsers it is desirable that the grammar be made unambiguous for if it is not we cannot uniquely determine which parse tree to select for a sentence. In other cases it is convenient to use carefully chosen ambiguous grammars together with disambiguating rules that throw away undesirable parse trees leaving only one tree for each sentence

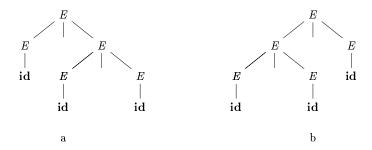

Figure 4.5 Two parse trees for id id id

4 2 6 Verifying the Language Generated by a Grammar

Although compiler designers rarely do so for a complete programming language grammar it is useful to be able to reason that a given set of productions gener ates a particular language. Troublesome constructs can be studied by writing a concise abstract grammar and studying the language that it generates. We shall construct such a grammar for conditional statements below

A proof that a grammar G generates a language L has two parts show that every string generated by G is in L and conversely that every string in L can indeed be generated by G

Example 4 12 Consider the following grammar

It may not be initially apparent but this simple grammar generates all strings of balanced parentheses and only such strings. To see why we shall show a rst that every sentence derivable from S is balanced and then that every balanced string is derivable from S. To show that every sentence derivable from S is balanced we use an inductive proof on the number of steps n in a derivation

BASIS The basis is n-1 The only string of terminals derivable from S in one step is the empty string which surely is balanced

INDUCTION Now assume that all derivations of fewer than n steps produce balanced sentences and consider a leftmost derivation of exactly n steps. Such a derivation must be of the form

$$S_{lm}$$
 S S_{lm} x S_{lm} x y

The derivations of x and y from S take fewer than n steps—so by the inductive hypothesis x and y are balanced. Therefore the string—x y must be balanced. That is it has an equal number of left and right parentheses—and every pre—x has at least as many left parentheses as right.

4.2 CONTEXT FREE GRAMMARS

Having thus shown that any string derivable from S is balanced we must next show that every balanced string is derivable from S. To do so use induction on the length of a string

BASIS If the string is of length 0 it must be which is balanced

INDUCTION First observe that every balanced string has even length. As sume that every balanced string of length less than 2n is derivable from S and consider a balanced string w of length 2n n 1 Surely w begins with a left parenthesis. Let x be the shortest nonempty pre x of w having an equal number of left and right parentheses. Then w can be written as w x y where both x and y are balanced. Since x and y are of length less than 2n they are derivable from S by the inductive hypothesis. Thus, we can indicate a derivation of the form

proving that w = x y is also derivable from $S = \Box$

4 2 7 Context Free Grammars Versus Regular Expressions

Before leaving this section on grammars and their properties we establish that grammars are a more powerful notation than regular expressions. Every construct that can be described by a regular expression can be described by a grammar but not vice versa. Alternatively every regular language is a context free language but not vice versa.

For example the regular expression **a**|**b abb** and the grammar

$$egin{array}{llll} A_0 & & aA_0 & | bA_0 & | aA_1 \\ A_1 & & bA_2 & & & \\ A_2 & & bA_3 & & & \\ A_3 & & & & & \end{array}$$

describe the same language the set of strings of a s and b s ending in abb

We can construct mechanically a grammar to recognize the same language as a nondeterministic nite automaton NFA. The grammar above was constructed from the NFA in Fig. 3.24 using the following construction

- 1 For each state i of the NFA create a nonterminal A_i
- 2 If state i has a transition to state j on input a add the production A_i aA_j If state i goes to state j on input add the production A_i A
- 3 If i is an accepting state add A_i
- 4 If i is the start state make A_i be the start symbol of the grammar

On the other hand the language $L = \{a^nb^n \mid n=1\}$ with an equal number of a s and b s is a prototypical example of a language that can be described by a grammar but not by a regular expression. To see why suppose L were the language defined by some regular expression. We could construct a DFA D with a nite number of states say k to accept L. Since D has only k states for an input beginning with more than k a s D must enter some state twice say s_i as in Fig. 4.6. Suppose that the path from s_i back to itself is labeled with a sequence a^j is Since a^ib^i is in the language there must be a path labeled b^i from s_i to an accepting state f. But then there is also a path from the initial state s_0 through s_i to f labeled a^jb^i as shown in Fig. 4.6. Thus D also accepts a^jb^i which is not in the language contradicting the assumption that L is the language accepted by D

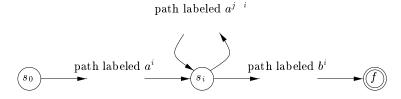

Figure 4.6 DFA D accepting both $a^i b^i$ and $a^j b^i$

Colloquially we say that nite automata cannot count meaning that a nite automaton cannot accept a language like $\{a^nb^n \mid n=1\}$ that would require it to keep count of the number of a s before it sees the b s. Likewise a grammar can count two items but not three as we shall see when we consider non context free language constructs in Section 4 3 5

4 2 8 Exercises for Section 4 2

Exercise 4 2 1 Consider the context free grammar

 $S \qquad S S \qquad |S S | a$

and the string aa = a

- a Give a leftmost derivation for the string
- b Give a rightmost derivation for the string
- c Give a parse tree for the string
- d Is the grammar ambiguous or unambiguous Justify your answer
- e Describe the language generated by this grammar

Exercise 4 2 2 Repeat Exercise 4 2 1 for each of the following grammars and strings

4.2 CONTEXT FREE GRAMMARS

- a $S = 0.51 \mid 0.1$ with string 000111
- b S $S \mid S \mid a$ with string aaa
- c S S S S | with string
- d S $S \mid S \mid S \mid S \mid S \mid a$ with string $a \mid a \mid a$
- e S $L \mid a \text{ and } L \quad L \quad S \mid S \text{ with string} \quad a \quad a \quad a$
- f S a S b S | b S a S | with string aabbab
- g The following grammar for boolean expressions

Exercise 4 2 3 Design grammars for the following languages

- a The set of all strings of 0s and 1s such that every 0 is immediately followed by at least one 1
- b The set of all strings of 0s and 1s that are *palindromes* that is the string reads the same backward as forward
- c The set of all strings of 0s and 1s with an equal number of 0s and 1s
- d The set of all strings of 0s and 1s with an unequal number of 0s and 1s
- e The set of all strings of 0s and 1s in which 011 does not appear as a substring
- The set of all strings of 0s and 1s of the form xy where x / y and x and y are of the same length

Exercise 4 2 4 There is an extended grammar notation in common use In this notation square and curly braces in production bodies are metasymbols like or | with the following meanings

- i Square braces around a grammar symbol or symbols denotes that these constructs are optional. Thus production A X Y Z has the same e ect as the two productions A X Y Z and A X Z
- ii Curly braces around a grammar symbol or symbols says that these symbols may be repeated any number of times including zero times. Thus $A = X \{Y Z\}$ has the same e ect as the infinite sequence of productions A = X A = X Y Z A = X Y Z Y Z and so on

CHAPTER 4 SYNTAX ANALYSIS

Show that these two extensions do not add power to grammars that is any language that can be generated by a grammar with these extensions can be generated by a grammar without the extensions

Exercise 4 2 5 Use the braces described in Exercise 4 2 4 to simplify the following grammar for statement blocks and conditional statements

stmt	if expr then stmt else stmt
	$\mathbf{if} \ stmt \ \mathbf{then} \ stmt$
	$\mathbf{begin} \; stmtList \; \mathbf{end}$
stmtList	$stmt - stmtList \mid stmt$

Exercise 4 2 6 Extend the idea of Exercise 4 2 4 to allow any regular expres sion of grammar symbols in the body of a production Show that this extension does not allow grammars to de ne any new languages

Exercise 4 2 7 A grammar symbol X terminal or nonterminal is *useless* if there is no derivation of the form S wXy wxy That is X can never appear in the derivation of any sentence

- a Give an algorithm to eliminate from a grammar all productions containing useless symbols
- b Apply your algorithm to the grammar

$$\begin{array}{ccc}
S & & 0 \mid A \\
A & & AB \\
B & & 1
\end{array}$$

Exercise 4 2 8 The grammar in Fig 4 7 generates declarations for a sin gle numerical identi er these declarations involve four di erent independent properties of numbers

Figure 4 7 $\,$ A grammar for multi attribute declarations

a Generalize the grammar of Fig 4 7 by allowing n options A_i for some xed n and for i 1 2 n where A_i can be either a_i or b_i Your grammar should use only O n grammar symbols and have a total length of productions that is O n

4.3 WRITING A GRAMMAR

b The grammar of Fig 47 and its generalization in part a allow declarations that are contradictory and or redundant such as

declare foo real fixed real floating

We could insist that the syntax of the language forbid such declarations that is every declaration generated by the grammar has exactly one value for each of the n options. If we do then for any xed n there is only a nite number of legal declarations. The language of legal declarations thus has a grammar and also a regular expression—as any nite language does. The obvious grammar in which the start symbol has a production for every legal declaration has n productions and a total production length of O(n) O(n) You must do better—a total production length that is O(n)

- c Show that any grammar for part b must have a total production length of at least 2^n
- d What does part c say about the feasibility of enforcing nonredundancy and noncontradiction among options in declarations via the syntax of the programming language

4 3 Writing a Grammar

Grammars are capable of describing most but not all of the syntax of programming languages. For instance, the requirement that identifiers be declared before they are used cannot be described by a context free grammar. Therefore, the sequences of tokens accepted by a parser form a superset of the program ming language subsequent phases of the compiler must analyze the output of the parser to ensure compliance with rules that are not checked by the parser

This section begins with a discussion of how to divide work between a lexical analyzer and a parser. We then consider several transformations that could be applied to get a grammar more suitable for parsing. One technique can eliminate ambiguity in the grammar and other techniques—left recursion elimination and left factoring—are useful for rewriting grammars so they become suitable for top down parsing. We conclude this section by considering some programming language constructs that cannot be described by any grammar.

4 3 1 Lexical Versus Syntactic Analysis

As we observed in Section 4 2 7 everything that can be described by a regular expression can also be described by a grammar We may therefore reasonably ask Why use regular expressions to de ne the lexical syntax of a language There are several reasons

- 1 Separating the syntactic structure of a language into lexical and non lexical parts provides a convenient way of modularizing the front end of a compiler into two manageable sized components
- 2 The lexical rules of a language are frequently quite simple and to describe them we do not need a notation as powerful as grammars
- 3 Regular expressions generally provide a more concise and easier to under stand notation for tokens than grammars
- 4 More e cient lexical analyzers can be constructed automatically from regular expressions than from arbitrary grammars

There are no rm guidelines as to what to put into the lexical rules as op posed to the syntactic rules Regular expressions are most useful for describing the structure of constructs such as identi ers constants keywords and white space Grammars on the other hand are most useful for describing nested structures such as balanced parentheses matching begin end s corresponding if then else s and so on These nested structures cannot be described by regular expressions

4 3 2 Eliminating Ambiguity

Sometimes an ambiguous grammar can be rewritten to eliminate the ambiguity As an example we shall eliminate the ambiguity from the following dangling else grammar

$$stmt$$
 if $expr$ then $stmt$ | if $expr$ then $stmt$ else $stmt$ 4 14 | other

Here other stands for any other statement According to this grammar the compound conditional statement

if E_1 then S_1 else if E_2 then S_2 else S_3

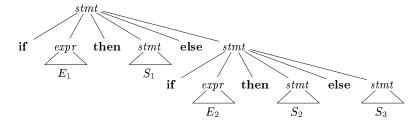

Figure 4.8 Parse tree for a conditional statement

4.3 WRITING A GRAMMAR

has the parse tree shown in Fig 4.8^{-1} Grammar 4.14 is ambiguous since the string

if
$$E_1$$
 then if E_2 then S_1 else S_2 4 15

has the two parse trees shown in Fig 49

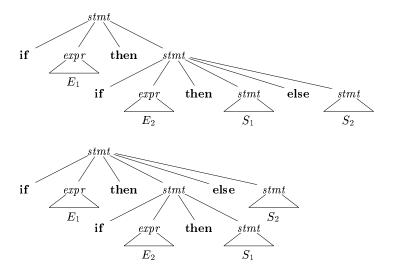

Figure 4.9 Two parse trees for an ambiguous sentence

In all programming languages with conditional statements of this form the rst parse tree is preferred. The general rule is. Match each **else** with the closest unmatched **then** ² This disambiguating rule can theoretically be in corporated directly into a grammar but in practice it is rarely built into the productions

Example 4 16 We can rewrite the dangling else grammar 4 14 as the following unambiguous grammar. The idea is that a statement appearing between a **then** and an **else** must be matched that is the interior statement must not end with an unmatched or open **then**. A matched statement is either an **if then else** statement containing no open statements or it is any other kind of unconditional statement. Thus we may use the grammar in Fig. 4 10. This grammar generates the same strings as the dangling else grammar 4 14 but it allows only one parsing for string 4 15 namely the one that associates each **else** with the closest previous unmatched **then**. □

 $^{^1\}mathrm{The}$ subscripts on E and S are just to distinguish di erent occurrences of the same nonterminal and do not imply distinct nonterminals

 $^{^2}$ We should note that C and its derivatives are included in this class. Even though the C family of languages do not use the keyword **then** its role is played by the closing parenthesis for the condition that follows **if**

```
stmt matched\_stmt open\_stmt if expr then matched\_stmt else matched\_stmt other open\_stmt if expr then stmt if expr then matched\_stmt else open\_stmt
```

Figure 4 10 Unambiguous grammar for if then else statements

4 3 3 Elimination of Left Recursion

A grammar is left recursive if it has a nonterminal A such that there is a derivation A and A for some string. Top down parsing methods cannot handle left recursive grammars so a transformation is needed to eliminate left recursion. In Section 2.4.5 we discussed immediate left recursion where there is a production of the form A and A. Here we study the general case. In Section 2.4.5 we showed how the left recursive pair of productions A and A are could be replaced by the non-left recursive productions.

without changing the strings derivable from A This rule by itself su ces for many grammars

Example 4 17 The non left recursive expression grammar 4 2 repeated here

$$\begin{array}{cccc} E & T \; E' \\ E' & T \; E' \mid \\ T & F \; T' \\ T' & F \; T' \mid \\ F & E \; \mid \; \mathbf{id} \end{array}$$

is obtained by eliminating immediate left recursion from the expression gram mar 4.1 The left recursive pair of productions E E T | T are replaced by E T E' and E' T E' | The new productions for T and T' are obtained similarly by eliminating immediate left recursion \Box

Immediate left recursion can be eliminated by the following technique which works for any number of A productions First group the productions as

$$A$$
 A $_1$ $|$ A $_2$ $|$ $|$ A $_m$ $|$ $_1$ $|$ $_2$ $|$ $|$ $_n$

where no $_i$ begins with an A Then replace the A productions by

4.3 WRITING A GRAMMAR

The nonterminal A generates the same strings as before but is no longer left recursive. This procedure eliminates all left recursion from the A and A' productions provided no $_i$ is but it does not eliminate left recursion involving derivations of two or more steps. For example, consider the grammar

The nonterminal S is left recursive because S — Aa — Sda but it is not immediately left recursive

Algorithm 4 19 below systematically eliminates left recursion from a gram mar. It is guaranteed to work if the grammar has no cycles derivations of the form A and A or productions productions of the form A. Cycles can be eliminated systematically from a grammar as can productions see Exercises 4 4 6 and 4 4 7

Algorithm 4 19 Eliminating left recursion

INPUT Grammar G with no cycles or productions

OUTPUT An equivalent grammar with no left recursion

METHOD Apply the algorithm in Fig. 4.11 to G Note that the resulting non left recursive grammar may have productions \Box

```
arrange the nonterminals in some order A_1 A_2 A_n

for each i from 1 to n {

for each j from 1 to i 1 {

replace each production of the form A_i A_j by the

productions A_i _1 _2 _1 _k where

A_j _1 _1 _2 _1 _k are all current A_j productions

A_j _1 _2 _1 _k are all current A_j productions

A_j _1 _2 _1 _k are all current A_j productions

A_j _1 _2 _1 _k are all current A_j productions

A_j _1 _2 _1 _1 _2 _1 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1 _2 _1
```

Figure 411 Algorithm to eliminate left recursion from a grammar

The procedure in Fig. 4.11 works as follows. In the first iteration for i 1 the outer for loop of lines 2 through 7 eliminates any immediate left recursion among A_1 productions. Any remaining A_1 productions of the form A_1 A_l must therefore have l 1. After the i 1st iteration of the outer for loop all nonterminals A_k where k i are cleaned that is any production A_k A_l must have l k As a result on the ith iteration the inner loop

of lines 3 through 5 progressively raises the lower limit in any production A_i A_m until we have m i Then eliminating immediate left recursion for the A_i productions at line 6 forces m to be greater than i

Example 4 20 Let us apply Algorithm 4 19 to the grammar 4 18 Technically the algorithm is not guaranteed to work because of the production but in this case the production A turns out to be harmless

We order the nonterminals S A There is no immediate left recursion among the S productions so nothing happens during the outer loop for i 1 For i 2 we substitute for S in A S d to obtain the following A productions

$$A \quad A \quad c \mid A \quad a \quad d \mid b \quad d \mid$$

Eliminating the immediate left recursion among these A productions yields the following grammar

4 3 4 Left Factoring

Left factoring is a grammar transformation that is useful for producing a gram mar suitable for predictive or top down parsing. When the choice between two alternative A productions is not clear, we may be able to rewrite the productions to defer the decision until enough of the input has been seen that we can make the right choice

For example if we have the two productions

on seeing the input **if** we cannot immediately tell which production to choose to expand stmt In general if A $_1$ | $_2$ are two A productions and the input begins with a nonempty string derived from — we do not know whether to expand A to $_1$ or $_2$ However we may defer the decision by expanding A to $_A'$ Then after seeing the input derived from — we expand A' to $_1$ or to $_2$ That is left factored the original productions become

$$A \qquad A' \\ A' \qquad {}_1 \mid {}_2$$

Algorithm 4 21 Left factoring a grammar

INPUT Grammar G

OUTPUT An equivalent left factored grammar

4.3 WRITING A GRAMMAR

METHOD For each nonterminal A and the longest pre x common to two or more of its alternatives If / i e there is a nontrivial common pre x replace all of the A productions A $_1 \mid _2 \mid _n \mid$ where represents all alternatives that do not begin with

Here A' is a new nonterminal Repeatedly apply this transformation until no two alternatives for a nonterminal have a common pre x \Box

Example 4 22 The following grammar abstracts the dangling else problem

Here i t and e stand for **if then** and **else** E and S stand for conditional expression and statement Left factored this grammar becomes

Thus we may expand S to iEtSS' on input i and wait until iEtS has been seen to decide whether to expand S' to eS or to Of course these grammars are both ambiguous and on input e it will not be clear which alternative for S' should be chosen Example 4 33 discusses a way out of this dilemma

4 3 5 Non Context Free Language Constructs

A few syntactic constructs found in typical programming languages cannot be speci ed using grammars alone. Here we consider two of these constructs using simple abstract languages to illustrate the di-culties

Example 4 25 The language in this example abstracts the problem of checking that identifiers are declared before they are used in a program. The language consists of strings of the form wcw where the right represents the declaration of an identifier wc represents an intervening program fragment and the second w represents the use of the identifier

The abstract language is $L_1 = \{wcw \mid w \text{ is in } \mathbf{a} | \mathbf{b} \}$ L_1 consists of all words composed of a repeated string of a s and b s separated by c such as aabcaab While it is beyond the scope of this book to prove it the non context freedom of L_1 directly implies the non context freedom of programming languages like C and Java which require declaration of identifiers before their use and which allow identifiers of arbitrary length

For this reason a grammar for C or Java does not distinguish among identi ers that are di erent character strings Instead all identi ers are represented by a token such as id in the grammar. In a compiler for such a language the semantic analysis phase checks that identifiers are declared before they are used \Box

Example 4 26 The non context free language in this example abstracts the problem of checking that the number of formal parameters in the declaration of a function agrees with the number of actual parameters in a use of the function. The language consists of strings of the form $a^nb^mc^nd^m$. Recall a^n means a written n times. Here a^n and b^m could represent the formal parameter lists of two functions declared to have n and m arguments respectively while c^n and d^m represent the actual parameter lists in calls to these two functions

The abstract language is $L_2 = \{a^nb^mc^nd^m \mid n=1 \text{ and } m=1\}$ That is L_2 consists of strings in the language generated by the regular expression $\mathbf{a} \mathbf{b} \mathbf{c} \mathbf{d}$ such that the number of a s and c s are equal and the number of b s and d s are equal. This language is not context free

Again the typical syntax of function declarations and uses does not concern itself with counting the number of parameters For example a function call in C like language might be specified by

$$\begin{array}{cccc} stmt & & \mathbf{id} & expr_list \\ expr_list & & expr_list & expr \\ & & & & \\ & & & & \\ \end{array}$$

with suitable productions for expr Checking that the number of parameters in a call is correct is usually done during the semantic analysis phase \Box

4 3 6 Exercises for Section 4 3

Exercise 4 3 1 The following is a grammar for regular expressions over symbols a and b only using in place of | for union to avoid conjict with the use of vertical bar as a metasymbol in grammars

- a Left factor this grammar
- b Does left factoring make the grammar suitable for top down parsing
- c In addition to left factoring eliminate left recursion from the original grammar
- d Is the resulting grammar suitable for top down parsing

Exercise 4 3 2 Repeat Exercise 4 3 1 on the following grammars

4.4 TOP DOWN PARSING

- a The grammar of Exercise 4 2 1
- b The grammar of Exercise 4 2 2 a
- c The grammar of Exercise 4 2 2 c
- d The grammar of Exercise 4 2 2 e
- e The grammar of Exercise 4 2 2 g

Exercise 4 3 3 The following grammar is proposed to remove the dangling else ambiguity discussed in Section 4 3 2

stmt	$\mathbf{if}\ expr\ \mathbf{then}\ stmt$
	matchedStmt
matchedStmt	if expr then matchedStmt else stmt
	other

Show that this grammar is still ambiguous

4 4 Top Down Parsing

Top down parsing can be viewed as the problem of constructing a parse tree for the input string starting from the root and creating the nodes of the parse tree in preorder depth rst as discussed in Section 2.3.4 Equivalently top down parsing can be viewed as nding a leftmost derivation for an input string

Example 4 27 The sequence of parse trees in Fig. 4 12 for the input id id is a top down parse according to grammar 4 2 repeated here

This sequence of trees corresponds to a leftmost derivation of the input \Box

At each step of a top down parse the key problem is that of determining the production to be applied for a nonterminal say A. Once an A production is chosen the rest of the parsing process consists of matching the terminal symbols in the production body with the input string

The section begins with a general form of top down parsing called recursive descent parsing which may require backtracking to $\,$ nd the correct $\,$ A production to be applied. Section 2.4.2 introduced predictive parsing a special case of recursive descent parsing where no backtracking is required. Predictive parsing chooses the correct $\,$ A production by looking ahead at the input a $\,$ xed number of symbols typically we may look only at one that is the next input symbol

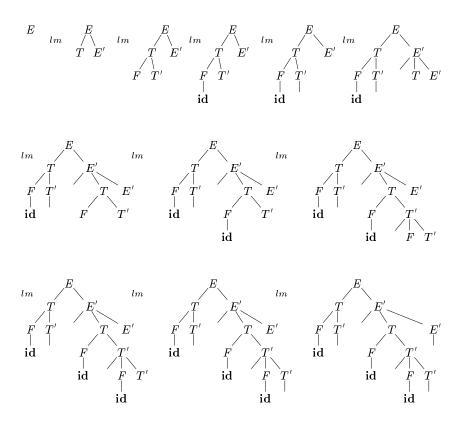

Figure 4 12 Top down parse for id id id

For example consider the top down parse in Fig. 4.12 which constructs a tree with two nodes labeled E'. At the rst E' node in preorder the production E'. TE' is chosen at the second E' node the production E' is chosen. A predictive parser can choose between E' productions by looking at the next input symbol

The class of grammars for which we can construct predictive parsers looking k symbols ahead in the input is sometimes called the $LL\ k$ class. We discuss the LL 1 class in Section 4.4.3 but introduce certain computations called FIRST and FOLLOW in a preliminary Section 4.4.2. From the FIRST and FOLLOW sets for a grammar we shall construct predictive parsing tables which make explicit the choice of production during top down parsing. These sets are also useful during bottom up parsing as we shall see

In Section 4 4 4 we give a nonrecursive parsing algorithm that maintains a stack explicitly rather than implicitly via recursive calls Finally in Section 4 4 5 we discuss error recovery during top down parsing

4 4 1 Recursive Descent Parsing

```
void A = \{
1
           Choose an A production A
                                          X_1X_2
                                                    X_k
2
           for i = 1 to k = \{
3
                 if X_i is a nonterminal
4
                        call procedure X_i
5
                  else if X_i equals the current input symbol a
6
                        advance the input to the next symbol
7
                  else
                          an error has occurred
    }
```

Figure 4 13 A typical procedure for a nonterminal in a top down parser

A recursive descent parsing program consists of a set of procedures one for each nonterminal Execution begins with the procedure for the start symbol which halts and announces success if its procedure body scans the entire input string Pseudocode for a typical nonterminal appears in Fig. 4.13. Note that this pseudocode is nondeterministic since it begins by choosing the A production to apply in a manner that is not specified

General recursive descent may require backtracking that is it may require repeated scans over the input. However, backtracking is rarely needed to parse programming language constructs so backtracking parsers are not seen frequently. Even for situations like natural language parsing backtracking is not very e-cient, and tabular methods such as the dynamic programming algorithm of Exercise 4.4.9 or the method of Earley—see the bibliographic notes are preferred

To allow backtracking the code of Fig 4 13 needs to be modi ed First we cannot choose a unique A production at line 1 so we must try each of several productions in some order Then failure at line 7 is not ultimate failure but suggests only that we need to return to line 1 and try another A production Only if there are no more A productions to try do we declare that an input error has been found. In order to try another A production we need to be able to reset the input pointer to where it was when we extreached line 1. Thus a local variable is needed to store this input pointer for future use

Example 4 29 Consider the grammar

To construct a parse tree top down for the input string w-cad begin with a tree consisting of a single node labeled S and the input pointer pointing to c the rst symbol of w-S has only one production so we use it to expand S and

obtain the tree of Fig. 4.14 a. The leftmost leaf-labeled c-matches the rst symbol of input w-so we advance the input pointer to a-the second symbol of w-and consider the next leaf-labeled A

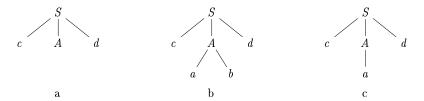

Figure 4 14 Steps in a top down parse

Now we expand A using the rst alternative A a b to obtain the tree of Fig 4 14 b. We have a match for the second input symbol a so we advance the input pointer to d the third input symbol and compare d against the next leaf labeled b. Since b does not match d we report failure and go back to A to see whether there is another alternative for A that has not been tried but that might produce a match

In going back to A we must reset the input pointer to position 2 the position it had when we rst came to A which means that the procedure for A must store the input pointer in a local variable

The second alternative for A produces the tree of Fig. 4.14 c. The leaf a matches the second symbol of w and the leaf d matches the third symbol. Since we have produced a parse tree for w we halt and announce successful completion of parsing.

A left recursive grammar can cause a recursive descent parser even one with backtracking to go into an in nite loop. That is when we try to expand a nonterminal A we may eventually and ourselves again trying to expand A without having consumed any input

4 4 2 FIRST and FOLLOW

The construction of both top down and bottom up parsers is aided by two functions first and follow associated with a grammar G During top down parsing first and follow allow us to choose which production to apply based on the next input symbol During panic mode error recovery sets of tokens produced by follow can be used as synchronizing tokens

De ne \it{FIRST} where is any string of grammar symbols to be the set of terminals that begin strings derived from If then is also in FIRST For example in Fig 4 15 \it{A} \it{c} so \it{c} is in FIRST \it{A}

For a preview of how FIRST can be used during predictive parsing consider two A productions A | where FIRST and FIRST are disjoint sets We can then choose between these A productions by looking at the next input

4.4 TOP DOWN PARSING

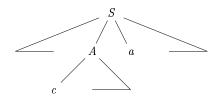

Figure 4.15 Terminal c is in FIRST A and a is in FOLLOW A

symbol a since a can be in at most one of FIRST—and FIRST—not both For instance—if a is in FIRST—choose the production A—This idea will be explored when LL 1—grammars are defined in Section 4.4.3

De ne $FOLLOW\ A$ for nonterminal A to be the set of terminals a that can appear immediately to the right of A in some sentential form that is the set of terminals a such that there exists a derivation of the form S Aa for some and as in Fig 4.15. Note that there may have been symbols between A and a at some time during the derivation but if so they derived and disappeared. In addition if A can be the rightmost symbol in some sentential form then is in FOLLOW A recall that is a special endmarker symbol that is assumed not to be a symbol of any grammar

To compute FIRST X for all grammar symbols X apply the following rules until no more terminals or — can be added to any FIRST set

- 1 If X is a terminal then FIRST $X = \{X\}$
- 2 If X is a nonterminal and X Y_1Y_2 Y_k is a production for some k-1 then place a in first X if for some i-a is in first Y_i and is in all of first Y_1 for all j-1 2 k then add to first X for example everything in first Y_1 is surely in first X If Y_1 does not derive then we add nothing more to first X but if Y_1 then we add first Y_2 and so on
- 3 If X is a production then add to FIRST X

Now we can compute FIRST for any string X_1X_2 X_n as follows Add to FIRST X_1X_2 X_n all non—symbols of FIRST X_1 Also add the non—symbols of FIRST X_2 if—is in FIRST X_1 —the non—symbols of FIRST X_3 —if—is in FIRST X_1 —and FIRST X_2 —and so on—Finally add—to FIRST X_1X_2 — X_n —if—for all i—is in FIRST X_i

To compute FOLLOW A for all nonterminals A apply the following rules until nothing can be added to any FOLLOW set

1 Place in FOLLOW S where S is the start symbol and is the input right endmarker

- 2 If there is a production A B then everything in FIRST except is in FOLLOW B
- 3 If there is a production A B or a production A B where FIRST contains then everything in FOLLOW A is in FOLLOW B

Example 4 30 Consider again the non left recursive grammar 4 28 Then

- 1 FIRST F FIRST T FIRST E { \mathbf{id} } To see why note that the two productions for F have bodies that start with these two terminal symbols \mathbf{id} and the left parenthesis T has only one production and its body starts with F Since F does not derive FIRST T must be the same as FIRST F. The same argument covers FIRST E
- 2 FIRST E' { } The reason is that one of the two productions for E' has a body that begins with terminal and the other s body is When ever a nonterminal derives we place in FIRST for that nonterminal
- 3 FIRST T' { } The reasoning is analogous to that for FIRST E'
- 4 FOLLOW E FOLLOW E' { } Since E is the start symbol FOLLOW E must contain The production body E explains why the right parenthesis is in FOLLOW E For E' note that this nonterminal appears only at the ends of bodies of E productions Thus FOLLOW E' must be the same as FOLLOW E
- 5 FOLLOW T FOLLOW T' { } Notice that T appears in bodies only followed by E' Thus everything except that is in FIRST E' must be in FOLLOW T that explains the symbol However since FIRST E' contains i e E' and E' is the entire string following T in the bodies of the E productions everything in FOLLOW E must also be in FOLLOW T That explains the symbols and the right parenthesis As for T' since it appears only at the ends of the T productions it must be that FOLLOW T' FOLLOW T
- 6 FOLLOW F $\{$ $\}$ The reasoning is analogous to that for T in point 5

4 4 3 LL 1 Grammars

Predictive parsers that is recursive descent parsers needing no backtracking can be constructed for a class of grammars called LL 1 The rst L in LL 1 stands for scanning the input from left to right the second L for producing a leftmost derivation and the 1 for using one input symbol of lookahead at each step to make parsing action decisions

Transition Diagrams for Predictive Parsers

Transition diagrams are useful for visualizing predictive parsers $\,$ For example the transition diagrams for nonterminals E and E' of grammar $\,$ 4 28 appear in Fig. 4 16 a $\,$ To construct the transition diagram from a grammar $\,$ rst eliminate left recursion and then left factor the grammar $\,$ Then for each nonterminal A

- 1 Create an initial and nal return state
- 2 For each production A X_1X_2 X_k create a path from the initial to the nal state with edges labeled X_1 X_2 X_k If A the path is an edge labeled

Transition diagrams for predictive parsers di er from those for lexical analyzers. Parsers have one diagram for each nonterminal. The labels of edges can be tokens or nonterminals. A transition on a token terminal means that we take that transition if that token is the next input symbol A transition on a nonterminal A is a call of the procedure for A

With an LL 1 grammar the ambiguity of whether or not to take an edge can be resolved by making transitions the default choice

Transition diagrams can be simplied provided the sequence of gram mar symbols along paths is preserved. We may also substitute the diagram for a nonterminal A in place of an edge labeled A. The diagrams in Fig. 4.16 a and be are equivalent if we trace paths from E to an accepting state and substitute for E' then in both sets of diagrams, the grammar symbols along the paths make up strings of the form T. T. The diagram in because obtained from a by transformations aking to those in Section 2.5.4 where we used tail recursion removal and substitution of procedure bodies to optimize the procedure for a nonterminal

The class of LL 1 grammars is rich enough to cover most programming constructs although care is needed in writing a suitable grammar for the source language. For example, no left recursive or ambiguous grammar can be LL 1

A grammar G is LL 1 if and only if whenever A | are two distinct productions of G the following conditions hold

- 1 For no terminal a do both and derive strings beginning with a
- 2 At most one of and can derive the empty string
- 3 If then does not derive any string beginning with a terminal in FOLLOW A Likewise if then does not derive any string beginning with a terminal in FOLLOW A

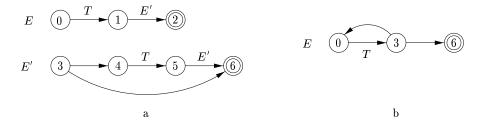

Figure 4.16 Transition diagrams for nonterminals E and E' of grammar 4.28

The rst two conditions are equivalent to the statement that FIRST and FIRST are disjoint sets. The third condition is equivalent to stating that if is in FIRST then FIRST and FOLLOW A are disjoint sets and likewise if is in FIRST.

Predictive parsers can be constructed for LL 1 grammars since the proper production to apply for a nonterminal can be selected by looking only at the current input symbol Flow of control constructs with their distinguishing key words generally satisfy the LL 1 constraints For instance if we have the productions

then the keywords **if while** and the symbol tell us which alternative is the only one that could possibly succeed if we are to nd a statement

The next algorithm collects the information from FIRST and FOLLOW sets into a predictive parsing table M A a a two dimensional array where A is a nonterminal and a is a terminal or the symbol—the input endmarker—The algorithm is based on the following idea—the production A—is chosen if the next input symbol a is in FIRST—The only complication occurs when

or more generally — In this case we should again choose A if the current input symbol is in FOLLOW A — or if the — on the input has been reached and — is in FOLLOW A

Algorithm 4 31 Construction of a predictive parsing table

INPUT Grammar G

OUTPUT Parsing table M

METHOD For each production A of the grammar do the following

- 1 For each terminal a in FIRST add A to M A a
- 2 If is in FIRST then for each terminal b in FOLLOW A add A to M A b If is in FIRST and is in FOLLOW A add A to M A as well

4.4 TOP DOWN PARSING

If after performing the above there is no production at all in M A a then set M A a to **error** which we normally represent by an empty entry in the table \square

Example 4 32 For the expression grammar 4 28 Algorithm 4 31 produces the parsing table in Fig 4 17 Blanks are error entries nonblanks indicate a production with which to expand a nonterminal

NON				I	NPUT	SYMI	30L			
TERMINAL		id								
E	E	TE'					E	TE'		
E'			E'	TE'					E'	E'
T	T	FT'					T	FT'		
T'			T'		T'	FT'			T'	T'
F	F	id					F	E		

Figure 4 17 Parsing table M for Example 4 32

Consider production E = TE' Since

FIRST
$$TE'$$
 FIRST T { id }

this production is added to M E and M E id Production E' TE' is added to M E' since FIRST TE' $\{\ \}$ Since FOLLOW E' $\{\ \}$ production E' is added to M E' and M E' \square

Algorithm 4 31 can be applied to any grammar G to produce a parsing table M. For every LL 1 grammar each parsing table entry uniquely identities a production or signals an error. For some grammars, however M may have some entries that are multiply defined. For example, if G is left recursive or ambiguous, then M will have at least one multiply defined entry. Although left recursion elimination and left factoring are easy to do there are some grammars for which no amount of alteration will produce an LL 1 grammar.

The language in the following example has no LL 1 grammar at all

Example 4 33 The following grammar which abstracts the dangling else problem is repeated here from Example 4 22

$$egin{array}{lll} S & & iEtSS' \mid a \ S' & & eS \mid \ E & & b \ \end{array}$$

The parsing table for this grammar appears in Fig. 4.18. The entry for M S' e contains both S' e and S'

The grammar is ambiguous and the ambiguity is manifested by a choice in what production to use when an *e* **else** is seen. We can resolve this ambiguity

Non		Input Symbol				
TERMINAL	a	b	e	i	t	
S	S a			S = iEtSS'		
C!			S'			S'
ß			S' eS			
\overline{E}		E b				

Figure 4.18 Parsing table M for Example 4.33

by choosing S' = eS This choice corresponds to associating an **else** with the closest previous **then** Note that the choice S' would prevent e from ever being put on the stack or removed from the input and is surely wrong \Box

4 4 4 Nonrecursive Predictive Parsing

A nonrecursive predictive parser can be built by maintaining a stack explicitly rather than implicitly via recursive calls. The parser mimics a leftmost derivation. If w is the input that has been matched so far then the stack holds a sequence of grammar symbols—such that

$$S = w$$

The table driven parser in Fig. 4-19 has an input buller a stack containing a sequence of grammar symbols a parsing table constructed by Algorithm 4-31 and an output stream. The input buller contains the string to be parsed followed by the endmarker. We reuse the symbol of the grammar on top of

The parser is controlled by a program that considers X the symbol on top of the stack and a the current input symbol. If X is a nonterminal, the parser chooses an X production by consulting entry M and of the parsing table M. Additional code could be executed here for example code to construct a node in a parse tree. Otherwise, it checks for a match between the terminal X and current input symbol a.

The behavior of the parser can be described in terms of its *con gurations* which give the stack contents and the remaining input—The next algorithm describes how con gurations are manipulated

Algorithm 4 34 Table driven predictive parsing

INPUT A string w and a parsing table M for grammar G

OUTPUT If w is in L G a leftmost derivation of w otherwise an error indication

4.4 TOP DOWN PARSING

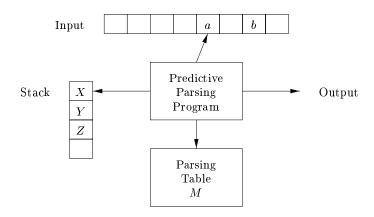

Figure 4 19 Model of a table driven predictive parser

METHOD Initially the parser is in a cong uration with w in the input buer and the start symbol S of G on top of the stack above. The program in Fig. 4.20 uses the predictive parsing table M to produce a predictive parse for the input. \square

```
let a be the rst symbol of w
let X be the top stack symbol
while X \neq \{ stack is not empty

if X a pop the stack and let a be the next symbol of w
else if X is a terminal error
else if M X a is an error entry error
else if M X a X Y_1Y_2 Y_k {

output the production X Y_1Y_2 Y_k

pop the stack

push Y_k Y_k _1 Y_1 onto the stack with Y_1 on top
}
let X be the top stack symbol
}
```

Figure 4 20 Predictive parsing algorithm

Example 4 35 Consider grammar 4 28 we have already seen its the parsing table in Fig 4 17 On input **id id id** the nonrecursive predictive parser of Algorithm 4 34 makes the sequence of moves in Fig 4 21 These moves correspond to a leftmost derivation see Fig 4 12 for the full derivation

$$E \mathop{}_{lm} TE' \mathop{}_{lm} FT'E' \mathop{}_{lm} \mathbf{id} T'E' \mathop{}_{lm} \mathbf{id} E' \mathop{}_{lm} \mathbf{id} TE'$$

MA	ТСНІ	ΞD	Stack		Inpu	Т	ACTION	
			E	id	id	id		
			TE'	id	id	id	output E	TE'
			FT'E'	id	id	id	output T	FT'
			id $T'E'$	id	id	id	output F	id
id			T'E'		id	id	$\mathrm{match}\;\mathbf{id}$	
id			E'		id	id	output T'	
id			TE'		id	id	output E'	TE'
id			TE'		id	id	match	
id			FT'E'		id	id	output T	FT'
id			id $T'E'$		id	id	output F	id
id	id		T'E'			id	$\mathrm{match}\;\mathbf{id}$	
id	id		FT'E'			id	output T'	FT'
id	id		FT'E'			id	match	
id	id		id $T'E'$			id	output F	id
id	id	id	T'E'				$\mathrm{match}\;\mathbf{id}$	
id	id	id	E'				output T'	
id	id	id					output E'	

Figure 4 21 Moves made by a predictive parser on input id id id

Note that the sentential forms in this derivation correspond to the input that has already been matched in column MATCHED followed by the stack contents. The matched input is shown only to highlight the correspondence. For the same reason the top of the stack is to the left, when we consider bottom up parsing it will be more natural to show the top of the stack to the right. The input pointer points to the leftmost symbol of the string in the INPUT column.

4 4 5 Error Recovery in Predictive Parsing

This discussion of error recovery refers to the stack of a table driven predictive parser since it makes explicit the terminals and nonterminals that the parser hopes to match with the remainder of the input the techniques can also be used with recursive descent parsing

An error is detected during predictive parsing when the terminal on top of the stack does not match the next input symbol or when nonterminal A is on top of the stack a is the next input symbol and M A a is **error** i e the parsing table entry is empty

Panic Mode

Panic mode error recovery is based on the idea of skipping over symbols on the input until a token in a selected set of synchronizing tokens appears Its

4.4 TOP DOWN PARSING

e ectiveness depends on the choice of synchronizing set. The sets should be chosen so that the parser recovers quickly from errors that are likely to occur in practice. Some heuristics are as follows

- 1 As a starting point place all symbols in FOLLOW A into the synchronizing set for nonterminal A If we skip tokens until an element of FOLLOW A is seen and pop A from the stack it is likely that parsing can continue
- 2 It is not enough to use FOLLOW A as the synchronizing set for A For example if semicolons terminate statements as in C then keywords that begin statements may not appear in the FOLLOW set of the nonterminal representing expressions. A missing semicolon after an assignment may therefore result in the keyword beginning the next statement be ing skipped. Often there is a hierarchical structure on constructs in a language for example expressions appear within statements which appear within blocks and so on. We can add to the synchronizing set of a lower level construct the symbols that begin higher level constructs. For example, we might add keywords that begin statements to the synchronizing sets for the nonterminals generating expressions.
- 3 If we add symbols in FIRST A to the synchronizing set for nonterminal A then it may be possible to resume parsing according to A if a symbol in FIRST A appears in the input
- 4 If a nonterminal can generate the empty string then the production de riving can be used as a default Doing so may postpone some error detection but cannot cause an error to be missed This approach reduces the number of nonterminals that have to be considered during error re covery
- 5 If a terminal on top of the stack cannot be matched a simple idea is to pop the terminal issue a message saying that the terminal was inserted and continue parsing In e ect this approach takes the synchronizing set of a token to consist of all other tokens

Example 4 36 Using FIRST and FOLLOW symbols as synchronizing tokens works reasonably well when expressions are parsed according to the usual gram mar 4 28 The parsing table for this grammar in Fig 4 17 is repeated in Fig 4 22 with synch indicating synchronizing tokens obtained from the FOLLOW set of the nonterminal in question The FOLLOW sets for the non terminals are obtained from Example 4 30

The table in Fig 4 22 is to be used as follows If the parser looks up entry M A a and nds that it is blank then the input symbol a is skipped. If the entry is synch, then the nonterminal on top of the stack is popped in an attempt to resume parsing. If a token on top of the stack does not match the input symbol, then we pop the token from the stack as mentioned above.

NON				I	NPU'	г Ѕүм	BOL			
TERMINAL		id								
\overline{E}	E	TE'					E	TE'	synch	synch
E'			E	TE'					E	E
T	T	FT'	sy	nch			T	FT'	synch	synch
T'			T'		T'	FT'			T'	T'
F	F	id	sy	nch	sy	nch	F	E	synch	synch

Figure 4 22 Synchronizing tokens added to the parsing table of Fig. 4 17

On the erroneous input $\,$ id $\,$ id the parser and error recovery mechanism of Fig 4 22 behave as in Fig 4 23 $\,$ \Box

E id id id is in FIRST E	
$TE' \qquad {f id} \qquad {f id}$	
$FT'E' \qquad {f id} \qquad {f id}$	
$\operatorname{id}\ T'E' \qquad \operatorname{id} \qquad \operatorname{id}$	
T'E' id	
FT'E' id	
FT'E' id error MF sy	nch
T'E' id F has been popped	
E^{\prime} id	
TE' id	
TE' id	
FT'E' id	
$\operatorname{id} T'E'$ id	
T'E'	
E'	

Figure 4 23 Parsing and error recovery moves made by a predictive parser

The above discussion of panic mode recovery does not address the important issue of error messages. The compiler designer must supply informative error messages that not only describe the error they must draw attention to where the error was discovered

4.4 TOP DOWN PARSING

Phrase level Recovery

Phrase level error recovery is implemented by lling in the blank entries in the predictive parsing table with pointers to error routines. These routines may change insert or delete symbols on the input and issue appropriate error messages. They may also pop from the stack. Alteration of stack symbols or the pushing of new symbols onto the stack is questionable for several reasons. First, the steps carried out by the parser might then not correspond to the derivation of any word in the language at all. Second, we must ensure that there is no possibility of an in nite loop. Checking that any recovery action eventually results in an input symbol being consumed or the stack being shortened if the end of the input has been reached is a good way to protect against such loops.

4 4 6 Exercises for Section 4 4

Exercise $4\ 4\ 1$ For each of the following grammars devise predictive parsers and show the parsing tables You may left factor and or eliminate left recursion from your grammars rst

- a The grammar of Exercise 4 2 2 a
- b The grammar of Exercise 4 2 2 b
- c The grammar of Exercise 4 2 2 c
- d The grammar of Exercise 4 2 2 d
- e The grammar of Exercise 4 2 2 e
- f The grammar of Exercise 4 2 2 g

Exercise 4 4 2 Is it possible by modifying the grammar in any way to construct a predictive parser for the language of Exercise 4 2 1 post x expressions with operand a

Exercise 4 4 3 Compute FIRST and FOLLOW for the grammar of Exercise 4 2 1

Exercise 4 4 4 Compute FIRST and FOLLOW for each of the grammars of Exercise 4 2 2

Exercise 4 4 5 The grammar S a S a | a a generates all even length strings of a s We can devise a recursive descent parser with backtrack for this grammar. If we choose to expand by production S a a rst then we shall only recognize the string aa. Thus, any reasonable recursive descent parser will try S a S a rst

a Show that this recursive descent parser recognizes inputs aa aaaa and aaaaaaaa but not aaaaaa

b What language does this recursive descent parser recognize

The following exercises are useful steps in the construction of a Chomsky Normal Form grammar from arbitrary grammars as de ned in Exercise 4 4 8

Exercise 4 4 6 A grammar is *free* if no production body is called an *production*

- a Give an algorithm to convert any grammar into an free grammar that generates the same language with the possible exception of the empty string no free grammar can generate *Hint* First nd all the nonterminals that are *nullable* meaning that they generate perhaps by a long derivation
- b Apply your algorithm to the grammar $S = aSbS \mid bSaS \mid$

Exercise 4 4 7 A *single production* is a production whose body is a single nonterminal i.e. a production of the form A B

- a Give an algorithm to convert any grammar into an free grammar with no single productions that generates the same language with the possible exception of the empty string Hint First eliminate productions and then nd for which pairs of nonterminals A and B does A B by a sequence of single productions
- b Apply your algorithm to the grammar 41 in Section 412
- c Show that as a consequence of part a we can convert a grammar into an equivalent grammar that has no cycles derivations of one or more steps in which A A for some nonterminal A

Exercise 4 4 8 A grammar is said to be in Chomsky Normal Form CNF if every production is either of the form A BC or of the form A a where A B and C are nonterminals and a is a terminal. Show how to convert any grammar into a CNF grammar for the same language with the possible exception of the empty string on CNF grammar can generate

Exercise 4 4 9 Every language that has a context free grammar can be recognized in at most O n^3 time for strings of length n A simple way to do so called the Cocke Younger Kasami or CYK algorithm is based on dynamic programming. That is given a string a_1a_2 a_n we construct an n by n table T such that T_{ij} is the set of nonterminals that generate the substring a_ia_{i-1} a_j . If the underlying grammar is in CNF see Exercise 4 4 8, then one table entry can be lied in in O n time provided well the entries in the proper order lowest value of j i rst. Write an algorithm that correctly lis in the entries of the table and show that your algorithm takes O n^3 time. Having lied in the table how do you determine whether a_1a_2 a_n is in the language

45 BOTTOM UP PARSING

Exercise 4 4 10 Show how having lled in the table as in Exercise 4 4 9 we can in O n time recover a parse tree for a_1a_2 a_n Hint modify the table so it records for each nonterminal A in each table entry T_{ij} some pair of nonterminals in other table entries that justiled putting A in T_{ij}

Exercise 4 4 11 Modify your algorithm of Exercise 4 4 9 so that it will not for any string the smallest number of insert delete and mutate errors each error a single character needed to turn the string into a string in the language of the underlying grammar

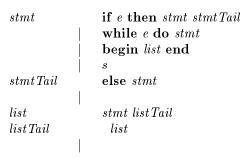

Figure 4 24 A grammar for certain kinds of statements

Exercise 4 4 12 In Fig 4 24 is a grammar for certain statements. You may take e and s to be terminals standing for conditional expressions and other statements respectively. If we resolve the conject regarding expansion of the optional else nonterminal stmtTail by preferring to consume an else from the input whenever we see one we can build a predictive parser for this grammar. Using the idea of synchronizing symbols described in Section 4 4 5.

- a Build an error correcting predictive parsing table for the grammar
- b Show the behavior of your parser on the following inputs

```
i if e then s if e then s end ii while e do begin s if e then s end
```

4 5 Bottom Up Parsing

A bottom up parse corresponds to the construction of a parse tree for an input string beginning at the leaves the bottom and working up towards the root the top—It is convenient to describe parsing as the process of building parse trees although a front end may in fact carry out a translation directly without building an explicit tree—The sequence of tree snapshots in Fig. 4.25 illustrates

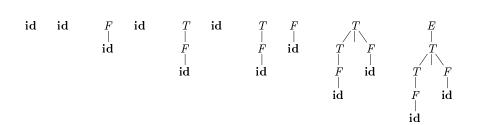

Figure 4 25 A bottom up parse for id id

a bottom up parse of the token stream id id with respect to the expression grammar 4.1

This section introduces a general style of bottom up parsing known as shift reduce parsing. The largest class of grammars for which shift reduce parsers can be built the LR grammars will be discussed in Sections 4.6 and 4.7. Although it is too much work to build an LR parser by hand tools called automatic parser generators make it easy to construct e-cient LR parsers from suitable grammars. The concepts in this section are helpful for writing suitable grammars to make e-ective use of an LR parser generator. Algorithms for implementing parser generators appear in Section 4.7.

451 Reductions

We can think of bottom up parsing as the process of reducing a string w to the start symbol of the grammar. At each reduction step, a special consisting matching the body of a production is replaced by the nonterminal at the head of that production

The key decisions during bottom up parsing are about when to reduce and about what production to apply as the parse proceeds

Example 4 37 The snapshots in Fig. 4.25 illustrate a sequence of reductions the grammar is the expression grammar 4.1. The reductions will be discussed in terms of the sequence of strings

$$\mathbf{id} \quad \mathbf{id} \quad F \quad \mathbf{id} \quad T \quad \mathbf{id} \quad T \quad F \quad T \quad E$$

The strings in this sequence are formed from the roots of all the subtrees in the snapshots. The sequence starts with the input string id id. The rst reduction produces F id by reducing the leftmost id to F using the production F id. The second reduction produces T id by reducing F to T

Now we have a choice between reducing the string T which is the body of E T and the string consisting of the second \mathbf{id} which is the body of F \mathbf{id} Rather than reduce T to E the second \mathbf{id} is reduced to F resulting in the string T F This string then reduces to T The parse completes with the reduction of T to the start symbol E \square

45 BOTTOM UP PARSING

By de nition a reduction is the reverse of a step in a derivation recall that in a derivation a nonterminal in a sentential form is replaced by the body of one of its productions The goal of bottom up parsing is therefore to construct a derivation in reverse The following corresponds to the parse in Fig. 4.25

$$E$$
 T T F T id F id id id

This derivation is in fact a rightmost derivation

4 5 2 Handle Pruning

Bottom up parsing during a left to right scan of the input constructs a right most derivation in reverse Informally a handle is a substring that matches the body of a production and whose reduction represents one step along the reverse of a rightmost derivation

For example adding subscripts to the tokens id for clarity the handles during the parse of id_1 id_2 according to the expression grammar 4.1 are as in Fig. 4.26. Although T is the body of the production E-T the symbol T is not a handle in the sentential form $T-\operatorname{id}_2$. If T were indeed replaced by E we would get the string $E-\operatorname{id}_2$ which cannot be derived from the start symbol E. Thus the leftmost substring that matches the body of some production need not be a handle

RIGHT SENTENTIAL FORM	HANDLE	REDUCING PRODUCTION
$\mathbf{id}_{\underline{1}} \mathbf{id}_{\underline{2}}$	\mathbf{id}_1	F id
$egin{array}{ccc} F & \mathbf{id}_2 \ T & \mathbf{id}_2 \end{array}$	F' : a	$\left egin{array}{ccc} T & F \ F & \mathbf{id} \end{array} ight $
$T ext{Id}_2$ $T ext{F}$	$egin{array}{c} \mathbf{id}_2 \ T & F \end{array}$	$\begin{bmatrix} F & IG \\ T & T & F \end{bmatrix}$
\overline{T}	T	$oxed{E} T$

Figure 4 26 Handles during a parse of id_1 id_2

Formally if S Aw w as in Fig. 4.27 then production A in the position following is a handle of w Alternatively a handle of a right sentential form is a production A and a position of where the string may be found such that replacing at that position by A produces the previous right sentential form in a rightmost derivation of

Notice that the string w to the right of the handle must contain only terminal symbols. For convenience, we refer to the body rather than A as a handle. Note we say a handle, rather than the handle, because the grammar could be ambiguous, with more than one rightmost derivation of w. If a grammar is unambiguous, then every right sentential form of the grammar has exactly one handle.

A rightmost derivation in reverse can be obtained by handle pruning That is we start with a string of terminals w to be parsed If w is a sentence

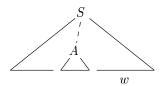

Figure 4 27 A handle A in the parse tree for w

of the grammar at hand then let w n where n is the nth right sentential form of some as yet unknown rightmost derivation

$$S = egin{pmatrix} 0 & & 1 & & 2 & & & n & 1 & & n & w \\ & rm & & rm & & rm & & rm & & n & 1 & & n & & w \end{bmatrix}$$

To reconstruct this derivation in reverse order we locate the handle n in n and replace n by the head of the relevant production A_n n to obtain the previous right sentential form n-1. Note that we do not yet know how handles are to be found but we shall see methods of doing so shortly

We then repeat this process That is we locate the handle n-1 in n-1 and reduce this handle to obtain the right sentential form n-2. If by continuing this process we produce a right sentential form consisting only of the start symbol S then we halt and announce successful completion of parsing. The reverse of the sequence of productions used in the reductions is a rightmost derivation for the input string

4 5 3 Shift Reduce Parsing

Shift reduce parsing is a form of bottom up parsing in which a stack holds grammar symbols and an input bu er holds the rest of the string to be parsed As we shall see the handle always appears at the top of the stack just before it is identified as the handle

We use to mark the bottom of the stack and also the right end of the input Conventionally when discussing bottom up parsing we show the top of the stack on the right rather than on the left as we did for top down parsing Initially the stack is empty and the string w is on the input as follows

$$\begin{array}{cc} \text{STACK} & \text{Input} \\ & w \end{array}$$

During a left to right scan of the input string the parser shifts zero or more input symbols onto the stack until it is ready to reduce a string of grammar symbols on top of the stack. It then reduces to the head of the appropriate production. The parser repeats this cycle until it has detected an error or until the stack contains the start symbol and the input is empty.

45 BOTTOM UP PARSING

$$\begin{array}{cc} {\rm STACK} & {\rm Input} \\ S \end{array}$$

Upon entering this con guration the parser halts and announces successful completion of parsing Figure 4 28 steps through the actions a shift reduce parser might take in parsing the input string \mathbf{id}_1 \mathbf{id}_2 according to the expression grammar 4 1

STACK	Input	ACTION	
$\begin{matrix} \mathbf{id}_1 \\ F \\ T \\ T \\ T \\ \mathbf{id}_2 \\ T \\ F \\ T \\ E \end{matrix}$	$egin{array}{ll} \mathbf{id}_1 & \mathbf{id}_2 \ \mathbf{id}_2 \ \mathbf{id}_2 \ \mathbf{id}_2 \ \mathbf{id}_2 \end{array}$	shift reduce by F reduce by T shift shift reduce by F reduce by F reduce by E	id F id T T

Figure 4.28 Con gurations of a shift reduce parser on input id₁ id₂

While the primary operations are shift and reduce there are actually four possible actions a shift reduce parser can make 1 shift 2 reduce 3 accept and 4 error

- 1 Shift Shift the next input symbol onto the top of the stack
- 2 Reduce The right end of the string to be reduced must be at the top of the stack Locate the left end of the string within the stack and decide with what nonterminal to replace the string
- 3 Accept Announce successful completion of parsing
- 4 Error Discover a syntax error and call an error recovery routine

The use of a stack in shift reduce parsing is justi ed by an important fact the handle will always eventually appear on top of the stack never inside. This fact can be shown by considering the possible forms of two successive steps in any rightmost derivation. Figure 4.29 illustrates the two possible cases. In case 1. A is replaced by By and then the rightmost nonterminal B in the body By is replaced by In case 2. A is again expanded a rst but this time the body is a string y of terminals only. The next rightmost nonterminal B will be somewhere to the left of y

In other words

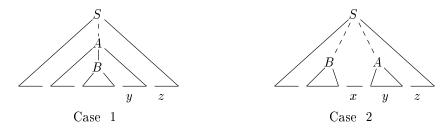

Figure 4 29 Cases for two successive steps of a rightmost derivation

Consider case 1 in reverse where a shift reduce parser has just reached the con guration

STACK INPUT yz

The parser reduces the handle $\,$ to B to reach the conguration

yz

The parser can now shift the string y onto the stack by a sequence of zero or more shift moves to reach the conguration

By z

with the handle By on top of the stack and it gets reduced to ANow consider case 2 In conguration

xyz

the handle—is on top of the stack—After reducing the handle—to B—the parser can shift the string xy to get the next handle y on top of the stack—ready to be reduced to A

Bxy z

In both cases after making a reduction the parser had to shift zero or more symbols to get the next handle onto the stack. It never had to go into the stack to nd the handle

4 5 4 Con icts During Shift Reduce Parsing

There are context free grammars for which shift reduce parsing cannot be used Every shift reduce parser for such a grammar can reach a cong uration in which the parser knowing the entire stack and also the next k input symbols cannot decide whether to shift or to reduce a *shift reduce con ict* or cannot decide

45 BOTTOM UP PARSING

which of several reductions to make a reduce reduce con ict. We now give some examples of syntactic constructs that give rise to such grammars. Technically these grammars are not in the LR k class of grammars defined in Section 4.7 we refer to them as non LR grammars. The k in LR k refers to the number of symbols of lookahead on the input. Grammars used in compiling usually fall in the LR 1 class with one symbol of lookahead at most

Example 4 38 An ambiguous grammar can never be LR For example con sider the dangling else grammar 4 14 of Section 4 3

$$stmt$$
 if $expr$ then $stmt$ | if $expr$ then $stmt$ else $stmt$ other

If we have a shift reduce parser in cong uration

STACK	Input
${f if}\ expr\ {f then}\ stmt$	${f else}$

we cannot tell whether **if** expr **then** stmt is the handle no matter what appears below it on the stack. Here there is a shift reduce con ict. Depending on what follows the **else** on the input it might be correct to reduce **if** expr **then** stmt to stmt or it might be correct to shift **else** and then to look for another stmt to complete the alternative **if** expr **then** stmt **else** stmt

Note that shift reduce parsing can be adapted to parse certain ambiguous grammars such as the if then else grammar above. If we resolve the shift reduce con ict on **else** in favor of shifting the parser will behave as we expect associating each **else** with the previous unmatched **then**. We discuss parsers for such ambiguous grammars in Section 4.8 \Box

Another common setting for con icts occurs when we know we have a han dle but the stack contents and the next input symbol are insu-cient to de termine which production should be used in a reduction. The next example illustrates this situation

Example 4 39 Suppose we have a lexical analyzer that returns the token name **id** for all names regardless of their type. Suppose also that our lan guage invokes procedures by giving their names with parameters surrounded by parentheses and that arrays are referenced by the same syntax. Since the translation of indices in array references and parameters in procedure calls are di erent, we want to use di erent productions to generate lists of actual parameters and indices. Our grammar might therefore have among others productions such as those in Fig. 4.30

A statement beginning with p i j would appear as the token stream id id id to the parser After shifting the rst three tokens onto the stack a shift reduce parser would be in conguration

1	stmt	$\mathbf{id} \textit{parameter_list}$
2	stmt	expr $expr$
3	$parameter_list$	$parameter_list parameter$
4	$parameter_list$	parameter
5	parameter	id
6	expr	$\mathbf{id} expr_list$
7	expr	id
8	$expr_list$	$expr_list = expr$
9	$expr_list$	expr

Figure 4 30 Productions involving procedure calls and array references

Stack		Input
id	id	id

It is evident that the **id** on top of the stack must be reduced but by which production The correct choice is production 5 if p is a procedure but production 7 if p is an array The stack does not tell which information in the symbol table obtained from the declaration of p must be used

One solution is to change the token **id** in production 1 to **procid** and to use a more sophisticated lexical analyzer that returns the token name **procid** when it recognizes a lexeme that is the name of a procedure Doing so would require the lexical analyzer to consult the symbol table before returning a token

If we made this modi cation then on processing p i j the parser would be either in the con guration

or in the con guration above In the former case we choose reduction by production 5 in the latter case by production 7 Notice how the symbol third from the top of the stack determines the reduction to be made even though it is not involved in the reduction Shift reduce parsing can utilize information far down in the stack to guide the parse \Box

4 6 Introduction to LR Parsing Simple LR

The most prevalent type of bottom up parser today is based on a concept called LR k parsing the L is for left to right scanning of the input the R for constructing a rightmost derivation in reverse and the k for the number of input symbols of lookahead that are used in making parsing decisions. The cases k=0 or k=1 are of practical interest, and we shall only consider LR parsers with k=1 here. When k is omitted k is assumed to be 1

This section introduces the basic concepts of LR parsing and the easiest method for constructing shift reduce parsers called simple LR or SLR for short. Some familiarity with the basic concepts is helpful even if the LR parser itself is constructed using an automatic parser generator. We begin with items and parser states the diagnostic output from an LR parser generator typically includes parser states which can be used to isolate the sources of parsing conficts.

Section 4.7 introduces two more complex methods canonical LR and LALR that are used in the majority of LR parsers

4 6 1 Why LR Parsers

LR parsers are table driven much like the nonrecursive LL parsers of Section 4 4 4 A grammar for which we can construct a parsing table using one of the methods in this section and the next is said to be an *LR grammar* Intuitively for a grammar to be LR it is su-cient that a left to right shift reduce parser be able to recognize handles of right sentential forms when they appear on top of the stack

LR parsing is attractive for a variety of reasons

LR parsers can be constructed to recognize virtually all programming language constructs for which context free grammars can be written Non LR context free grammars exist but these can generally be avoided for typical programming language constructs

The LR parsing method is the most general nonbacktracking shift reduce parsing method known yet it can be implemented as e ciently as other more primitive shift reduce methods see the bibliographic notes

An LR parser can detect a syntactic error as soon as it is possible to do so on a left to right scan of the input

The class of grammars that can be parsed using LR methods is a proper superset of the class of grammars that can be parsed with predictive or LL methods. For a grammar to be LR k—we must be able to recognize the occurrence of the right side of a production in a right sentential form with k input symbols of lookahead. This requirement is far less stringent than that for LL k—grammars where we must be able to recognize the use of a production seeing only the rst k—symbols of what its right side derives. Thus it should not be surprising that LR grammars can describe more languages than LL grammars.

The principal drawback of the LR method is that it is too much work to construct an LR parser by hand for a typical programming language grammar A specialized tool an LR parser generator is needed Fortunately many such generators are available and we shall discuss one of the most commonly used ones Yacc in Section 4.9 Such a generator takes a context free grammar and automatically produces a parser for that grammar. If the grammar contains ambiguities or other constructs that are discult to parse in a left to right scan of the input then the parser generator locates these constructs and provides detailed diagnostic messages

4 6 2 Items and the LR 0 Automaton

How does a shift reduce parser know when to shift and when to reduce For example with stack contents T and next input symbol in Fig 4 28 how does the parser know that T on the top of the stack is not a handle so the appropriate action is to shift and not to reduce T to E

An LR parser makes shift reduce decisions by maintaining states to keep track of where we are in a parse States represent sets of items. An LR θ item item for short of a grammar G is a production of G with a dot at some position of the body. Thus production A XYZ yields the four items

 $\begin{array}{ccc}
A & XYZ \\
A & XYZ \\
A & XYZ \\
A & XYZ
\end{array}$

The production A generates only one item A

Intuitively an item indicates how much of a production we have seen at a given point in the parsing process. For example, the item A = XYZ indicates that we hope to see a string derivable from XYZ next on the input. Item

Representing Item Sets

A parser generator that produces a bottom up parser may need to represent items and sets of items conveniently. Note that an item can be represented by a pair of integers the rst of which is the number of one of the productions of the underlying grammar and the second of which is the position of the dot. Sets of items can be represented by a list of these pairs. However, as we shall see the necessary sets of items often include closure items where the dot is at the beginning of the body. These can always be reconstructed from the other items in the set, and we do not have to include them in the list.

A X Y Z indicates that we have just seen on the input a string derivable from X and that we hope next to see a string derivable from Y Z Item A X Y Z indicates that we have seen the body X Y Z and that it may be time to reduce X Y Z to A

One collection of sets of LR 0 items called the canonical LR 0 collection provides the basis for constructing a deterministic nite automaton that is used to make parsing decisions Such an automaton is called an LR 0 automaton 3 In particular each state of the LR 0 automaton represents a set of items in the canonical LR 0 collection. The automaton for the expression grammar 4.1 shown in Fig. 4.31 will serve as the running example for discussing the canonical LR 0 collection for a grammar

To construct the canonical LR 0 collection for a grammar we de ne an augmented grammar and two functions CLOSURE and GOTO If G is a grammar with start symbol S then G' the augmented grammar for G is G with a new start symbol S' and production S' S The purpose of this new starting production is to indicate to the parser when it should stop parsing and announce acceptance of the input That is acceptance occurs when and only when the parser is about to reduce by S' S

Closure of Item Sets

If I is a set of items for a grammar G then CLOSURE I is the set of items constructed from I by the two rules

- 1 Initially add every item in I to CLOSURE I
- 2 If A B is in CLOSURE I and B is a production then add the item B to CLOSURE I if it is not already there. Apply this rule until no more new items can be added to CLOSURE I

³Technically the automaton misses being deterministic according to the de nition of Section 3 6 4 because we do not have a dead state corresponding to the empty set of items. As a result, there are some state input pairs for which no next state exists

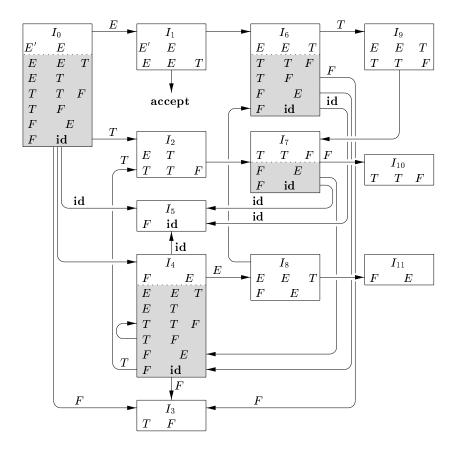

Figure 4 31 $\,$ LR $\,$ 0 $\,$ automaton for the expression grammar $\,$ 4 1

Intuitively A B in CLOSURE I indicates that at some point in the parsing process we think we might next see a substring derivable from B as input. The substring derivable from B will have a pre-x derivable from B by applying one of the B productions. We therefore add items for all the B productions that is if B is a production we also include B in CLOSURE I

Example 4 40 Consider the augmented expression grammar

If I is the set of one item $\{E' E\}$ then CLOSURE I contains the set of items I_0 in Fig. 4.31

4.6 INTRODUCTION TO LR PARSING SIMPLE LR

To see how the closure is computed E' E is put in CLOSURE I by rule 1. Since there is an E immediately to the right of a dot, we add the E productions with dots at the left ends E E T and E T. Now there is a T immediately to the right of a dot in the latter item, so we add T T F and T F Next, the F to the right of a dot forces us to add F E and F id but no other items need to be added.

The closure can be computed as in Fig. 4.32. A convenient way to imple ment the function closure is to keep a boolean array added indexed by the nonterminals of G such that added B is set to true if and when we add the item B for each B production B

Figure 4 32 Computation of CLOSURE

Note that if one B production is added to the closure of I with the dot at the left end then all B productions will be similarly added to the closure. Hence it is not necessary in some circumstances actually to list the items B added to I by CLOSURE. A list of the nonterminals B whose productions were so added will surge. We divide all the sets of items of interest into two classes

- 1 Kernel items the initial item S' S and all items whose dots are not at the left end
- 2 Nonkernel items all items with their dots at the left end except for S'-S

Moreover each set of items of interest is formed by taking the closure of a set of kernel items the items added in the closure can never be kernel items of course. Thus we can represent the sets of items we are really interested in with very little storage if we throw away all nonkernel items knowing that they could be regenerated by the closure process. In Fig. 4.31, nonkernel items are in the shaded part of the box for a state

The Function GOTO

The second useful function is GOTO I X where I is a set of items and X is a grammar symbol GOTO I X is defined to be the closure of the set of all items A X such that A X is in I Intuitively the GOTO function is used to define the transitions in the LR 0 automaton for a grammar. The states of the automaton correspond to sets of items and GOTO I X specifies the transition from the state for I under input X

Example 4 41 If I is the set of two items $\{E' \ E \ E \ E \ T\}$ then GOTO I contains the items

$$\begin{array}{cccc} E & E & T \\ T & T & F \\ T & F \\ E & E \\ \end{array}$$

We are now ready for the algorithm to construct C the canonical collection of sets of LR 0 items for an augmented grammar G' the algorithm is shown in Fig. 4.33

Figure 4 33 Computation of the canonical collection of sets of LR 0 items

Example 4 42 The canonical collection of sets of LR 0 items for grammar 4 1 and the GOTO function are shown in Fig 4 31 GOTO is encoded by the transitions in the gure \Box

4.6 INTRODUCTION TO LR PARSING SIMPLE LR

Use of the LR 0 Automaton

The central idea behind Simple LR or SLR parsing is the construction from the grammar of the LR 0 automaton. The states of this automaton are the sets of items from the canonical LR 0 collection, and the transitions are given by the GOTO function. The LR 0 automaton for the expression grammar 4.1 appeared earlier in Fig. 4.31

The start state of the LR 0 automaton is CLOSURE $\{S' \mid S\}$ where S' is the start symbol of the augmented grammar. All states are accepting states. We say state j to refer to the state corresponding to the set of items I_i

How can LR 0 automata help with shift reduce decisions. Shift reduce decisions can be made as follows. Suppose that the string of grammar symbols takes the LR 0 automaton from the start state 0 to some state j. Then shift on next input symbol a if state j has a transition on a. Otherwise, we choose to reduce the items in state j will tell us which production to use

The LR parsing algorithm to be introduced in Section 4 6 3 uses its stack to keep track of states as well as grammar symbols in fact the grammar symbol can be recovered from the state so the stack holds states. The next example gives a preview of how an LR $\,0\,$ automaton and a stack of states can be used to make shift reduce parsing decisions

Example 4 43 Figure 4 34 illustrates the actions of a shift reduce parser on input **id id** using the LR 0 automaton in Fig 4 31. We use a stack to hold states for clarity the grammar symbols corresponding to the states on the stack appear in column Symbols. At line 1—the stack holds the start state 0 of the automaton—the corresponding symbol is the bottom of stack marker

LINE	STACK	Symbols	Input	ACTION
1 2 3 4 5 6 7 8	$\begin{array}{c} 0 \\ 0.5 \\ 0.3 \\ 0.2 \\ 0.2.7 \\ 0.2.75 \\ 0.2.710 \\ 0.2 \\ 0.1 \end{array}$	id F T T id T F T	id id id id id id	$\begin{array}{cccccccccccccccccccccccccccccccccccc$

Figure 4 34 The parse of id id

The next input symbol is \mathbf{id} and state 0 has a transition on \mathbf{id} to state 5 We therefore shift. At line 2 state 5 symbol \mathbf{id} has been pushed onto the stack. There is no transition from state 5 on input—so we reduce. From item F— \mathbf{id} —in state 5 the reduction is by production F— \mathbf{id}

With symbols a reduction is implemented by popping the body of the production from the stack on line 2 the body is id and pushing the head of the production in this case F With states we pop state 5 for symbol id which brings state 0 to the top and look for a transition on F the head of the production In Fig 4 31 state 0 has a transition on F to state 3 so we push state 3 with corresponding symbol F see line 3

As another example consider line 5 with state 7 symbol on top of the stack. This state has a transition to state 5 on input id so we push state 5 symbol id. State 5 has no transitions so we reduce by F id. When we pop state 5 for the body id state 7 comes to the top of the stack. Since state 7 has a transition on F to state 10 we push state 10 symbol F

4 6 3 The LR Parsing Algorithm

A schematic of an LR parser is shown in Fig 4 35. It consists of an input an output a stack a driver program and a parsing table that has two parts ACTION and GOTO. The driver program is the same for all LR parsers only the parsing table changes from one parser to another. The parsing program reads characters from an input buser one at a time. Where a shift reduce parser would shift a symbol an LR parser shifts a *state*. Each state summarizes the information contained in the stack below it

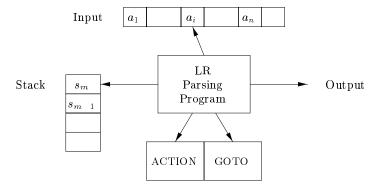

Figure 4 35 Model of an LR parser

The stack holds a sequence of states s_0s_1 s_m where s_m is on top. In the SLR method, the stack holds states from the LR 0 automaton, the canonical LR and LALR methods are similar. By construction, each state has a corresponding grammar symbol. Recall that states correspond to sets of items, and that there is a transition from state i to state j if GOTO I_i X I_j . All transitions to state j must be for the same grammar symbol X. Thus, each state except the start state 0 has a unique grammar symbol associated with it 4 .

⁴The converse need not hold that is more than one state may have the same grammar

4.6 INTRODUCTION TO LR PARSING SIMPLE LR

Structure of the LR Parsing Table

The parsing table consists of two parts a parsing action function ACTION and a goto function GOTO

- 1 The ACTION function takes as arguments a state i and a terminal a or the input endmarker. The value of ACTION i a can have one of four forms
 - a Shift j where j is a state. The action taken by the parser exectively shifts input a to the stack but uses state j to represent a
 - b Reduce A The action of the parser exectively reduces on the top of the stack to head A
 - c Accept The parser accepts the input and nishes parsing
 - d Error The parser discovers an error in its input and takes some corrective action. We shall have more to say about how such error recovery routines work in Sections 4 8 3 and 4 9 4
- 2 We extend the GOTO function de ned on sets of items to states if GOTO I_i A I_j then GOTO also maps a state i and a nonterminal A to state j

LR Parser Con gurations

To describe the behavior of an LR parser it helps to have a notation representing the complete state of the parser its stack and the remaining input A con guration of an LR parser is a pair

$$s_0s_1$$
 s_m a_ia_{i-1} a_n

where the rst component is the stack contents top on the right and the second component is the remaining input. This con guration represents the right sentential form

$$X_1X_2 \quad X_ma_ia_{i-1} \quad a_n$$

in essentially the same way as a shift reduce parser would the only di erence is that instead of grammar symbols the stack holds states from which grammar symbols can be recovered. That is X_i is the grammar symbol represented by state s_i . Note that s_0 the start state of the parser does not represent a grammar symbol and serves as a bottom of stack marker as well as playing an important role in the parse

symbol See for example states 1 and 8 in the LR 0 automaton in Fig. 4.31 which are both entered by transitions on E or states 2 and 9 which are both entered by transitions on T

Behavior of the LR Parser

The next move of the parser from the con guration above is determined by reading a_i the current input symbol and s_m the state on top of the stack and then consulting the entry ACTION s_m a_i in the parsing action table. The con gurations resulting after each of the four types of move are as follows

1 If ACTION s_m a_i shift s the parser executes a shift move it shifts the next state s onto the stack entering the conguration

$$s_0s_1$$
 s_ms a_{i-1} a_n

The symbol a_i need not be held on the stack—since it can be recovered from s—if needed—which in practice it never is—The current input symbol is now a_{i-1}

2 If ACTION s_m a_i reduce A then the parser executes a reduce move entering the conguration

$$s_0s_1$$
 s_m rs a_ia_i 1 a_n

where r is the length of and s GOTO $s_{m-r}A$ Here the parser rst popped r state symbols of the stack exposing state s_{m-r} . The parser then pushed s the entry for GOTO $s_{m-r}A$ onto the stack. The current input symbol is not changed in a reduce move. For the LR parsers we shall construct $X_{m-r-1} - X_m$ the sequence of grammar symbols corresponding to the states popped of the stack will always match the right side of the reducing production

The output of an LR parser is generated after a reduce move by executing the semantic action associated with the reducing production. For the time being we shall assume the output consists of just printing the reducing production

- 3 If ACTION s_m a_i accept parsing is completed
- 4 If ACTION s_m a_i error the parser has discovered an error and calls an error recovery routine

The LR parsing algorithm is summarized below. All LR parsers behave in this fashion, the only difference between one LR parser and another is the information in the ACTION and GOTO, elds of the parsing table.

Algorithm 4 44 LR parsing algorithm

INPUT An input string w and an LR parsing table with functions ACTION and GOTO for a grammar G

4.6 INTRODUCTION TO LR PARSING SIMPLE LR

OUTPUT If w is in L G —the reduction steps of a bottom up parse for w otherwise an error indication

METHOD Initially the parser has s_0 on its stack where s_0 is the initial state and w in the input bu er. The parser then executes the program in Fig. 4.36 \Box

```
let a be the rst symbol of w
while 1 { repeat forever
      let s be the state on top of the stack
      if ACTION s a
                         shift t \in \{
            push t onto the stack
            let a be the next input symbol
      \} else if ACTION s a
                               reduce A
            pop | | symbols o the stack
            let state t now be on top of the stack
            push GOTO t A onto the stack
            output the production A
      \} else if ACTION s a
                                accept break
                                                  parsing is done
      else call error recovery routine
}
```

Figure 4 36 LR parsing program

Example 4 45 Figure 4 37 shows the ACTION and GOTO functions of an LR parsing table for the expression grammar 4.1 repeated here with the productions numbered

The codes for the actions are

- 1 si means shift and stack state i
- 2 rj means reduce by the production numbered j
- 3 acc means accept
- 4 blank means error

Note that the value of GOTO s a for terminal a is found in the ACTION eld connected with the shift action on input a for state s The GOTO eld gives GOTO s A for nonterminals A Although we have not yet explained how the entries for Fig. 4.37 were selected we shall deal with this issue shortly

STATE			AC	TION	-		(GOT	0
DIAIL	id						E	T	F
0	s5			s4			1	2	3
1		s6				acc			
2		r2	s7		r2	r2			
3		r4	r4		r4	r4			
4	s5			s4			8	2	3
5		r6	r6		r6	r6			
6	s5			s4				9	3
7	s5			s4					10
8		s6			s11				
9		r1	s7		r1	r1			
10		r3	r3		r3	r3			
11		r5	r5		r5	r5			

Figure 4 37 Parsing table for expression grammar

On input id id id the sequence of stack and input contents is shown in Fig 4 38. Also shown for clarity are the sequences of grammar symbols corresponding to the states held on the stack. For example, at line 1, the LR parser is in state 0, the initial state with no grammar symbol, and with id the rst input symbol. The action in row 0 and column id of the action, eld of Fig 4 37 is s5 meaning shift by pushing state 5. That is what has happened at line 2, the state symbol 5 has been pushed onto the stack, and id has been removed from the input

Then becomes the current input symbol and the action of state 5 on input is to reduce by F id One state symbol is popped on the stack. State 0 is then exposed. Since the goto of state 0 on F is 3 state 3 is pushed onto the stack. We now have the configuration in line 3. Each of the remaining moves is determined similarly. \square

4 6 4 Constructing SLR Parsing Tables

The SLR method for constructing parsing tables is a good starting point for studying LR parsing. We shall refer to the parsing table constructed by this method as an SLR table, and to an LR parser using an SLR parsing table as an SLR parser. The other two methods augment the SLR method with lookahead information.

The SLR method begins with LR 0 items and LR 0 automata introduced in Section 4.5 That is given a grammar G we augment G to produce G' with a new start symbol S' From G' we construct C the canonical collection of sets of items for G' together with the GOTO function

46 INTRODUCTION TO LR PARSING SIMPLE LR

	STACK	Symbols		Inp	UT	ACTION	
1	0		id	id	id	shift	
2	0.5	id		id	id	reduce by F	id
3	0.3	F		id	id	reduce by T	F
4	0 2	T		id	id	shift	
5	0 2 7	T		id	id	shift	
6	$0\ 2\ 7\ 5$	T id			id	reduce by F	id
7	0 2 7 10	T F			id	reduce by T	T F
8	0 2	T			id	reduce by E	T
9	0 1	E			id	shift	
10	0 1 6	E			id	shift	
11	$0\ 1\ 6\ 5$	E id				reduce by F	id
12	0 1 6 3	E F				reduce by T	F
13	0169	E T				reduce by E	E - T
14	0 1	E				accept	

Figure 4 38 Moves of an LR parser on id id id

The ACTION and GOTO entries in the parsing table are then constructed using the following algorithm. It requires us to know FOLLOW A for each nonterminal A of a grammar see Section 4.4

Algorithm 4 46 Constructing an SLR parsing table

INPUT An augmented grammar G'

OUTPUT The SLR parsing table functions ACTION and GOTO for G'

METHOD

- 1 Construct $C = \{I_0 \ I_1 = I_n\}$ the collection of sets of LR 0 items for C'
- 2 State i is constructed from I_i The parsing actions for state i are determined as follows
 - a If A a is in I_i and GOTO I_i a I_j then set ACTION i a to shift j Here a must be a terminal
 - b If A is in I_i then set ACTION i a to reduce A for all a in FOLLOW A here A may not be S'
 - c If S' S is in I_i then set ACTION i to accept

If any con icting actions result from the above rules we say the grammar is not $SLR\ 1$ The algorithm fails to produce a parser in this case

- 3 The goto transitions for state i are constructed for all nonterminals A using the rule If GOTO I_i A I_j then GOTO i A j
- 4 All entries not de ned by rules 2 and 3 are made error
- 5 The initial state of the parser is the one constructed from the set of items containing S'-S

The parsing table consisting of the ACTION and GOTO functions determined by Algorithm 4 46 is called the SLR 1 table for G An LR parser using the SLR 1 table for G is called the SLR 1 parser for G and a grammar having an SLR 1 parsing table is said to be SLR 1 We usually omit the 1 after the SLR since we shall not deal here with parsers having more than one symbol of lookahead

Example 4 47 Let us construct the SLR table for the augmented expression grammar. The canonical collection of sets of LR 0 items for the grammar was shown in Fig. 4.31. First consider the set of items I_0

The item F E gives rise to the entry ACTION 0 shift 4 and the item F id to the entry ACTION 0 id shift 5 Other items in I_0 yield no actions Now consider I_1

$$E'$$
 E E T

The rst item yields ACTION 1 accept and the second yields ACTION 1 shift 6 Next consider I_2

Since FOLLOW E { } the rst item makes

ACTION 2 ACTION 2 ACTION 2 reduce
$$E = T$$

The second item makes ACTION 2 shift 7 Continuing in this fashion we obtain the ACTION and GOTO tables that were shown in Fig. 4.31 In that gure the numbers of productions in reduce actions are the same as the order in which they appear in the original grammar 4.1 That is E E T is number 1 E T is 2 and so on \Box

4.6 INTRODUCTION TO LR PARSING SIMPLE LR

Example 4 48 Every SLR 1 grammar is unambiguous but there are many unambiguous grammars that are not SLR 1 Consider the grammar with productions

Think of L and R as standing for l value and r value respectively and as an operator indicating contents of 5 The canonical collection of sets of LR 0 items for grammar 4.49 is shown in Fig. 4.39

Figure 4 39 Canonical LR 0 collection for grammar 4 49

Consider the set of items I_2 The rst item in this set makes ACTION 2 be shift 6 Since FOLLOW R contains to see why consider the derivation S L R R the second item sets ACTION 2 to reduce R L Since there is both a shift and a reduce entry in ACTION 2 state 2 has a shift reduce con ict on input symbol

Grammar 4 49 is not ambiguous. This shift reduce con ict arises from the fact that the SLR parser construction method is not powerful enough to remember enough left context to decide what action the parser should take on input—having seen a string reducible to L—The canonical and LALR methods to be discussed next—will succeed on a larger collection of grammars—including

 $^{^5\}mathrm{As}$ in Section 2 8 3 an l value designates a location and an r value is a value that can be stored in a location

grammar 4 49 Note however that there are unambiguous grammars for which every LR parser construction method will produce a parsing action table with parsing action con icts Fortunately such grammars can generally be avoided in programming language applications

4 6 5 Viable Pre xes

Why can LR 0 automata be used to make shift reduce decisions The LR 0 automaton for a grammar characterizes the strings of grammar symbols that can appear on the stack of a shift reduce parser for the grammar The stack contents must be a pre x of a right sentential form. If the stack holds and the rest of the input is x then a sequence of reductions will take x to S. In terms of derivations S

Not all pre xes of right sentential forms can appear on the stack however since the parser must not shift past the handle For example suppose

$$E_{rm} F \quad \mathbf{id}_{rm} \quad E \quad \mathbf{id}$$

Then at various times during the parse the stack will hold E and E but it must not hold E since E is a handle which the parser must reduce to E before shifting

The pre xes of right sentential forms that can appear on the stack of a shift reduce parser are called *viable pre xes*. They are de ned as follows a viable pre x is a pre x of a right sentential form that does not continue past the right end of the rightmost handle of that sentential form. By this de nition it is always possible to add terminal symbols to the end of a viable pre x to obtain a right sentential form

SLR parsing is based on the fact that LR 0 automata recognize viable pre xes. We say item A 1 2 is valid for a viable pre x 1 if there is a derivation S' Aw 1 2 w In general an item will be valid for many viable pre xes.

The fact that A $_1$ $_2$ is valid for $_1$ tells us a lot about whether to shift or reduce when we $_1$ on the parsing stack. In particular if $_2$ / then it suggests that we have not yet shifted the handle onto the stack so shift is our move. If $_2$ then it looks as if A $_1$ is the handle and we should reduce by this production. Of course, two valid items may tell us to do dierent things for the same viable pre $_1$ Some of these conficts can be resolved by looking at the next input symbol and others can be resolved by the methods of Section 4.8 but we should not suppose that all parsing action conficts can be resolved if the LR method is applied to an arbitrary grammar

We can easily compute the set of valid items for each viable pre x that can appear on the stack of an LR parser. In fact, it is a central theorem of LR parsing theory that the set of valid items for a viable pre x—is exactly the set of items reached from the initial state along the path labeled—in the LR 0—automaton for the grammar—In essence—the set of valid items embodies

Items as States of an NFA

A nondeterministic nite automaton N for recognizing viable pre xes can be constructed by treating the items themselves as states. There is a transition from A X to A X labeled X and there is a transition from A B to B labeled. Then CLOSURE I for set of items states of N I is exactly the closure of a set of NFA states de ned in Section 3.7.1 Thus GOTO I X gives the transition from I on symbol X in the DFA constructed from N by the subset construction Viewed in this way the procedure items G' in Fig. 4.33 is just the subset construction itself applied to the NFA N with items as states

all the useful information that can be gleaned from the stack While we shall not prove this theorem here we shall give an example

Example 4 50 Let us consider the augmented expression grammar again whose sets of items and GOTO function are exhibited in Fig. 4 31 Clearly the string E T is a viable pre x of the grammar. The automaton of Fig. 4 31 will be in state 7 after having read E T State 7 contains the items

$$egin{array}{cccc} T & T & F \ F & E \ F & \mathbf{id} \ \end{array}$$

which are precisely the items valid for E - T — To see why consider the following three rightmost derivations

The rst derivation shows the validity of T T F the second the validity of F E and the third the validity of F id It can be shown that there are no other valid items for E T although we shall not prove that fact here \Box

Exercise 4 6 2 Construct the SLR sets of items for the augmented grammar of Exercise 4 2 1 Compute the GOTO function for these sets of items Show the parsing table for this grammar Is the grammar SLR

Exercise 4 6 3 Show the actions of your parsing table from Exercise 4 6 2 on the input aa a

Exercise 4 6 4 For each of the augmented grammars of Exercise 4 2 2 a g

- a Construct the SLR sets of items and their GOTO function
- b Indicate any action con icts in your sets of items
- c Construct the SLR parsing table if one exists

Exercise 4 6 5 Show that the following grammar

$$S \qquad \qquad A \ a \ A \ b \mid B \ b \ B \ a$$

$$A \qquad B$$

is LL 1 but not SLR 1

Exercise 4 6 6 Show that the following grammar

$$S \qquad S \mid A \mid A$$
 $A \qquad a$

is SLR 1 but not LL 1

Exercise 4 6 7 Consider the family of grammars G_n defined by

Show that

a G_n has $2n^2$ n productions

b G_n has 2^n n^2 n sets of LR 0 items

c G_n is SLR 1

What does this analysis say about how large LR parsers can get

47 MORE POWERFUL LR PARSERS

- a Draw the transition diagram NFA for the valid items of this grammar according to the rule given in the box cited above
- b Apply the subset construction Algorithm 3 20 to your NFA from part a How does the resulting DFA compare to the set of LR 0 items for the grammar
- c Show that in all cases the subset construction applied to the NFA that comes from the valid items for a grammar produces the LR 0 sets of items

Exercise 4 6 9 The following is an ambiguous grammar

$$S$$
 $A S \mid b$ $A S \mid a$

Construct for this grammar its collection of sets of LR 0 items. If we try to build an LR parsing table for the grammar there are certain concicting actions. What are they Suppose we tried to use the parsing table by nondeterministically choosing a possible action whenever there is a concict. Show all the possible sequences of actions on input abab

4 7 More Powerful LR Parsers

In this section we shall extend the previous LR parsing techniques to use one symbol of lookahead on the input There are two di erent methods

- 1 The canonical LR or just LR method which makes full use of the lookahead symbol s This method uses a large set of items called the LR 1 items
- 2 The lookahead LR or LALR method which is based on the LR 0 sets of items and has many fewer states than typical parsers based on the LR 1 items By carefully introducing lookaheads into the LR 0 items we can handle many more grammars with the LALR method than with the SLR method and build parsing tables that are no bigger than the SLR tables LALR is the method of choice in most situations

After introducing both these methods we conclude with a discussion of how to compact LR parsing tables for environments with limited memory

471 Canonical LR 1 Items

We shall now present the most general technique for constructing an LR parsing table from a grammar Recall that in the SLR method state i calls for reduction by A if the set of items I_i contains item A and input symbol a is in FOLLOW A. In some situations however when state i appears on top of the stack the viable pre \mathbf{x} on the stack is such that A cannot be followed by a in any right sentential form. Thus the reduction by A should be invalid on input a

Example 4 51 Let us reconsider Example 4 48 where in state 2 we had item R L which could correspond to A above and a could be the sign which is in FOLLOW R. Thus the SLR parser calls for reduction by R L in state 2 with as the next input the shift action is also called for because of item S L R in state 2. However, there is no right sentential form of the grammar in Example 4 48 that begins R. Thus state 2 which is the state corresponding to viable pre x L only should not really call for reduction of that L to R.

It is possible to carry more information in the state that will allow us to rule out some of these invalid reductions by A By splitting states when necessary we can arrange to have each state of an LR parser indicate exactly which input symbols can follow a handle—for which there is a possible reduction to A

The extra information is incorporated into the state by rede ning items to include a terminal symbol as a second component. The general form of an item a where Ais a production and a is a terminal or We call such an object an LR 1 item The 1 refers the right endmarker to the length of the second component called the lookahead of the item ⁶ The lookahead has no e ect in an item of the form Aa where is not but an item of the form Aa calls for a reduction by Aonly if the next input symbol is a Thus we are compelled to reduce by Aonly on those input symbols a for which A a is an LR 1 item in the state on top of the stack The set of such a s will always be a subset of FOLLOW A but it could be a proper subset as in Example 451

Formally we say LR 1 item A a is valid for a viable pre x if there is a derivation S Aw w where

- 1 and
- 2 Either a is the rst symbol of w or w is and a is

Example 4 52 Let us consider the grammar

 $^{^6}$ Lookaheads that are strings of length greater than one are possible of course but we shall not consider such lookaheads here

47 MORE POWERFUL LR PARSERS

There is a rightmost derivation S aaBab aaaBab We see that item B a B a is valid for a viable pre X aaa by letting aa A B w ab a and B in the above definition. There is also a rightmost derivation S BaB BaaB. From this derivation we see that item B a B is valid for viable pre X Ba

4 7 2 Constructing LR 1 Sets of Items

The method for building the collection of sets of valid LR 1 items is essentially the same as the one for building the canonical collection of sets of LR 0 items. We need only to modify the two procedures CLOSURE and GOTO

```
SetOfItems CLOSURE I {
      repeat
             for
                 each item A
                                   B \quad a \quad \text{in } I
                                                 in G'
                   for each production B
                          for each terminal b in FIRST a
                                 add B
                                              b to set I
      until no more items are added to I
      return I
}
SetOfItems Goto IX {
      initialize J to be the empty set
      for each item A
                              X \quad a \text{ in } I
             add item A
                             X a to set J
      return CLOSURE J
}
void items G' {
      initialize C to CLOSURE { S'
      repeat
                 each set of items I in C
             for
                    {\bf for} \quad {\rm each \ grammar \ symbol} \ X 
                          if GOTO IX is not empty and not in C
                                 add GOTO IX to C
      until no new sets of items are added to C
}
```

Figure 4 40 Sets of LR 1 items construction for grammar G'

To appreciate the new de nition of the CLOSURE operation in particular why b must be in FIRST a consider an item of the form AB a in the set of items valid for some viable pre x Then there is a rightmost derivation Aax_{rm} Suppose ax derives terminal string B ax where by Then for each production of the form Bfor some we have derivation b is valid for Bby by Thus BNote that b can be the rst terminal derived from or it is possible that derives in the derivation by and b can therefore be a To summarize both possibilities we say that b can be any terminal in FIRST ax where FIRST is the function from Section 4.4 Note that x cannot contain the rst terminal of by so FIRST axFIRST a We now give the LR 1 sets of items construction

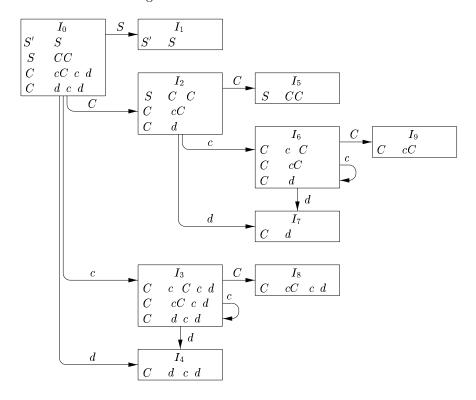

Figure 4 41 The GOTO graph for grammar 4 55

Algorithm 4 53 Construction of the sets of LR 1 items

INPUT An augmented grammar G'

OUTPUT The sets of LR 1 items that are the set of items valid for one or more viable pre xes of G^\prime

47 MORE POWERFUL LR PARSERS

METHOD The procedures CLOSURE and GOTO and the main routine *items* for constructing the sets of items were shown in Fig. 4.40 \Box

Example 4 54 Consider the following augmented grammar

$$\begin{array}{cccc} S' & S \\ S & C C \\ C & c C \mid d \end{array} \tag{4.55}$$

We begin by computing the closure of $\{S'\}$ S } To close we match the item S'S with the item A B a in the procedure CLOSURE That is AB Sand aFunction CLOSURE tells us to add Bb for each production Band terminal b in FIRST a In terms of the present grammar Bmust be SCC and since is and a is b may only be Thus we add SCC

b for bWe continue to compute the closure by adding all items CThat is matching SCC against A $B \quad a \quad \text{we have}$ C and a Since C does not derive the empty B - Cstring first CSince FIRST C contains terminals c and d we FIRST C $cC \ c \ C$ cC d Cd c and Cd d None of the add items Cnew items has a nonterminal immediately to the right of the dot so we have completed our rst set of LR 1 items. The initial set of items is

The brackets have been omitted for notational convenience and we use the notation C cC c d as a shorthand for the two items C c c and C c c d

Now we compute GOTO I_0 X for the various values of X For X S we must close the item S' S No additional closure is possible since the dot is at the right end. Thus we have the next set of items

$$I_1$$
 S' S

For X C we close S C C We add the C productions with second component and then can add no more yielding

$$\begin{array}{ccc} I_2 & S & C C \\ & C & cC \\ & C & d \end{array}$$

Next let X c We must close $\{C$ c C d $\}$ We add the C productions with second component c d yielding

CHAPTER 4 SYNTAX ANALYSIS

Finally let X = d and we wind up with the set of items

$$I_4$$
 C d c d

We have $\$ nished considering GOTO on I_0 We get no new sets from I_1 but I_2 has goto s on C c and d For GOTO I_2 C we get

$$I_5$$
 S CC

no closure being needed $\,$ To compute GOTO $I_2\,$ $\,c\,$ we take the closure of $\{\,C\,$ $\,c\,C\,$ $\,$ } to obtain

$$\begin{matrix} I_6 & C & c C \\ C & cC \\ C & d \end{matrix}$$

Note that I_6 di ers from I_3 only in second components. We shall see that it is common for several sets of LR 1 items for a grammar to have the same rst components and di er in their second components. When we construct the collection of sets of LR 0 items for the same grammar each set of LR 0 items will coincide with the set of rst components of one or more sets of LR 1 items. We shall have more to say about this phenomenon when we discuss LALR parsing

Continuing with the GOTO function for I_2 GOTO I_2 d is seen to be

$$I_7$$
 C d

Turning now to I_3 the GOTO s of I_3 on c and d are I_3 and I_4 respectively and GOTO I_3 C is

$$I_8$$
 C cC c d

 I_4 and I_5 have no GOTO s since all items have their dots at the right end. The GOTO s of I_6 on c and d are I_6 and I_7 respectively and GOTO I_6 C is

$$I_9$$
 C cC

The remaining sets of items yield no GOTO s so we are done $\,$ Figure 4.41 shows the ten sets of items with their goto s $\,$ \Box

4 7 3 Canonical LR 1 Parsing Tables

We now give the rules for constructing the LR 1 ACTION and GOTO functions from the sets of LR 1 items. These functions are represented by a table as before. The only difference is in the values of the entries

Algorithm 4 56 Construction of canonical LR parsing tables

INPUT An augmented grammar G'

OUTPUT The canonical LR parsing table functions ACTION and GOTO for G^\prime METHOD

- 1 Construct $C' = \{I_0 \ I_1 = I_n\}$ the collection of sets of LR 1 items for G'
- 2 State i of the parser is constructed from I_i The parsing action for state i is determined as follows
 - a If A a b is in I_i and GOTO I_i a I_j then set ACTION i a to shift j Here a must be a terminal
 - b If A a is in I_i A / S' then set ACTION i a to reduce A
 - c If S' S is in I_i then set ACTION i to accept

If any con icting actions result from the above rules we say the grammar is not LR 1 The algorithm fails to produce a parser in this case

- 3 The goto transitions for state i are constructed for all nonterminals A using the rule If GOTO I_i A I_j then GOTO i A j
- 4 All entries not de ned by rules 2 and 3 are made error
- 5 The initial state of the parser is the one constructed from the set of items containing S'-S

The table formed from the parsing action and goto functions produced by Algorithm 4 56 is called the *canonical* LR 1 parsing table. An LR parser using this table is called a canonical LR 1 parser. If the parsing action function has no multiply defined entries then the given grammar is called an LR 1 grammar. As before we omit the 1 if it is understood

Example 4 57 The canonical parsing table for grammar 4 55 is shown in Fig 4 42 Productions 1 2 and 3 are S CC C cC and C d respectively \square

Every SLR 1 grammar is an LR 1 grammar but for an SLR 1 grammar the canonical LR parser may have more states than the SLR parser for the same grammar. The grammar of the previous examples is SLR and has an SLR parser with seven states compared with the ten of Fig. 4.42

STATE	A	СТІО	GOTO		
DIAIL	c	d		S	C
0	s3	s4		1	2
1			acc		
$\frac{2}{3}$	s6	$_{\rm s7}$			5
	s3	s4			8
4	r3	r3			
5			r1		
6	s6	s7			9
7			r3		
8	r2	r2			
9			r2		

Figure 4 42 Canonical parsing table for grammar 4 55

474 Constructing LALR Parsing Tables

We now introduce our last parser construction method the LALR lookahead LR technique This method is often used in practice because the tables ob tained by it are considerably smaller than the canonical LR tables yet most common syntactic constructs of programming languages can be expressed conveniently by an LALR grammar The same is almost true for SLR grammars but there are a few constructs that cannot be conveniently handled by SLR techniques see Example 4 48 for example

For a comparison of parser size the SLR and LALR tables for a grammar always have the same number of states and this number is typically several hundred states for a language like C. The canonical LR table would typically have several thousand states for the same size language. Thus, it is much easier and more economical to construct SLR and LALR tables than the canonical LR tables.

By way of introduction let us again consider grammar 455 whose sets of LR 1 items were shown in Fig 441 Take a pair of similar looking states such as I_4 and I_7 Each of these states has only items with rst component C d In I_4 the lookaheads are c or d in I_7 is the only lookahead

To see the difference between the roles of I_4 and I_7 in the parser note that the grammar generates the regular language \mathbf{c} dc d When reading an input cc cdc cd the parser shifts the first group of c s and their following d onto the stack entering state 4 after reading the d. The parser then calls for a reduction by C d provided the next input symbol is c or d. The requirement that c or d follow makes sense since these are the symbols that could begin strings in \mathbf{c} d. If follows the first d we have an input like ccd which is not in the language and state 4 correctly declares an error if d is the next input

The parser enters state 7 after reading the second d Then the parser must

see on the input or it started with a string not of the form \mathbf{c} \mathbf{dc} \mathbf{d} It thus makes sense that state 7 should reduce by C-d on input—and declare error on inputs c or d

Let us now replace I_4 and I_7 by I_{47} the union of I_4 and I_7 consisting of the set of three items represented by C-d-c-d. The gotos on d to I_4 or I_7 from I_0 I_2 I_3 and I_6 now enter I_{47} . The action of state 47 is to reduce on any input. The revised parser behaves essentially like the original although it might reduce d to C in circumstances where the original would declare error for example on input like ccd or cdcdc. The error will eventually be caught in fact it will be caught before any more input symbols are shifted

More generally we can look for sets of LR 1 items having the same *core* that is set of rst components and we may merge these sets with common cores into one set of items. For example, in Fig. 4.41 I_4 and I_7 form such a pair with core $\{C \ c \ C \ c \ C \ d\}$. Similarly, I_3 and I_6 form another pair with core $\{C \ c \ C \ C \ d\}$. There is one more pair, I_8 and I_9 with common core $\{C \ c \ C\}$. Note that in general, a core is a set of LR 0, items for the grammar at hand, and that an LR 1 grammar may produce more than two sets of items with the same core.

Since the core of GOTO I X depends only on the core of I the goto s of merged sets can themselves be merged. Thus there is no problem revising the goto function as we merge sets of items. The action functions are modiled to reject the non-error actions of all sets of items in the merger.

Suppose we have an LR 1 grammar that is one whose sets of LR 1 items produce no parsing action con icts If we replace all states having the same core with their union it is possible that the resulting union will have a con ict but it is unlikely for the following reason Suppose in the union there is a con ict on lookahead a because there is an item Aa calling for a reduction by Aand there is another item Ba b calling for a shift Then some set of items from which the union was formed has item Aa and since the cores of all these states are the same it must have an item Bfor some c But then this state has the same shift reduce con ict on a and the grammar was not LR 1 as we assumed Thus the merging of states with common cores can never produce a shift reduce con ict that was not present in one of the original states because shift actions depend only on the core not the lookahead

It is possible however that a merger will produce a reduce reduce con ict as the following example shows

Example 4 58 Consider the grammar

which generates the four strings acd ace bcd and bce. The reader can check that the grammar is LR 1 by constructing the sets of items. Upon doing so

we nd the set of items $\{A \ c \ d \ B \ c \ e \}$ valid for viable pre x ac and $\{A \ c \ e \ B \ c \ d \}$ valid for bc Neither of these sets has a confict and their cores are the same. However, their union which is

$$\begin{array}{ccccc} A & c & d & e \\ B & c & d & e \end{array}$$

generates a reduce reduce con ict since reductions by both A-c and B-c are called for on inputs d and $e-\Box$

We are now prepared to give the rst of two LALR table construction al gorithms. The general idea is to construct the sets of LR 1 items and if no con icts arise merge sets with common cores. We then construct the parsing table from the collection of merged sets of items. The method we are about to describe serves primarily as a de nition of LALR 1 grammars. Constructing the entire collection of LR 1 sets of items requires too much space and time to be useful in practice.

Algorithm 4 59 An easy but space consuming LALR table construction

INPUT An augmented grammar G'

OUTPUT The LALR parsing table functions ACTION and GOTO for G'METHOD

- 1 Construct $C = \{I_0 \mid I_1 = I_n\}$ the collection of sets of LR 1 items
- 2 For each core present among the set of LR 1 items nd all sets having that core—and replace these sets by their union
- 3 Let $C' = \{J_0 \ J_1 \ J_m\}$ be the resulting sets of LR 1 items. The parsing actions for state i are constructed from J_i in the same manner as in Algorithm 4.56. If there is a parsing action confict the algorithm fails to produce a parser, and the grammar is said not to be LALR 1.
- 4 The GOTO table is constructed as follows If J is the union of one or more sets of LR 1 items that is J I_1 I_2 I_k then the cores of GOTO I_1 X GOTO I_2 X GOTO I_k X are the same since I_1 I_2 I_k all have the same core Let K be the union of all sets of items having the same core as GOTO I_1 X Then GOTO J X

The table produced by Algorithm 4 59 is called the LALR parsing table for G If there are no parsing action con icts then the given grammar is said to be an LALR 1 grammar The collection of sets of items constructed in step 3 is called the LALR 1 collection

47 MORE POWERFUL LR PARSERS

Example 4 60 Again consider grammar 4 55 whose GOTO graph was shown in Fig 4 41 As we mentioned there are three pairs of sets of items that can be merged I_3 and I_6 are replaced by their union

 I_4 and I_7 are replaced by their union

$$I_{47}$$
 C d c d

and I_8 and I_9 are replaced by their union

$$I_{89}$$
 C cC c d

The LALR action and goto functions for the condensed sets of items are shown in Fig. $4\,43$

Figure 4 43 LALR parsing table for the grammar of Example 4 54

To see how the GOTO s are computed consider GOTO I_{36} C In the original set of LR 1 items GOTO I_3 C I_8 and I_8 is now part of I_{89} so we make GOTO I_{36} C be I_{89} We could have arrived at the same conclusion if we considered I_6 the other part of I_{36} That is GOTO I_6 C I_9 and I_9 is now part of I_{89} For another example consider GOTO I_2 c an entry that is exercised after the shift action of I_2 on input c In the original sets of LR 1 items GOTO I_2 c I_6 Since I_6 is now part of I_{36} GOTO I_2 c becomes I_{36} Thus the entry in Fig 4 43 for state 2 and input c is made s36 meaning shift and push state 36 onto the stack \Box

When presented with a string from the language \mathbf{c} \mathbf{dc} \mathbf{d} both the LR parser of Fig. 4-42 and the LALR parser of Fig. 4-43 make exactly the same sequence of shifts and reductions although the names of the states on the stack may di er. For instance, if the LR parser puts I_3 or I_6 on the stack, the LALR

parser will put I_{36} on the stack. This relationship holds in general for an LALR grammar. The LR and LALR parsers will mimic one another on correct inputs

When presented with erroneous input the LALR parser may proceed to do some reductions after the LR parser has declared an error However the LALR parser will never shift another symbol after the LR parser declares an error For example on input ccd followed by the LR parser of Fig 4 42 will put

0 3 3 4

on the stack and in state 4 will discover an error because is the next input symbol and state 4 has action error on — In contrast the LALR parser of Fig 4 43 will make the corresponding moves putting

0 36 36 47

on the stack But state 47 on input has action reduce C d The LALR parser will thus change its stack to

0 36 36 89

Now the action of state 89 on input c is reduce c c c The stack becomes

0 36 89

whereupon a similar reduction is called for obtaining stack

0 2

Finally state 2 has action error on input—so the error is now discovered

4 7 5 E cient Construction of LALR Parsing Tables

There are several modi cations we can make to Algorithm 4 59 to avoid con structing the full collection of sets of LR 1 items in the process of creating an LALR 1 parsing table

First we can represent any set of LR 0 or LR 1 items I by its kernel that is by those items that are either the initial item S' S or S' S or that have the dot somewhere other than at the beginning of the production body

We can construct the LALR 1 item kernels from the LR 0 item kernels by a process of propagation and spontaneous generation of lookaheads that we shall describe shortly

If we have the LALR 1 kernels we can generate the LALR 1 parsing table by closing each kernel using the function CLOSURE of Fig 4 40 and then computing table entries by Algorithm 4 56 as if the LALR 1 sets of items were canonical LR 1 sets of items

47 MORE POWERFUL LR PARSERS

Example 4 61 We shall use as an example of the e cient LALR 1 table construction method the non SLR grammar from Example 4 48 which we re produce below in its augmented form

The complete sets of LR 0 $\,$ items for this grammar were shown in Fig. 4.39 The kernels of these items are shown in Fig. 4.44 $\,$ \Box

I_0	S'	S	I_5	L	id	
I_1	S'	S	I_6	S	L	R
I_2		$egin{array}{ccc} L & R \ L \end{array}$	I_7	L	R	
I_3	S	R	I_8	R	L	
I_4	L	R	I_9	S	L	R

Figure 4 44 Kernels of the sets of LR 0 items for grammar 4 49

Now we must attach the proper lookaheads to the LR $\,0\,$ items in the kernels to create the kernels of the sets of LALR $\,1\,$ items. There are two ways a lookahead $\,b\,$ can get attached to an LR $\,0\,$ item $\,B\,$ in some set of LALR $\,1\,$ items $\,J\,$

1 There is a set of items I with a kernel item A and J GOTO I X and the construction of

GOTO CLOSURE
$$\{A \quad a \} X$$

as given in Fig. 4.40 contains B b regardless of a Such a looka head b is said to be generated spontaneously for B As a special case lookahead is generated spontaneously for the item S' S in the initial set of items

2 All is as in 1 but a b and GOTO CLOSURE { A b } X as given in Fig 4 40 contains B b only because A has b as one of its associated lookaheads. In such a case, we say that lookaheads propagate from A in the kernel of I to B in the kernel of I Note that propagation does not depend on the particular lookahead symbol either all lookaheads propagate from one item to another or none do

We need to determine the spontaneously generated lookaheads for each set of LR 0 items and also to determine which items propagate lookaheads from which The test is actually quite simple Let be a symbol not in the grammar at hand Let Abe a kernel LR 0 item in set I Compute for each XJGOTO CLOSURE $\{A\}$ } X For each kernel item in J we examine its set of lookaheads If is a lookahead then lookaheads propagate to that item from AAny other lookahead is spontaneously generated These ideas are made precise in the following algorithm which also makes use of the fact that the only kernel items in J must have X immediately to the left of the dot that is they must be of the form B

Algorithm 4 62 Determining lookaheads

INPUT The kernel K of a set of LR 0 items I and a grammar symbol X

OUTPUT The lookaheads spontaneously generated by items in I for kernel items in GOTO I X and the items in I from which lookaheads are propagated to kernel items in GOTO I X

METHOD The algorithm is given in Fig 4.45

```
for each item A
                       in K = \{
      J
           CLOSURE \{A\}
      if
                 X a is in J and a is not
            conclude that lookahead a is generated spontaneously for item
               B
                     X in GOTO I X
      if
                 X
                        is in J
            conclude that lookaheads propagate from A
                                                            in I to
               B
                     X in GOTO IX
}
```

Figure 4 45 Discovering propagated and spontaneous lookaheads

We are now ready to attach lookaheads to the kernels of the sets of LR 0 items to form the sets of LALR 1 items. First, we know that is a lookahead for S'-S in the initial set of LR 0 items. Algorithm 4.62 gives us all the lookaheads generated spontaneously. After listing all those lookaheads we must allow them to propagate until no further propagation is possible. There are many different approaches all of which in some sense keep track of new lookaheads that have propagated into an item but which have not yet propagated out. The next algorithm describes one technique to propagate lookaheads to all items.

Algorithm 4 63 E cient computation of the kernels of the LALR 1 collection of sets of items

INPUT An augmented grammar G'

47 MORE POWERFUL LR PARSERS

OUTPUT The kernels of the LALR 1 collection of sets of items for G'

METHOD

- 1 Construct the kernels of the sets of LR 0 items for G If space is not at a premium the simplest way is to construct the LR 0 sets of items as in Section 4.6.2 and then remove the nonkernel items. If space is severely constrained we may wish instead to store only the kernel items for each set and compute GOTO for a set of items I by rst computing the closure of I
- 2 Apply Algorithm 4 62 to the kernel of each set of LR 0 items and gram mar symbol X to determine which lookaheads are spontaneously gener ated for kernel items in GOTO I X and from which items in I lookaheads are propagated to kernel items in GOTO I X
- 3 Initialize a table that gives for each kernel item in each set of items the associated lookaheads Initially each item has associated with it only those lookaheads that we determined in step 2 were generated sponta neously
- 4 Make repeated passes over the kernel items in all sets. When we visit an item i we look up the kernel items to which i propagates its lookaheads using information tabulated in step 2. The current set of lookaheads for i is added to those already associated with each of the items to which i propagates its lookaheads. We continue making passes over the kernel items until no more new lookaheads are propagated.

Example 4 64 Let us construct the kernels of the LALR 1 items for the grammar of Example 4 61 The kernels of the LR 0 items were shown in Fig 4 44 When we apply Algorithm 4 62 to the kernel of set of items I_0 we rst compute CLOSURE $\{S' \mid S\}$ which is

Among the items in the closure we see two where the lookahead has been generated spontaneously. The rst of these is L=R. This item with to the right of the dot gives rise to L=R. That is is a spontaneously generated lookahead for L=R which is in set of items I_4 . Similarly, L id tells us that is a spontaneously generated lookahead for L id in I_5

As is a lookahead for all six items in the closure we determine that the item S' S in I_0 propagates lookaheads to the following six items

S'	S in I_1	L	$R \text{ in } I_4$
S	$L = R \text{ in } I_2$	L	$\mathbf{id} \ \text{in} \ I_5$
S	R in I_3	R	L in I_2

	FRO	ЭМ			То		
$\overline{I_0}$	S'	S		I_1	S'	S	
				I_2	S	L	R
				I_2	R	L	
				I_3	S	R	
				I_4	L	R	
				I_5	L	id	
I_2	S	L	R	I_6	S	L	R
$\overline{I_4}$	L	R		I_4	L	R	
				I_5	L	id	
				I_7	L	R	
				I_8	R	L	
I_6	S	L	R	I_4	L	R	
				I_5	L	id	
				I_8	R	L	
				I_9	S	L	R

Figure 4 46 Propagation of lookaheads

In Fig. 4.47 we show steps. 3 and 4 of Algorithm 4.63. The column labeled INIT shows the spontaneously generated lookaheads for each kernel item. These are only the two occurrences of discussed earlier and the spontaneous lookahead for the initial item S'-S

On the rst pass the lookahead propagates from S' S in I_0 to the six items listed in Fig 4 46. The lookahead propagates from L R in I_4 to items L R in I_7 and R L in I_8 . It also propagates to itself and to L id in I_5 but these lookaheads are already present. In the second and third passes the only new lookahead propagated is discovered for the successors of I_2 and I_4 on pass 2 and for the successor of I_6 on pass 3. No new lookaheads are propagated on pass 4 so the nal set of lookaheads is shown in the rightmost column of Fig. 4.47

Note that the shift reduce con ict found in Example 4 48 using the SLR method has disappeared with the LALR technique. The reason is that only lookahead—is associated with R—L in I_2 so there is no con ict with the parsing action of shift on—generated by item S—L—R in I_2 — \square

4 7 6 Compaction of LR Parsing Tables

A typical programming language grammar with 50 to 100 terminals and 100 productions may have an LALR parsing table with several hundred states. The action function may easily have 20 000 entries each requiring at least 8 bits to encode. On small devices a more excient encoding than a two dimensional array may be important. We shall mention brie y a few techniques that have been used to compress the ACTION and GOTO elds of an LR parsing table.

One useful technique for compacting the action—eld is to recognize that usually many rows of the action table are identical—For example—in Fig. 4-42 states 0 and 3 have identical action entries—and so do 2 and 6. We can therefore save considerable space—at little cost in time—if we create a pointer for each state—into a one dimensional array—Pointers for states with the same actions point to the same location—To access information from this array—we assign each terminal a number from zero to one less than the number of terminals and we use this integer as an o-set from the pointer value for each state—In a given state—the parsing action for the ith terminal will be found i locations past the pointer value for that state

Further space e ciency can be achieved at the expense of a somewhat slower parser by creating a list for the actions of each state. The list consists of terminal symbol action pairs. The most frequent action for a state can be

CHAPTER 4 SYNTAX ANALYSIS

placed at the end of the list and in place of a terminal we may use the notation **any** meaning that if the current input symbol has not been found so far on the list we should do that action no matter what the input is Moreover error entries can safely be replaced by reduce actions for further uniformity along a row The errors will be detected later before a shift move

Example 4 65 Consider the parsing table of Fig. 4 37. First note that the actions for states 0 4 6 and 7 agree. We can represent them all by the list

Symbol	ACTION
id	s5
	s4
anv	error

State 1 has a similar list

In state 2 we can replace the error entries by r2 so reduction by production 2 will occur on any input but Thus the list for state 2 is

$$\begin{array}{cc} & s7 \\ \mathbf{any} & r2 \end{array}$$

State 3 has only error and r4 entries We can replace the former by the latter so the list for state 3 consists of only the pair **any** r4 States 5 10 and 11 can be treated similarly. The list for state 8 is

and for state 9

We can also encode the GOTO table by a list but here it appears more e cient to make a list of pairs for each nonterminal A Each pair on the list for A is of the form currentState nextState indicating

GOTO
$$currentState$$
 A $nextState$

47 MORE POWERFUL LR PARSERS

This technique is useful because there tend to be rather few states in any one column of the GOTO table. The reason is that the GOTO on nonterminal A can only be a state derivable from a set of items in which some items have A immediately to the left of a dot. No set has items with X and Y immediately to the left of a dot if $X \ / \ Y$. Thus, each state appears in at most one GOTO column.

For more space reduction we note that the error entries in the goto table are never consulted We can therefore replace each error entry by the most common non error entry in its column This entry becomes the default it is represented in the list for each column by one pair with **any** in place of *currentState*

Example 4 66 Consider Fig 4 37 again The column for F has entry 10 for state 7 and all other entries are either 3 or error. We may replace error by 3 and create for column F the list

Currentstate	Nextstate
7	10
any	3

Similarly a suitable list for column T is

For column E we may choose either 1 or 8 to be the default two entries are necessary in either case. For example, we might create for column E the list

This space savings in these small examples may be misleading because the total number of entries in the lists created in this example and the previous one together with the pointers from states to action lists and from nonterminals to next state lists result in unimpressive space savings over the matrix imple mentation of Fig 4 37 For practical grammars the space needed for the list representation is typically less than ten percent of that needed for the matrix representation. The table compression methods for nite automata that were discussed in Section 3 9 8 can also be used to represent LR parsing tables

Exercise 4 7 5 Show that the following grammar

is LR 1 but not LALR 1

48 Using Ambiguous Grammars

It is a fact that every ambiguous grammar fails to be LR and thus is not in any of the classes of grammars discussed in the previous two sections. How ever certain types of ambiguous grammars are quite useful in the specification and implementation of languages. For language constructs like expressions an ambiguous grammar provides a shorter more natural specification than any equivalent unambiguous grammar. Another use of ambiguous grammars is in isolating commonly occurring syntactic constructs for special case optimization. With an ambiguous grammar we can specify the special case constructs by carefully adding new productions to the grammar.

Although the grammars we use are ambiguous in all cases we specify dis ambiguating rules that allow only one parse tree for each sentence. In this way the overall language specification becomes unambiguous and sometimes it be comes possible to design an LR parser that follows the same ambiguity resolving choices. We stress that ambiguous constructs should be used sparingly and in a strictly controlled fashion otherwise, there can be no guarantee as to what language is recognized by a parser

481 Precedence and Associativity to Resolve Con icts

Consider the ambiguous grammar 4 3 for expressions with operators and repeated here for convenience

$$E \quad E \quad E \mid E \quad E \mid E \mid \mathbf{id}$$

This grammar is ambiguous because it does not specify the associativity or precedence of the operators $\quad \text{and} \quad$ The unambiguous grammar 41 which includes productions EET and TT F generates the same language lower precedence than and makes both operators left associative but gives There are two reasons why we might prefer to use the ambiguous grammar First as we shall see we can easily change the associativity and precedence of the operators and without disturbing the productions of 43 or the number of states in the resulting parser Second the parser for the unam biguous grammar will spend a substantial fraction of its time reducing by the F whose sole function is to enforce associativity productions ET and Tand precedence The parser for the ambiguous grammar 43 will not waste time reducing by these single productions productions whose body consists of a single nonterminal

The sets of LR 0 items for the ambiguous expression grammar 43 aug mented by E'E are shown in Fig. 4.48 Since grammar 4.3 is ambiguous there will be parsing action con icts when we try to produce an LR parsing table from the sets of items. The states corresponding to sets of items I_7 and I_8 generate these con icts. Suppose we use the SLR approach to constructing the parsing action table The con ict generated by I_7 between reduction by E and shift on or cannot be resolved because in FOLLOW EThus both actions would be called for on inputs similar con ict is generated by I_8 between reduction by EE and shift on inputs $\quad \text{and} \quad$ In fact each of our LR parsing table construction methods will generate these con icts

However these problems can be resolved using the precedence and associa tivity information for and Consider the input **id id id** which causes a parser based on Fig 4 48 to enter state 7 after processing **id id** in particular the parser reaches a conguration

PREFIX STACK INPUT
$$E$$
 E 0 1 4 7 \mathbf{id}

For convenience the symbols corresponding to the states $1\ 4$ and 7 are also shown under Prefix

If takes precedence over we know the parser should shift onto the stack preparing to reduce the and its surrounding **id** symbols to an expression. This choice was made by the SLR parser of Fig. 4.37 based on an unambiguous grammar for the same language. On the other hand, if takes precedence over we know the parser should reduce E = E to E. Thus the relative precedence

CHAPTER 4 SYNTAX ANALYSIS

I_0	E' E E E E	$egin{array}{ccc} E & & & & & & & & & & & & & & & & & & $	I_5	E E E E	$egin{array}{ccc} E & E \ E & E \ E \ E \ \end{array} \ \ \mathbf{id} \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ \$
I_1	$E' \\ E \\ E$	$egin{array}{ccc} E & & & & & & & & & & & & & & & & & & $	I_6	$E \\ E \\ E$	$egin{array}{ccc} E & & & & & & & & & & & & & & & & & & $
I_2	$E \ E \ E$	$egin{array}{ccc} E & & & & & & & & & & & & & & & & & & $	I_7	$E \\ E \\ E$	$egin{array}{ccc} E & E \ E & E \ E & E \end{array}$
I_3	E	id id	I_8	$E \ E \ E$	$egin{array}{ccc} E & E \ E & E \ E & E \end{array}$
I_4	$E \\ E \\ E \\ E \\ E$	$egin{array}{ccc} E & E \ E & E \ E \end{array} \ egin{array}{ccc} E & E \ \end{array} \ egin{array}{cccc} E & E \ \end{array} \ egin{array}{ccccc} E & E \ \end{array} \ egin{array}{ccccc} E & E \ \end{array} \ egin{array}{cccccc} E & E \ \end{array} \ egin{array}{cccccc} E & E \ \end{array} \ egin{array}{cccccc} E & E \ \end{array} \ egin{array}{ccccccccc} E & E \ \end{array} \ egin{array}{cccccccccc} E & E \ \end{array} \ egin{array}{cccccccccccccccc} E & E \ \end{array} \ egin{array}{cccccccccccccc} E & E \ \end{array} \ egin{array}{ccccccccccccc} E & E \ \end{array} \ egin{array}{ccccccccccccccc} E & E \ \end{array} \ egin{array}{cccccccccccccccccccccccccccccccccccc$	I_9	E	E

Figure 4 48 Sets of LR 0 items for an augmented expression grammar

of followed by uniquely determines how the parsing action con ict between reducing E E and shifting on in state 7 should be resolved

If the input had been id id instead the parser would still reach a con guration in which it had stack 0 1 4 7 after processing input id id On input—there is again a shift reduce con ict in state 7. Now however—the associativity of the—operator determines how this con ict should be resolved. If—is left associative—the correct action is to reduce by E—E—E—That is the id symbols surrounding the—rst—must be grouped—rst—Again this choice coincides with what the SLR parser for the unambiguous grammar would do

In summary assuming is left associative the action of state 7 on input should be to reduce by E E E and assuming that takes precedence over the action of state 7 on input should be to shift Similarly assuming that is left associative and takes precedence over we can argue that state 8 which can appear on top of the stack only when E E are the top three grammar symbols should have the action reduce E E on both and inputs In the case of input the reason is that takes precedence over while in the case of input the rationale is that is left associative

4.8 USING AMBIGUOUS GRAMMARS

Proceeding in this way we obtain the LR parsing table shown in Fig. 4.49 Productions 1 through 4 are E E E E E E E E and E id respectively. It is interesting that a similar parsing action table would be produced by eliminating the reductions by the single productions E T and T F from the SLR table for the unambiguous expression grammar 4.1 shown in Fig. 4.37. Ambiguous grammars like the one for expressions can be handled in a similar way in the context of LALR and canonical LR parsing

9		r3	r3		r3	r3	

Figure 4 49 Parsing table for grammar 4 3

482 The Dangling Else Ambiguity

Consider again the following grammar for conditional statements

$$stmt$$
 if $expr$ then $stmt$ else $stmt$ | if $expr$ then $stmt$ | other

As we noted in Section 4.3.2 this grammar is ambiguous because it does not resolve the dangling else ambiguity. To simplify the discussion let us consider an abstraction of this grammar where i stands for **if** expr **then** e stands for **else** and a stands for all other productions. We can then write the grammar with augmenting production S' S as

The sets of LR 0 items for grammar 4 67 are shown in Fig 4 50. The ambiguity in 4 67 gives rise to a shift reduce confict in I_4 . There S is S calls for a shift of S and since FOLLOW S and S item S is calls for reduction by S is on input S in S on input S in S or input S in S in S or input S in S in S or input S in S in

Translating back to the if then else terminology given

	S	a			

Figure 4 50 LR 0 states for augmented grammar 4 67

if expr then stmt

on the stack and **else** as the rst input symbol should we shift **else** onto the stack i e shift e or reduce **if** expr **then** stmt i e reduce by S is. The answer is that we should shift **else** because it is associated with the previous **then** In the terminology of grammar 4 67 the e on the input standing for **else** can only form part of the body beginning with the iS now on the top of the stack. If what follows e on the input cannot be parsed as an S completing body iSeS then it can be shown that there is no other parse possible

We conclude that the shift reduce con ict in I_4 should be resolved in favor of shift on input e. The SLR parsing table constructed from the sets of items of Fig. 4.50 using this resolution of the parsing action con ict in I_4 on input e is shown in Fig. 4.51. Productions 1 through 3 are S is S is and S a respectively

4.8 USING AMBIGUOUS GRAMMARS

For example on input iiaea the parser makes the moves shown in Fig. 4.52 corresponding to the correct resolution of the dangling else. At line 5 state 4 selects the shift action on input e whereas at line 9 state 4 calls for reduction by S iS on input

	Stack	Symbols	Input	ACTION	
1	0		iiaea	shift	
2	0 2	i	i a e a	$_{ m shift}$	
3	$0\ 2\ 2$	i i	a e a	$_{ m shift}$	
4	$0\ 2\ 2\ 3$	i i a	e a	$_{ m shift}$

9	$0\ 2\ 4$	i S		reduce by S	iS
10	0 1	S		accept	

Figure 4 52 Parsing actions on input *iiaea*

By way of comparison if we are unable to use an ambiguous grammar to specify conditional statements then we would have to use a bulkier grammar along the lines of Example 4 16

4 8 3 Error Recovery in LR Parsing

An LR parser will detect an error when it consults the parsing action table and nds an error entry. Errors are never detected by consulting the goto table. An LR parser will announce an error as soon as there is no valid continuation for the portion of the input thus far scanned. A canonical LR parser will not make even a single reduction before announcing an error. SLR and LALR parsers may make several reductions before announcing an error but they will never shift an erroneous input symbol onto the stack.

In LR parsing we can implement panic mode error recovery as follows. We scan down the stack until a state s with a goto on a particular nonterminal A is found. Zero or more input symbols are then discarded until a symbol a is found that can legitimately follow A. The parser then stacks the state GOTO s A and resumes normal parsing. There might be more than one choice for the nonterminal A. Normally these would be nonterminals representing major program pieces such as an expression statement or block. For example, if A is the nonterminal stmt a might be semicolon or a which marks the end of a statement sequence.

This method of recovery attempts to eliminate the phrase containing the syntactic error. The parser determines that a string derivable from A contains an error. Part of that string has already been processed, and the result of this

processing is a sequence of states on top of the stack. The remainder of the string is still in the input and the parser attempts to skip over the remainder of this string by looking for a symbol on the input that can legitimately follow A. By removing states from the stack skipping over the input and pushing GOTO s A on the stack the parser pretends that it has found an instance of A and resumes normal parsing

Phrase level recovery is implemented by examining each error entry in the LR parsing table and deciding on the basis of language usage the most likely programmer error that would give rise to that error. An appropriate recovery procedure can then be constructed presumably the top of the stack and or rst input symbols would be modiled in a way deemed appropriate for each error entry.

In designing speci c error handling routines for an LR parser we can ll in each blank entry in the action eld with a pointer to an error routine that will take the appropriate action selected by the compiler designer. The actions may include insertion or deletion of symbols from the stack or the input or both or alteration and transposition of input symbols. We must make our choices so that the LR parser will not get into an in nite loop. A safe strategy will assure that at least one input symbol will be removed or shifted eventually or that the stack will eventually shrink if the end of the input has been reached. Popping a stack state that covers a nonterminal should be avoided because this modi cation eliminates from the stack a construct that has already been successfully parsed.

Example 4 68 Consider again the expression grammar

$$E \quad E \quad E \mid E \quad E \mid E \mid \mathbf{id}$$

Figure 4 53 shows the LR parsing table from Fig 4 49 for this grammar modi ed for error detection and recovery. We have changed each state that calls for a particular reduction on some input symbols by replacing error entries in that state by the reduction. This change has the elect of postponing the error detection until one or more reductions are made but the error will still be caught before any shift move takes place. The remaining blank entries from Fig. 4 49 have been replaced by calls to error routines.

The error routines are as follows

e1 This routine is called from states 0 2 4 and 5 all of which expect the beginning of an operand either an id or a left parenthesis Instead or the end of the input was found

push state 3 the goto of states 0 2 4 and 5 on id issue diagnostic missing operand

e2 Called from states 0 1 2 4 and 5 on nding a right parenthesis

remove the right parenthesis from the input issue diagnostic unbalanced right parenthesis

4 9 Parser Generators

This section shows how a parser generator can be used to facilitate the construction of the front end of a compiler. We shall use the LALR parser generator Yacc as the basis of our discussion since it implements many of the concepts discussed in the previous two sections and it is widely available. Yacc stands for yet another compiler compiler, rejecting the popularity of parser generators in the early 1970s when the jet version of Yacc was created by S. C. Johnson Yacc is available as a command on the UNIX system, and has been used to help implement many production compilers.

491 The Parser Generator Yacc

A translator can be constructed using Yacc in the manner illustrated in Fig 457 First a le say translate y containing a Yacc speci cation of the translator is prepared. The UNIX system command

```
yacc translate y
```

transforms the le translate y into a C program called y tab c using the LALR method outlined in Algorithm 463. The program y tab c is a representation of an LALR parser written in C along with other C routines that the user may have prepared. The LALR parsing table is compacted as described in Section 47. By compiling y tab c along with the ly library that contains the LR parsing program using the command.

we obtain the desired object program a out that performs the translation spec i ed by the original Yacc program ⁷ If other procedures are needed they can be compiled or loaded with y tab c just as with any C program

A Yacc source program has three parts

⁷The name ly is system dependent

CHAPTER 4 SYNTAX ANALYSIS

declarations

translation rules

supporting C routines

Example 4 69 To illustrate how to prepare a Yacc source program let us construct a simple desk calculator that reads an arithmetic expression evaluates it and then prints its numeric value We shall build the desk calculator starting with the with the following grammar for arithmetic expressions

The token **digit** is a single digit between 0 and 9 A Yacc desk calculator program derived from this grammar is shown in Fig. 4 58 \Box

The Declarations Part

There are two sections in the declarations part of a Yacc program both are optional In the rst section we put ordinary C declarations delimited by and Here we place declarations of any temporaries used by the translation rules or procedures of the second and third sections In Fig 458 this section contains only the include statement

that causes the C preprocessor to include the standard header le ctype h that contains the predicate isdigit

Also in the declarations part are declarations of grammar tokens. In Fig $4\,58$ the statement

token DIGIT

49 PARSER GENERATORS

```
include ctype h
 token DIGIT

        getchar
    if isdigit c
        yylval
                 c 0
        return DIGIT
    return c
```

Figure 4 58 Yacc speci cation of a simple desk calculator

declares DIGIT to be a token. Tokens declared in this section can then be used in the second and third parts of the Yacc speci cation. If Lex is used to create the lexical analyzer that passes token to the Yacc parser, then these token declarations are also made available to the analyzer generated by Lex as discussed in Section 3.5.2

The Translation Rules Part

In the part of the Yacc specication after the rst pair we put the translation rules Each rule consists of a grammar production and the associated semantic action. A set of productions that we have been writing

```
\langle \text{head} \rangle \langle \text{body} \rangle_1 \mid \langle \text{body} \rangle_2 \mid \langle \text{body} \rangle_n
```

would be written in Yacc as

CHAPTER 4 SYNTAX ANALYSIS

$$\begin{array}{ccc} \langle \operatorname{head} \rangle & \langle \operatorname{body} \rangle_1 & \langle \operatorname{semantic action} \rangle_1 \\ \langle \operatorname{body} \rangle_2 & \langle \operatorname{semantic action} \rangle_2 \\ \\ \langle \operatorname{body} \rangle_n & \langle \operatorname{semantic action} \rangle_n \end{array}$$

In a Yacc production unquoted strings of letters and digits not declared to be tokens are taken to be nonterminals. A quoted single character e.g. c is taken to be the terminal symbol c as well as the integer code for the token represented by that character i.e. Lex would return the character code for c to the parser as an integer. Alternative bodies can be separated by a vertical bar and a semicolon follows each head with its alternatives and their semantic actions. The rst head is taken to be the start symbol.

A Yacc semantic action is a sequence of C statements. In a semantic action the symbol—refers to the attribute value associated with the nonterminal of the head—while—i refers to the value associated with the ith grammar symbol terminal or nonterminal—of the body. The semantic action is performed when ever we reduce by the associated production—so normally the semantic action computes a value for—in terms of the—is—In the Yacc speci—cation—we have written the two E—productions

$$E \quad E \quad T \mid T$$

and their associated semantic actions as

Note that the nonterminal term in the set production is the third grammar symbol of the body while is the second. The semantic action associated with the set production adds the value of the expr and the term of the body and assigns the result as the value for the nonterminal expr of the head. We have omitted the semantic action for the second production altogether since copying the value is the default action for productions with a single grammar symbol in the body. In general 1 is the default semantic action

Notice that we have added a new starting production

to the Yacc speci cation This production says that an input to the desk calculator is to be an expression followed by a newline character The semantic action associated with this production prints the decimal value of the expression followed by a newline character

49 PARSER GENERATORS

The Supporting C Routines Part

The third part of a Yacc speci cation consists of supporting C routines A lexical analyzer by the name yylex must be provided Using Lex to produce yylex is a common choice see Section 493 Other procedures such as error recovery routines may be added as necessary

The lexical analyzer yylex produces tokens consisting of a token name and its associated attribute value. If a token name such as DIGIT is returned the token name must be declared in the rst section of the Yacc speci cation. The attribute value associated with a token is communicated to the parser through a Yacc de ned variable yylval

The lexical analyzer in Fig 458 is very crude. It reads input characters one at a time using the C function getchar. If the character is a digit, the value of the digit is stored in the variable yylval, and the token name DIGIT is returned. Otherwise, the character itself is returned as the token name.

4 9 2 Using Yacc with Ambiguous Grammars

Let us now modify the Yacc speci cation so that the resulting desk calculator becomes more useful. First, we shall allow the desk calculator to evaluate a sequence of expressions one to a line. We shall also allow blank lines between expressions. We do so by changing the rst rule to

In Yacc an empty alternative as the third line is denotes

Second we shall enlarge the class of expressions to include numbers with a decimal point instead of single digits and to include the arithmetic operators both binary and unary and The easiest way to specify this class of expressions is to use the ambiguous grammar

The resulting Yacc speci cation is shown in Fig 4 59

Since the grammar in the Yacc speci cation in Fig 459 is ambiguous the LALR algorithm will generate parsing action con icts Yacc reports the num ber of parsing action con icts that are generated. A description of the sets of items and the parsing action con icts can be obtained by invoking Yacc with a voption. This option generates an additional le youtput that contains the kernels of the sets of items found for the grammar a description of the parsing action con icts generated by the LALR algorithm and a readable representation of the LR parsing table showing how the parsing action con icts were resolved. Whenever Yacc reports that it has found parsing action con icts it

Figure $4\,59\,$ Yacc speci cation for a more advanced desk calculator

49 PARSER GENERATORS

is wise to create and consult the le y output to see why the parsing action con icts were generated and to see whether they were resolved correctly

Unless otherwise instructed Yacc will resolve all parsing action con icts using the following two rules

- 1 A reduce reduce con ict is resolved by choosing the con icting production listed rst in the Yacc speci cation
- 2 A shift reduce con ict is resolved in favor of shift. This rule resolves the shift reduce con ict arising from the dangling else ambiguity correctly

Since these default rules may not always be what the compiler writer wants Yacc provides a general mechanism for resolving shift reduce con icts. In the declarations portion, we can assign precedences and associativities to terminals. The declaration

left

makes and be of the same precedence and be left associative. We can declare an operator to be right associative by writing

right

and we can force an operator to be a nonassociative binary operator ie two occurrences of the operator cannot be combined at all by writing

nonassoc

The tokens are given precedences in the order in which they appear in the declarations part lowest rst Tokens in the same declaration have the same precedence. Thus the declaration

right UMINUS

in Fig 4.59 gives the token UMINUS a precedence level higher than that of the ve preceding terminals

Yacc resolves shift reduce con icts by attaching a precedence and associa tivity to each production involved in a con ict as well as to each terminal involved in a con ict. If it must choose between shifting input symbol a and reducing by production A. Yacc reduces if the precedence of the production is greater than that of a or if the precedences are the same and the associativity of the production is left. Otherwise shift is the chosen action

Normally the precedence of a production is taken to be the same as that of its rightmost terminal This is the sensible decision in most cases For example given productions

E E E E

CHAPTER 4 SYNTAX ANALYSIS

we would prefer to reduce by E E E with lookahead because the in the body has the same precedence as the lookahead but is left associative With lookahead we would prefer to shift because the lookahead has higher precedence than the in the production

In those situations where the rightmost terminal does not supply the proper precedence to a production we can force a precedence by appending to a production the tag

prec (terminal)

The precedence and associativity of the production will then be the same as that of the terminal which presumably is de ned in the declaration section Yacc does not report shift reduce con icts that are resolved using this precedence and associativity mechanism

This terminal can be a placeholder like UMINUS in Fig 459 this terminal is not returned by the lexical analyzer but is declared solely to de ne a precedence for a production. In Fig 459 the declaration

right UMINUS

assigns to the token UMINUS a precedence that is higher than that of — and In the translation rules part—the tag

prec UMINUS

at the end of the production

expr expr

makes the unary minus operator in this production have a higher precedence than any other operator

493 Creating Yacc Lexical Analyzers with Lex

Lex was designed to produce lexical analyzers that could be used with Yacc The Lex library 11 will provide a driver program named yylex—the name required by Yacc for its lexical analyzer—If Lex is used to produce the lexical analyzer—we replace the routine yylex—in the third part of the Yacc speci cation by the statement

include lex yy c

and we have each Lex action return a terminal known to Yacc By using the include lex yy c statement the program yylex has access to Yaccs names for tokens since the Lex output le is compiled as part of the Yacc output le y tab c

Under the UNIX system if the Lex speci cation is in the lefirst 1 and the Yacc speci cation in second y we can say

49 PARSER GENERATORS

lex first 1
yacc second y
cc y tab c ly ll

to obtain the desired translator

The Lex speci cation in Fig 4 60 can be used in place of the lexical analyzer in Fig 4 59. The last pattern meaning any character must be written n since the dot in Lex matches any character except newline

number 0 9 0 9 0 9

skip blanks
number sscanf yytext lf yylval
return NUMBER
n return yytext 0

Figure 4 60 Lex speci cation for yylex in Fig 4 59

494 Error Recovery in Yacc

In Yacc error recovery uses a form of error productions. First the user decides what major nonterminals will have error recovery associated with them Typical choices are some subset of the nonterminals generating expressions statements blocks and functions. The user then adds to the grammar error productions of the form A error where A is a major nonterminal and is a string of grammar symbols perhaps the empty string error is a Yacc reserved word. Yacc will generate a parser from such a specification treating the error productions as ordinary productions.

However when the parser generated by Yacc encounters an error it treats the states whose sets of items contain error productions in a special way. On encountering an error Yacc pops symbols from its stack until it inds the top most state on its stack whose underlying set of items includes an item of the form A error. The parser then shifts a ctitious token error onto the stack as though it saw the token error on its input

When is a reduction to A occurs immediately and the semantic action associated with the production A error which might be a user speci ed error recovery routine is invoked. The parser then discards input symbols until it and an input symbol on which normal parsing can proceed

If is not empty Yacc skips ahead on the input looking for a substring that can be reduced to If consists entirely of terminals then it looks for this string of terminals on the input and reduces them by shifting them onto the stack At this point the parser will have \mathbf{error} on top of its stack. The parser will then reduce \mathbf{error} to A and resume normal parsing

For example an error production of the form

Figure 4 61 Desk calculator with error recovery

stmt error

would specify to the parser that it should skip just beyond the next semicolon on seeing an error and assume that a statement had been found. The semantic routine for this error production would not need to manipulate the input but could generate a diagnostic message and set a ag to inhibit generation of object code for example

Example 4 70 Figure 4 61 shows the Yacc desk calculator of Fig. 4 59 with the error production

lines error n

This error production causes the desk calculator to suspend normal parsing when a syntax error is found on an input line On encountering the error

4 10 SUMMARY OF CHAPTER 4

the parser in the desk calculator starts popping symbols from its stack until it encounters a state that has a shift action on the token **error** State 0 is such a state in this example it s the only such state since its items include

lines error n

Also state 0 is always on the bottom of the stack. The parser shifts the token **error** onto the stack and then proceeds to skip ahead in the input until it has found a newline character. At this point the parser shifts the newline onto the stack reduces **error** n to lines and emits the diagnostic message reenter previous line. The special Yacc routine yyerrok resets the parser to its normal mode of operation. \square

495 Exercises for Section 49

Exercise 4 9 1 Write a Yacc program that takes boolean expressions as input as given by the grammar of Exercise 4 2 2 g and produces the truth value of the expressions

Exercise 4 9 2 Write a Yacc program that takes lists as de ned by the grammar of Exercise 4 2 2 e but with any single character as an element not just a and produces as output a linear representation of the same list i e a single list of the elements in the same order that they appear in the input

Exercise 4 9 3 Write a Yacc program that tells whether its input is a *palin* drome sequence of characters that read the same forward and backward

Exercise 4 9 4 Write a Yacc program that takes regular expressions as de ned by the grammar of Exercise 4 2 2 d but with any single character as an argument not just a and produces as output a transition table for a nonde terministic nite automaton recognizing the same language

4 10 Summary of Chapter 4

- ◆ Parsers A parser takes as input tokens from the lexical analyzer and treats the token names as terminal symbols of a context free grammar. The parser then constructs a parse tree for its input sequence of tokens the parse tree may be constructed guratively by going through the corresponding derivation steps or literally
- ◆ Context Free Grammars A grammar speci es a set of terminal symbols inputs another set of nonterminals symbols representing syntactic con structs and a set of productions each of which gives a way in which strings represented by one nonterminal can be constructed from terminal symbols and strings represented by certain other nonterminals A production consists of a head the nonterminal to be replaced and a body the replacing string of grammar symbols

CHAPTER 4 SYNTAX ANALYSIS

- ◆ Derivations The process of starting with the start nonterminal of a gram mar and successively replacing it by the body of one of its productions is called a derivation If the leftmost or rightmost nonterminal is always replaced then the derivation is called leftmost respectively rightmost
- ◆ Parse Trees A parse tree is a picture of a derivation in which there is a node for each nonterminal that appears in the derivation The children of a node are the symbols by which that nonterminal is replaced in the derivation There is a one to one correspondence between parse trees left most derivations and rightmost derivations of the same terminal string
- → Ambiguity A grammar for which some terminal string has two or more
 di erent parse trees or equivalently two or more leftmost derivations or
 two or more rightmost derivations is said to be ambiguous In most cases
 of practical interest it is possible to redesign an ambiguous grammar so
 it becomes an unambiguous grammar for the same language However
 ambiguous grammars with certain tricks applied sometimes lead to more
 e cient parsers
- ◆ Top Down and Bottom Up Parsing Parsers are generally distinguished by whether they work top down start with the grammar's start symbol and construct the parse tree from the top or bottom up start with the terminal symbols that form the leaves of the parse tree and build the tree from the bottom Top down parsers include recursive descent and LL parsers while the most common forms of bottom up parsers are LR parsers
- ♦ Design of Grammars Grammars suitable for top down parsing often are harder to design than those used by bottom up parsers. It is necessary to eliminate left recursion a situation where one nonterminal derives a string that begins with the same nonterminal. We also must left factor group productions for the same nonterminal that have a common pre-x in the body.
- ♦ Recursive Descent Parsers These parsers use a procedure for each non terminal The procedure looks at its input and decides which production to apply for its nonterminal Terminals in the body of the production are matched to the input at the appropriate time while nonterminals in the body result in calls to their procedure Backtracking in the case when the wrong production was chosen is a possibility
- → LL 1 Parsers A grammar such that it is possible to choose the correct production with which to expand a given nonterminal looking only at the next input symbol is called LL 1 These grammars allow us to construct a predictive parsing table that gives for each nonterminal and each lookahead symbol the correct choice of production Error correction can be facilitated by placing error routines in some or all of the table entries that have no legitimate production

4 10 SUMMARY OF CHAPTER 4

- ◆ Shift Reduce Parsing Bottom up parsers generally operate by choosing on the basis of the next input symbol lookahead symbol and the contents of the stack whether to shift the next input onto the stack or to reduce some symbols at the top of the stack A reduce step takes a production body at the top of the stack and replaces it by the head of the production
- ♦ Viable Pre xes In shift reduce parsing the stack contents are always a viable pre x that is a pre x of some right sentential form that ends no further right than the end of the handle of that right sentential form. The handle is the substring that was introduced in the last step of the rightmost derivation of that sentential form.
- ◆ Valid Items An item is a production with a dot somewhere in the body An item is valid for a viable pre x if the production of that item is used to generate the handle and the viable pre x includes all those symbols to the left of the dot but not those below
- ◆ LR Parsers Each of the several kinds of LR parsers operate by rst constructing the sets of valid items called LR states for all possible viable pre xes and keeping track of the state for each pre x on the stack. The set of valid items guide the shift reduce parsing decision. We prefer to reduce if there is a valid item with the dot at the right end of the body and we prefer to shift the lookahead symbol onto the stack if that symbol appears immediately to the right of the dot in some valid item.
- ◆ Simple LR Parsers In an SLR parser we perform a reduction implied by a valid item with a dot at the right end provided the lookahead symbol can follow the head of that production in some sentential form. The grammar is SLR and this method can be applied if there are no parsing action con icts that is for no set of items and for no lookahead symbol are there two productions to reduce by nor is there the option to reduce or to shift
- ◆ Canonical LR Parsers This more complex form of LR parser uses items
 that are augmented by the set of lookahead symbols that can follow the use
 of the underlying production Reductions are only chosen when there is a
 valid item with the dot at the right end and the current lookahead symbol
 is one of those allowed for this item A canonical LR parser can avoid some
 of the parsing action con icts that are present in SLR parsers but often
 has many more states than the SLR parser for the same grammar
- ♦ Lookahead LR Parsers LALR parsers o er many of the advantages of SLR and Canonical LR parsers by combining the states that have the same kernels sets of items ignoring the associated lookahead sets. Thus the number of states is the same as that of the SLR parser but some parsing action con icts present in the SLR parser may be removed in the LALR parser. LALR parsers have become the method of choice in practice.

- ♦ Bottom Up Parsing of Ambiguous Grammars In many important situations such as parsing arithmetic expressions we can use an ambiguous grammar and exploit side information such as the precedence of operators to resolve conficts between shifting and reducing or between reduction by two different productions. Thus LR parsing techniques extend to many ambiguous grammars.
- ◆ Yacc The parser generator Yacc takes a possibly ambiguous grammar and con ict resolution information and constructs the LALR states It then produces a function that uses these states to perform a bottom up parse and call an associated function each time a reduction is performed

4 11 References for Chapter 4

The context free grammar formalism originated with Chomsky 5 as part of a study on natural language. The idea also was used in the syntax description of two early languages. Fortran by Backus 2 and Algol 60 by Naur 26. The scholar Panini devised an equivalent syntactic notation to specify the rules of Sanskrit grammar between 400 B C and 200 B C. 19.

The phenomenon of ambiguity was observed—rst by Cantor 4 and Floyd 13—Chomsky Normal Form—Exercise 4 4 8—is from 6—The theory of context free grammars is summarized in 17

Recursive descent parsing was the method of choice for early compilers such as 16 and compiler writing systems such as META 28 and TMG 25 LL grammars were introduced by Lewis and Stearns 24 Exercise 445 the linear time simulation of recursive descent is from 3

One of the earliest parsing techniques due to Floyd 14 involved the prece dence of operators The idea was generalized to parts of the language that do not involve operators by Wirth and Weber 29 These techniques are rarely used today but can be seen as leading in a chain of improvements to LR parsing

LR parsers were introduced by Knuth 22 and the canonical LR parsing tables originated there. This approach was not considered practical because the parsing tables were larger than the main memories of typical computers of the day until Korenjak 23 gave a method for producing reasonably sized parsing tables for typical programming languages. DeRemer developed the LALR 8 and SLR 9 methods that are in use today. The construction of LR parsing tables for ambiguous grammars came from 1 and 12

Johnson's Yacc very quickly demonstrated the practicality of generating parsers with an LALR parser generator for production compilers. The manual for the Yacc parser generator is found in 20. The open source version Bison is described in 10. A similar LALR based parser generator called CUP 18 supports actions written in Java. Top down parser generators incude Antlr 27 a recursive descent parser generator that accepts actions in C. Java or C. and LLGen 15. which is an LL 1. based generator

Dain 7 gives a bibliography on syntax error handling

Chapter 5

Syntax Directed Translation

This chapter develops the theme of Section 2.3 the translation of languages guided by context free grammars. The translation techniques in this chapter will be applied in Chapter 6 to type checking and intermediate code generation. The techniques are also useful for implementing little languages for specialized tasks this chapter includes an example from typesetting.

We associate information with a language construct by attaching attributes to the grammar symbol's representing the construct as discussed in Section 2.3.2. A syntax directed de nition speci es the values of attributes by associating semantic rules with the grammar productions. For example, an in x to post x translator might have a production and rule

This production has two nonterminals E and T the subscript in E_1 distinguishes the occurrence of E in the production body from the occurrence of E as the head. Both E and T have a string valued attribute code. The semantic rule specifies that the string E code is formed by concatenating E_1 code and the character ' 'While the rule makes it explicit that the translation of E is built up from the translations of E_1 T and ' ' it may be inescient to implement the translation directly by manipulating strings

From Section 2 3 5 $\,$ a syntax directed translation scheme embeds program fragments called semantic actions within production bodies as in

$$E \quad E_1 \quad T \quad \{ \text{ print } ' \ ' \ \}$$
 5 2

By convention semantic actions are enclosed within curly braces If curly braces occur as grammar symbols we enclose them within single quotes as in

'{' and '}' The position of a semantic action in a production body determines the order in which the action is executed In production 5.2 the action occurs at the end after all the grammar symbols in general semantic actions may occur at any position in a production body

Between the two notations syntax directed de nitions can be more readable and hence more useful for speci cations. However translation schemes can be more e cient and hence more useful for implementations

The most general approach to syntax directed translation is to construct a parse tree or a syntax tree and then to compute the values of attributes at the nodes of the tree by visiting the nodes of the tree. In many cases translation can be done during parsing without building an explicit tree. We shall therefore study a class of syntax directed translations called. Lattributed translations. L for left to right—which encompass virtually all translations that can be performed during parsing. We also study a smaller class called. S attributed translations. S for synthesized—which can be performed easily in connection with a bottom up parse.

5 1 Syntax Directed De nitions

A syntax directed de nition SDD is a context free grammar together with attributes and rules Attributes are associated with grammar symbols and rules are associated with productions. If X is a symbol and a is one of its attributes then we write X a to denote the value of a at a particular parse tree node labeled X. If we implement the nodes of the parse tree by records or objects then the attributes of X can be implemented by data elds in the records that represent the nodes for X. Attributes may be of any kind numbers types table references or strings for instance. The strings may even be long sequences of code say code in the intermediate language used by a compiler

5 1 1 Inherited and Synthesized Attributes

We shall deal with two kinds of attributes for nonterminals

- 1 A synthesized attribute for a nonterminal A at a parse tree node N is defined by a semantic rule associated with the production at N. Note that the production must have A as its head. A synthesized attribute at node N is defined only in terms of attribute values at the children of N and at N itself
- 2 An *inherited attribute* for a nonterminal B at a parse tree node N is defined by a semantic rule associated with the production at the parent of N Note that the production must have B as a symbol in its body. An inherited attribute at node N is defined only in terms of attribute values at N s parent N itself and N s siblings

5.1 SYNTAX DIRECTED DEFINITIONS

An Alternative De nition of Inherited Attributes

No additional translations are enabled if we allow an inherited attribute $B\ c$ at a node N to be defined in terms of attribute values at the children of N as well as at N itself at its parent and at its siblings. Such rules can be simulated by creating additional attributes of B say $B\ c_1\ B\ c_2$. These are synthesized attributes that copy the needed attributes of the children of the node labeled B. We then compute $B\ c$ as an inherited attribute using the attributes $B\ c_1\ B\ c_2$ in place of attributes at the children. Such attributes are rarely needed in practice

While we do not allow an inherited attribute at node N to be defined in terms of attribute values at the children of node N we do allow a synthesized attribute at node N to be defined in terms of inherited attribute values at node N itself

Terminals can have synthesized attributes but not inherited attributes At tributes for terminals have lexical values that are supplied by the lexical ana lyzer there are no semantic rules in the SDD itself for computing the value of an attribute for a terminal

Example 5 1 The SDD in Fig 5 1 is based on our familiar grammar for arithmetic expressions with operators and It evaluates expressions terminated by an endmarker $\bf n$ In the SDD each of the nonterminals has a single synthesized attribute called val We also suppose that the terminal $\bf digit$ has a synthesized attribute lexval which is an integer value returned by the lexical analyzer

	PRODUCTION			SEMANTIC RULES		
1	_	E n		L val		
2	E	E_1	T	E val	$E_1 \ val \ T \ val$	
3	E	T		E val	$E_1 \ val \ T \ val \ T \ val$	
4	T	T_1 I	F	$T \ val$	$T_1 \ val \ F \ val$	
5	T	F		$T \ val$	$F\ val$	
6	F	E		$F\ val$	$E\ val$	
7	F	digit		$F\ val$	$\mathbf{digit}\ \mathrm{lexval}$	

Figure 5.1 Syntax directed de nition of a simple desk calculator

The rule for production 1 L E \mathbf{n} sets L val to E val which we shall see is the numerical value of the entire expression

Production 2 E E_1 T also has one rule which computes the val attribute for the head E as the sum of the values at E_1 and T At any parse

tree node N labeled E the value of val for E is the sum of the values of val at the children of node N labeled E and T

Production 3 E T has a single rule that defines the value of val for E to be the same as the value of val at the child for T Production 4 is similar to the second production its rule multiplies the values at the children instead of adding them. The rules for productions 5 and 6 copy values at a child like that for the third production. Production 7 gives F val the value of a digit that is the numerical value of the token \mathbf{digit} that the lexical analyzer returned.

An SDD that involves only synthesized attributes is called S attributed the SDD in Fig. 5.1 has this property. In an S attributed SDD each rule computes an attribute for the nonterminal at the head of a production from attributes taken from the body of the production

For simplicity the examples in this section have semantic rules without side e ects. In practice, it is convenient to allow SDD s to have limited side e ects such as printing the result computed by a desk calculator or interacting with a symbol table. Once the order of evaluation of attributes is discussed in Section 5.2 we shall allow semantic rules to compute arbitrary functions possibly involving side e ects.

An S attributed SDD can be implemented naturally in conjunction with an LR parser. In fact, the SDD in Fig. 5.1 mirrors the Yacc program of Fig. 4.58 which illustrates translation during LR parsing. The difference is that in the rule for production 1, the Yacc program prints the value $E\ val$ as a side elect instead of defining the attribute $L\ val$

An SDD without side e ects is sometimes called an attribute grammar. The rules in an attribute grammar de ne the value of an attribute purely in terms of the values of other attributes and constants

5 1 2 Evaluating an SDD at the Nodes of a Parse Tree

To visualize the translation speci ed by an SDD it helps to work with parse trees even though a translator need not actually build a parse tree Imagine therefore that the rules of an SDD are applied by rst constructing a parse tree and then using the rules to evaluate all of the attributes at each of the nodes of the parse tree A parse tree showing the value s of its attribute s is called an annotated parse tree

How do we construct an annotated parse tree $\,$ In what order do we evaluate attributes $\,$ Before we can evaluate an attribute at a node of a parse tree $\,$ we must evaluate all the attributes upon which its value depends $\,$ For example if all attributes are synthesized as in Example 5 1 then we must evaluate the $\,$ $\,$ $\,$ $\,$ attributes at all of the children of a node before we can evaluate the $\,$ $\,$ attribute at the node itself

With synthesized attributes we can evaluate attributes in any bottom up order such as that of a postorder traversal of the parse tree the evaluation of S attributed de nitions is discussed in Section 5 2 3

5 1 SYNTAX DIRECTED DEFINITIONS

For SDD s with both inherited and synthesized attributes there is no guar antee that there is even one order in which to evaluate attributes at nodes For instance consider nonterminals A and B with synthesized and inherited attributes A s and B i respectively along with the production and rules

PRODUCTION	SEMAN	TIC	RULES
A B	A s	B i	
	B i	A s	1

These rules are circular it is impossible to evaluate either A s at a node N or B i at the child of N without rst evaluating the other. The circular dependency of A s and B i at some pair of nodes in a parse tree is suggested by Fig. 5.2

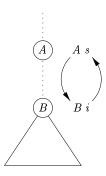

Figure 5.2 The circular dependency of A s and B i on one another

It is computationally discult to determine whether or not there exist any circularities in any of the parse trees that a given SDD could have to translate 1 Fortunately there are useful subclasses of SDD s that are suscient to guarantee that an order of evaluation exists as we shall see in Section 5.2

Example 5 2 Figure 5 3 shows an annotated parse tree for the input string 3 5 4 n constructed using the grammar and rules of Fig 5 1 The values of lexval are presumed supplied by the lexical analyzer Each of the nodes for the nonterminals has attribute val computed in a bottom up order and we see the resulting values associated with each node. For instance at the node with a child labeled after computing T val 3 and F val 5 at its rst and third children, we apply the rule that says T val is the product of these two values or 15 \square

Inherited attributes are useful when the structure of a parse tree does not match the abstract syntax of the source code. The next example shows how inherited attributes can be used to overcome such a mismatch due to a grammar designed for parsing rather than translation

¹Without going into details while the problem is decidable it cannot be solved by a polynomial time algorithm even if \mathcal{P} \mathcal{NP} since it has exponential time complexity

CHAPTER 5 SYNTAX DIRECTED TRANSLATION

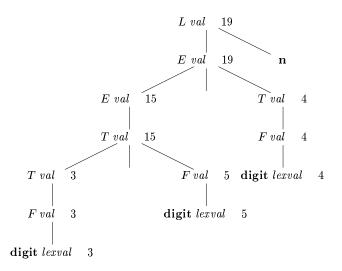

Figure 5 3 Annotated parse tree for 3 5 4 n

Example 5 3 The SDD in Fig 5 4 computes terms like 3 5 and 3 5 7 The top down parse of input 3 5 begins with the production T FT' Here F generates the digit 3 but the operator—is generated by T'—Thus—the left operand 3 appears in a di-erent subtree of the parse tree from—An inherited attribute will therefore be used to pass the operand to the operator

The grammar in this example is an excerpt from a non left recursive version of the familiar expression grammar we used such a grammar as a running example to illustrate top down parsing in Section 4.4

	PRODUCTION	SEMANTIC RULES		
1	T - F T'	$egin{array}{cccccccccccccccccccccccccccccccccccc$		
2	$T' \qquad F T'_1$	$egin{array}{cccccccccccccccccccccccccccccccccccc$		
3	T'	T' syn T' inh		
4	F digit	F val digit lexval		

Figure 5 4 An SDD based on a grammar suitable for top down parsing

Each of the nonterminals T and F has a synthesized attribute val the terminal **digit** has a synthesized attribute lexval. The nonterminal T' has two attributes an inherited attribute inh and a synthesized attribute syn

5 1 SYNTAX DIRECTED DEFINITIONS

To see how the semantic rules are used consider the annotated parse tree for 3 5 in Fig 5.5. The leftmost leaf in the parse tree labeled **digit** has attribute value lexval 3 where the 3 is supplied by the lexical analyzer. Its parent is for production 4 F digit. The only semantic rule associated with this production de nes Fval digit lexval which equals 3

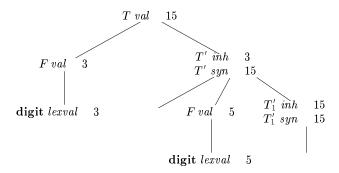

Figure 5 5 Annotated parse tree for 3 5

At the second child of the root the inherited attribute T' inh is defined by the semantic rule T' inh F val associated with production 1. Thus the left operand 3 for the operator is passed from left to right across the children of the root

The production at the node for T' is T' FT'_1 We retain the subscript 1 in the annotated parse tree to distinguish between the two nodes for T' The inherited attribute T'_1 inh is defined by the semantic rule T'_1 inh T' inh T' inh T' inh associated with production 2

With T' inh 3 and F val 5 we get T'_1 inh 15 At the lower node for T'_1 the production is T' . The semantic rule T' syn T' inh de nes T'_1 syn 15 The syn attributes at the nodes for T' pass the value 15 up the tree to the node for T where T val 15 \square

5 1 3 Exercises for Section 5 1

Exercise 5 1 1 For the SDD of Fig 5 1 give annotated parse trees for the following expressions

a 3 4 5 6 **n**

b 1 2 3 4 5 **n** c 9 8 7 6 5 4 **n**

Exercise 5 1 2 Extend the SDD of Fig 5 4 to handle expressions as in Fig 5 1

Exercise 5 1 3 Repeat Exercise 5 1 1 using your SDD from Exercise 5 1 2

5 2 Evaluation Orders for SDD s

Dependency graphs are a useful tool for determining an evaluation order for the attribute instances in a given parse tree While an annotated parse tree shows the values of attributes a dependency graph helps us determine how those values can be computed

In this section in addition to dependency graphs we de ne two important classes of SDDs the Sattributed and the more general Lattributed SDDs. The translations specified by these two classes it well with the parsing methods we have studied and most translations encountered in practice can be written to conform to the requirements of at least one of these classes

5 2 1 Dependency Graphs

A dependency graph depicts the ow of information among the attribute in stances in a particular parse tree an edge from one attribute instance to an other means that the value of the rst is needed to compute the second Edges express constraints implied by the semantic rules In more detail

For each parse tree node say a node labeled by grammar symbol X the dependency graph has a node for each attribute associated with X

Suppose that a semantic rule associated with a production p de nest he value of synthesized attribute A b in terms of the value of X c the rule may de ne A b in terms of other attributes in addition to X c. Then the dependency graph has an edge from X c to A b. More precisely at every node N labeled A where production p is applied create an edge to attribute b at b from the attribute b at the child of b corresponding to this instance of the symbol b in the body of the production b

Suppose that a semantic rule associated with a production p de nest he value of inherited attribute B c in terms of the value of X a. Then the dependency graph has an edge from X a to B c. For each node N labeled B that corresponds to an occurrence of this B in the body of production p create an edge to attribute c at N from the attribute a at the node M

 $^{^2}$ Since a node N can have several children labeled X we again assume that subscripts distinguish among uses of the same symbol at di erent places in the production

5 2 EVALUATION ORDERS FOR SDD S

that corresponds to this occurrence of X Note that M could be either the parent or a sibling of N

Example 5 4 Consider the following production and rule

Pro	DUCT	ION	Sem.	ANTIC R	ULE
E	E_1	T	$E\ val$	$E_1 \ val$	$T \ val$

At every node N labeled E with children corresponding to the body of this production the synthesized attribute val at N is computed using the values of val at the two children labeled E and T. Thus, a portion of the dependency graph for every parse tree in which this production is used looks like Fig. 5.6 As a convention, we shall show the parse tree edges as dotted lines, while the edges of the dependency graph are solid.

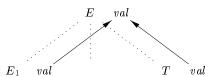

Figure 5 6 E val is synthesized from E_1 val and T val

Example 5 5 An example of a complete dependency graph appears in Fig 5 7 The nodes of the dependency graph represented by the numbers 1 through 9 correspond to the attributes in the annotated parse tree in Fig 5 5

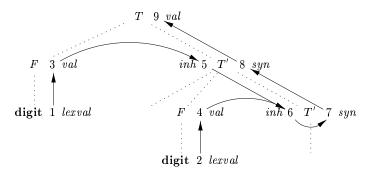

Figure 5 7 Dependency graph for the annotated parse tree of Fig. 5 5

Nodes 1 and 2 represent the attribute lexval associated with the two leaves labeled digit Nodes 3 and 4 represent the attribute val associated with the two nodes labeled F The edges to node 3 from 1 and to node 4 from 2 result

from the semantic rule that de nes F val in terms of **digit** lexval In fact F val equals **digit** lexval but the edge represents dependence not equality

Nodes 5 and 6 represent the inherited attribute T' inh associated with each of the occurrences of nonterminal T'. The edge to 5 from 3 is due to the rule T' inh F val which de nes T' inh at the right child of the root from F val at the left child. We see edges to 6 from node 5 for T' inh and from node 4 for F val because these values are multiplied to evaluate the attribute inh at node 6

Nodes 7 and 8 represent the synthesized attribute syn associated with the occurrences of T' The edge to node 7 from 6 is due to the semantic rule T' syn T' inh associated with production 3 in Fig. 5.4. The edge to node 8 from 7 is due to a semantic rule associated with production 2

Finally node 9 represents the attribute T val The edge to 9 from 8 is due to the semantic rule T val T' syn associated with production 1 \Box

5 2 2 Ordering the Evaluation of Attributes

The dependency graph characterizes the possible orders in which we can evalu ate the attributes at the various nodes of a parse tree. If the dependency graph has an edge from node M to node N, then the attribute corresponding to M must be evaluated before the attribute of N. Thus, the only allowable orders of evaluation are those sequences of nodes N_1 , N_2 , N_k such that if there is an edge of the dependency graph from N_i to N_j , then i-j Such an ordering embeds a directed graph into a linear order, and is called a topological sort of the graph

If there is any cycle in the graph then there are no topological sorts that is there is no way to evaluate the SDD on this parse tree. If there are no cycles however then there is always at least one topological sort. To see why since there are no cycles we can surely an anode with no edge entering. For if there were no such node we could proceed from predecessor to predecessor until we came back to some node we had already seen yielding a cycle. Make this node the rst in the topological order remove it from the dependency graph and repeat the process on the remaining nodes

Example 5 6 The dependency graph of Fig. 5 7 has no cycles. One topological sort is the order in which the nodes have already been numbered $1\ 2\ 9$. Notice that every edge of the graph goes from a node to a higher numbered node so this order is surely a topological sort. There are other topological sorts as well such as $1\ 3\ 5\ 2\ 4\ 6\ 7\ 8\ 9$. \square

5 2 3 S Attributed De nitions

As mentioned earlier given an SDD it is very hard to tell whether there exist any parse trees whose dependency graphs have cycles In practice translations can be implemented using classes of SDD s that guarantee an evaluation order

5 2 EVALUATION ORDERS FOR SDD S

since they do not permit dependency graphs with cycles Moreover the two classes introduced in this section can be implemented e ciently in connection with top down or bottom up parsing

The rst class is de ned as follows

An SDD is S attributed if every attribute is synthesized

Example 5 7 The SDD of Fig. 5.1 is an example of an S attributed definition Each attribute L val E val T val and F val is synthesized \Box

When an SDD is S attributed we can evaluate its attributes in any bottom up order of the nodes of the parse tree. It is often especially simple to evaluate the attributes by performing a postorder traversal of the parse tree and evaluating the attributes at a node N when the traversal leaves N for the last time. That is we apply the function postorder defined below to the root of the parse tree see also the box. Preorder and Postorder Traversals in Section 2.3.4

S attributed de nitions can be implemented during bottom up parsing since a bottom up parse corresponds to a postorder traversal Speci cally postorder corresponds exactly to the order in which an LR parser reduces a production body to its head. This fact will be used in Section 5.4.2 to evaluate synthesized attributes and store them on the stack during LR parsing without creating the tree nodes explicitly.

5 2 4 L Attributed De nitions

The second class of SDDs is called *L* attributed de nitions. The idea behind this class is that between the attributes associated with a production body dependency graph edges can go from left to right but not from right to left hence. L attributed. More precisely each attribute must be either

- 1 Synthesized or
- 2 Inherited but with the rules limited as follows. Suppose that there is a production $A = X_1 X_2 = X_n$ and that there is an inherited attribute X_i a computed by a rule associated with this production. Then the rule may use only
 - a Inherited attributes associated with the head A
 - b Either inherited or synthesized attributes associated with the occur rences of symbols X_1 X_2 X_{i-1} located to the left of X_i

CHAPTER 5 SYNTAX DIRECTED TRANSLATION

c Inherited or synthesized attributes associated with this occurrence of X_i itself but only in such a way that there are no cycles in a dependency graph formed by the attributes of this X_i

Example 5 8 The SDD in Fig 5 4 is L attributed To see why consider the semantic rules for inherited attributes which are repeated here for convenience

$$\begin{array}{lll} \text{Production} & \text{Semantic Rule} \\ T & F \, T' & T' \, inh \, F \, val \\ T' & F \, T'_1 & T'_1 \, inh \, T' \, inh \, F \, val \end{array}$$

The rst of these rules de nes the inherited attribute T' inh using only F val and F appears to the left of T' in the production body as required. The second rule de nes T'_1 inh using the inherited attribute T' inh associated with the head and F val where F appears to the left of T'_1 in the production body

In each of these cases the rules use information from above or from the left—as required by the class—The remaining attributes are synthesized—Hence the SDD is L attributed— \Box

Example 5 9 Any SDD containing the following production and rules cannot be L attributed

PRODUCTION SEMANTIC RULES
$$A \ B \ C$$
 $A \ s \ B \ b$ $B \ i \ f \ C \ c \ A \ s$

The rst rule As Bb is a legitimate rule in either an S attributed or L attributed SDD. It do not a synthesized attribute As in terms of an attribute at a child that is a symbol within the production body

The second rule de nes an inherited attribute B i so the entire SDD cannot be S attributed. Further although the rule is legal the SDD cannot be L attributed because the attribute C c is used to help de ne B i and C is to the right of B in the production body. While attributes at siblings in a parse tree may be used in L attributed SDD s. they must be to the left of the symbol whose attribute is being defined. \Box

5 2 5 Semantic Rules with Controlled Side E ects

In practice translations involve side e ects—a desk calculator might print a result—a code generator might enter the type of an identi—er into a symbol table With SDD s—we strike a balance between attribute grammars and translation schemes—Attribute grammars have no side—e ects and allow any evaluation order consistent with the dependency graph—Translation schemes impose left to right evaluation and allow semantic actions to contain any program fragment translation schemes are discussed in Section 5 4

We shall control side e ects in SDD s in one of the following ways

5 2 EVALUATION ORDERS FOR SDD S

Permit incidental side e ects that do not constrain attribute evaluation In other words permit side e ects when attribute evaluation based on any topological sort of the dependency graph produces a correct translation where correct depends on the application

Constrain the allowable evaluation orders so that the same translation is produced for any allowable order. The constraints can be thought of as implicit edges added to the dependency graph

As an example of an incidental side e ect let us modify the desk calculator of Example 5 1 to print a result. Instead of the rule $L\ val$ $E\ val$ which saves the result in the synthesized attribute $L\ val$ consider

$$\begin{array}{ccc} & \text{Production} & \text{Semantic Rule} \\ 1 & L & E \; \mathbf{n} & print \; E \; val \end{array}$$

Semantic rules that are executed for their side e ects such as $print\ E\ val$ will be treated as the de nitions of dummy synthesized attributes associated with the head of the production. The modi ed SDD produces the same translation under any topological sort since the print statement is executed at the end after the result is computed into $E\ val$

Example 5 10 The SDD in Fig. 5.8 takes a simple declaration D consisting of a basic type T followed by a list L of identifiers T can be **int** or **oat**. For each identifier on the list, the type is entered into the symbol table entry for the identifier. We assume that entering the type for one identifier does not a ect the symbol table entry for any other identifier. Thus, entries can be updated in any order. This SDD does not check whether an identifier is declared more than once it can be modified to do so

	Pro	ODUCTION	SEMANTIC RULES
1	D	TL	L inh T type
2	T	int	T type integer
3	T	oat	T type oat
4	L	L_1 id	$oxedsymbol{L}_1 \ inh \ oxedsymbol{L} \ inh$
			addType id entry L inh
5	L	id	addType id entry L inh

Figure 5 8 Syntax directed de nition for simple type declarations

Nonterminal D represents a declaration which from production 1 consists of a type T followed by a list L of identifiers T has one attribute T type which is the type in the declaration D. Nonterminal L also has one attribute which we call inh to emphasize that it is an inherited attribute. The purpose of L inh

CHAPTER 5 SYNTAX DIRECTED TRANSLATION

is to pass the declared type down the list of identiers so that it can be added to the appropriate symbol table entries

Productions 2 and 3 each evaluate the synthesized attribute T type giving it the appropriate value integer or oat. This type is passed to the attribute L inh in the rule for production 1. Production 4 passes L inh down the parse tree. That is the value L_1 inh is computed at a parse tree node by copying the value of L inh from the parent of that node the parent corresponds to the head of the production.

Productions 4 and 5 also have a rule in which a function add Type is called with two arguments

- 1 id entry a lexical value that points to a symbol table object and
- 2 L inh the type being assigned to every identi er on the list

We suppose that function addType properly installs the type L inh as the type of the represented identifier

A dependency graph for the input string oat id_1 id_2 id_3 appears in Fig 5 9 Numbers 1 through 10 represent the nodes of the dependency graph Nodes 1 2 and 3 represent the attribute *entry* associated with each of the leaves labeled id Nodes 6 8 and 10 are the dummy attributes that represent the application of the function addType to a type and one of these *entry* values

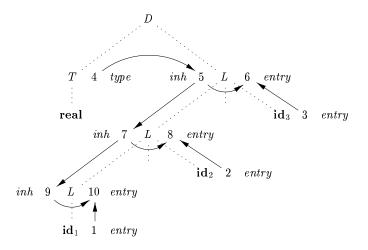

Figure 5 9 Dependency graph for a declaration oat id₁ id₂ id₃

Node 4 represents the attribute T type and is actually where attribute evaluation begins. This type is then passed to nodes 5–7 and 9 representing L inh associated with each of the occurrences of the nonterminal L

5 2 6 Exercises for Section 5 2

Exercise 5 2 1 What are all the topological sorts for the dependency graph of Fig 5 7

Exercise 5 2 2 For the SDD of Fig 5 8 give annotated parse trees for the following expressions

```
a int a b c
b float w x y z
```

Exercise 5 2 3 Suppose that we have a production A BCD Each of the four nonterminals A B C and D have two attributes s is a synthesized attribute and i is an inherited attribute. For each of the sets of rules below tell whether i the rules are consistent with an S attributed de nition ii the rules are consistent with an L attributed de nition and iii whether the rules are consistent with any evaluation order at all

```
a As Bi Cs b As Bi Cs and Di Ai Bs c As Bs Ds d As Di Bi As Cs Ci Bs and Di Bi Ci
```

Exercise 5 2 4 $\,$ This grammar generates binary numbers with a $\,$ decimal point

Design an L attributed SDD to compute $S\ val$ the decimal number value of an input string. For example, the translation of string 101 101 should be the decimal number 5 625. Hint use an inherited attribute $L\ side$ that tells which side of the decimal point a bit is on

Exercise 5 2 5 Design an S attributed SDD for the grammar and translation described in Exercise 5 2 4

Exercise 5 2 6 Implement Algorithm 3 23 which converts a regular expression into a nondeterministic nite automaton by an L attributed SDD on a top down parsable grammar. Assume that there is a token **char** representing any character and that **char** lexval is the character it represents. You may also assume the existence of a function new—that returns a new state that is a state never before returned by this function. Use any convenient notation to specify the transitions of the NFA

5 3 Applications of Syntax Directed Translation

The syntax directed translation techniques in this chapter will be applied in Chapter 6 to type checking and intermediate code generation. Here we consider selected examples to illustrate some representative SDD s

The main application in this section is the construction of syntax trees. Since some compilers use syntax trees as an intermediate representation a common form of SDD turns its input string into a tree. To complete the translation to intermediate code the compiler may then walk the syntax tree using another set of rules that are in e. ect an SDD on the syntax tree rather than the parse tree. Chapter 6 also discusses approaches to intermediate code generation that apply an SDD without ever constructing a tree explicitly

We consider two SDD s for constructing syntax trees for expressions. The rst an S attributed de nition is suitable for use during bottom up parsing. The second L attributed is suitable for use during top down parsing.

The nal example of this section is an L attributed de nition that deals with basic and array types

5 3 1 Construction of Syntax Trees

As discussed in Section 2 8 2 each node in a syntax tree represents a construct the children of the node represent the meaningful components of the construct A syntax tree node representing an expression E_1 E_2 has label and two children representing the subexpressions E_1 and E_2

We shall implement the nodes of a syntax tree by objects with a suitable number of elds Each object will have an op eld that is the label of the node The objects will have additional elds as follows

If the node is a leaf an additional eld holds the lexical value for the leaf A constructor function *Leaf op val* creates a leaf object. Alternatively if nodes are viewed as records then *Leaf* returns a pointer to a new record for a leaf

If the node is an interior node there are as many additional elds as the node has children in the syntax tree A constructor function Node takes two or more arguments Node op c_1 c_2 c_k creates an object with rst eld op and k additional elds for the k children c_1 c_k

Example 5 11 The S attributed de nition in Fig 5 10 constructs syntax trees for a simple expression grammar involving only the binary operators and As usual these operators are at the same precedence level and are jointly left associative All nonterminals have one synthesized attribute node which represents a node of the syntax tree

Every time the rst production E E_1 T is used its rule creates a node with ' ' for op and two children E_1 node and T node for the subexpressions. The second production has a similar rule

5 3 APPLICATIONS OF SYNTAX DIRECTED TRANSLATION

PRODUCTION		SEMANTIC RULES		
1	E	E_1 T	E node	$\mathbf{new} \ Node' \ ' \ E_1 \ node \ T \ node$
2	E	E_1 T	E node	${f new}\ Node' \ ' \ E_1\ node\ T\ node$
3	E	T	E $node$	$T \; node$
4	T	E	$T\ node$	$E\ node$
5	T	id	$T\ node$	new Leaf id id entry
6	T	num	$T\ node$	${f new} \ Leaf \ {f num} \ {f num} \ val$

Figure 5 10 Constructing syntax trees for simple expressions

For production 3 E T no node is created since E node is the same as T node Similarly no node is created for production 4 T E The value of T node is the same as E node since parentheses are used only for grouping they in uence the structure of the parse tree and the syntax tree but once their job is done there is no further need to retain them in the syntax tree

The last two T productions have a single terminal on the right. We use the constructor Leaf to create a suitable node which becomes the value of T node

Figure 5 11 shows the construction of a syntax tree for the input a=4=c. The nodes of the syntax tree are shown as records with the op eld rst Syntax tree edges are now shown as solid lines. The underlying parse tree which need not actually be constructed is shown with dotted edges. The third type of line shown dashed represents the values of E node and T node each line points to the appropriate syntax tree node.

At the bottom we see leaves for a 4 and c constructed by Leaf We suppose that the lexical value id entry points into the symbol table and the lexical value num val is the numerical value of a constant. These leaves or pointers to them become the value of T node at the three parse tree nodes labeled T according to rules 5 and 6. Note that by rule 3, the pointer to the leaf for a is also the value of E node for the leftmost E in the parse tree

Rule 2 causes us to create a node with op equal to the minus sign and pointers to the rst two leaves. Then rule 1 produces the root node of the syntax tree by combining the node for o with the third leaf

If the rules are evaluated during a postorder traversal of the parse tree or with reductions during a bottom up parse then the sequence of steps shown in Fig. 5-12 ends with p_5 pointing to the root of the constructed syntax tree \Box

With a grammar designed for top down parsing the same syntax trees are constructed using the same sequence of steps even though the structure of the parse trees di ers signi cantly from that of syntax trees

Example 5 12 The L attributed de nition in Fig. 5 13 performs the same translation as the S attributed de nition in Fig. 5 10. The attributes for the grammar symbols $E \ T$ id and num are as discussed in Example 5 11.

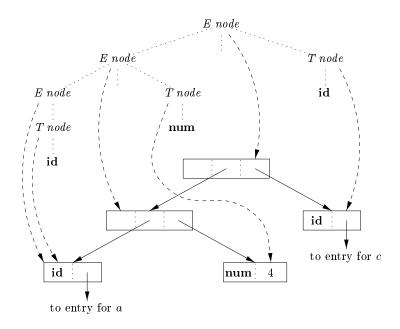

Figure 5 11 Syntax tree for a = 4 = c

- $3 \quad p_3 \quad \mathbf{new} \; Node' \quad p_1 p_2$
- 4 p_4 new Leaf id entry c
- $5 \quad p_5 \quad \mathbf{new} \; Node' \quad p_3 \quad p_4$

Figure 5 12 Steps in the construction of the syntax tree for a=4=c

The rules for building syntax trees in this example are similar to the rules for the desk calculator in Example 5.3. In the desk calculator example a term x y was evaluated by passing x as an inherited attribute since x and y appeared in different portions of the parse tree. Here the idea is to build a syntax tree for x y by passing x as an inherited attribute since x and y appear in different subtrees. Nonterminal E' is the counterpart of nonterminal E' in Example 5.3. Compare the dependency graph for a 4 c in Fig. 5.14 with that for 3.5 in Fig. 5.7

Nonterminal E' has an inherited attribute inh and a synthesized attribute syn Attribute E' inh represents the partial syntax tree constructed so far Speci cally it represents the root of the tree for the pre x of the input string that is to the left of the subtree for E' At node 5 in the dependency graph in Fig 5 14 E' inh denotes the root of the partial syntax tree for the identi er a that is the leaf for a At node 6 E' inh denotes the root for the partial syntax

5 3 APPLICATIONS OF SYNTAX DIRECTED TRANSLATION

	PRODUCTION		SEMANTIC RULES	
1	E	T E'		E' syn
2	E'	$T E_1'$		new Node' ' E' inh T node
3	E'	$T~E_1'$	E' syn E'_1 inh	new Node' ' E' inh T node
			E' syn	E_1' syn E' $inhE$ $node$
4	E'		E' syn	E' inh
5	T	E	$T \ node$	$E\ node$
6	T	id	$T \ node$	new Leaf id id entry
7	T	num	$T\ node$	new Leaf num num val

Figure 5 13 Constructing syntax trees during top down parsing

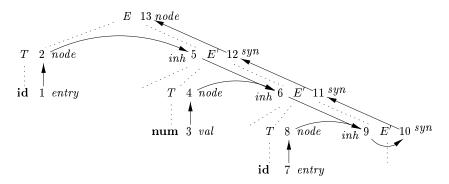

Figure 5 14 Dependency graph for a 4 c with the SDD of Fig 5 13

tree for the input a=4 At node 9 E' inh denotes the syntax tree for a=4 c. Since there is no more input—at node 9 E' inh points to the root of the entire syntax tree—The syn attributes pass this value back up the parse tree until it becomes the value of E node—Speci—cally the attribute value at node 10 is de ned by the rule E' syn—E' inh associated with the production E'. The attribute value at node 11 is de ned by the rule E' syn— E'_1 syn associated with production 2 in Fig—5 13—Similar rules de ne the attribute values at nodes 12 and 13—

5 3 2 The Structure of a Type

Inherited attributes are useful when the structure of the parse tree diers from the abstract syntax of the input attributes can then be used to carry informa

tion from one part of the parse tree to another. The next example shows how a mismatch in structure can be due to the design of the language, and not due to constraints imposed by the parsing method

Example 5 13 In C the type int 2 3 can be read as array of 2 arrays of 3 integers. The corresponding type expression array 2 array 3 integer is represented by the tree in Fig. 5 15. The operator array takes two parameters a number and a type. If types are represented by trees, then this operator returns a tree node labeled array with two children for a number and a type.

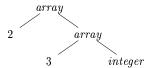

Figure 5 15 Type expression for int 2 3

With the SDD in Fig. 5.16 nonterminal T generates either a basic type or an array type. Nonterminal B generates one of the basic types \mathbf{int} and \mathbf{oat} T generates a basic type when T derives BC and C derives. Otherwise C generates array components consisting of a sequence of integers each integer surrounded by brackets

PB	CODUCTION	S	EMANTIC RULES
\overline{T}	B C		C t
		C b	B t
B	$_{ m int}$	B t	integer
B	oat	B t	oat
C	$\mathbf{num} C_1$	C t	$array$ num val C_1 t
		C_1 b	$C\ b$
C		C t	C b

Figure 5 16 T generates either a basic type or an array type

The nonterminals B and T have a synthesized attribute t representing a type. The nonterminal C has two attributes an inherited attribute b and a synthesized attribute t. The inherited b attributes pass a basic type down the tree and the synthesized t attributes accumulate the result

An annotated parse tree for the input string int 2-3 is shown in Fig 5 17. The corresponding type expression in Fig 5 15 is constructed by passing the type integer from B down the chain of C s through the inherited attributes b. The array type is synthesized up the chain of C s through the attributes t.

In more detail at the root for T — B C nonterminal C inherits the type from B —using the inherited attribute C b —At the rightmost node for C —the

5 3 APPLICATIONS OF SYNTAX DIRECTED TRANSLATION

production is C so C t equals C b. The semantic rules for the production C num C_1 form C t by applying the operator array to the operands num val and C_1 t

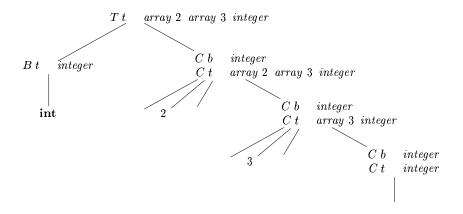

Figure 5 17 Syntax directed translation of array types

5 3 3 Exercises for Section 5 3

Exercise 5 3 1 Below is a grammar for expressions involving operator and integer or oating point operands Floating point numbers are distinguished by having a decimal point

$$\begin{array}{cccc} E & E & T \mid T \\ T & \mathbf{num} & \mathbf{num} \mid \mathbf{num} \end{array}$$

- a Give an SDD to determine the type of each term T and expression E
- b Extend your SDD of a to translate expressions into post x notation Use the unary operator **intToFloat** to turn an integer into an equivalent

Exercise 5 3 2 Give an SDD to translate in x expressions with and into equivalent expressions without redundant parentheses. For example, since both operators associate from the left, and takes precedence over a b c d translates into a b c d

Exercise 5 3 3 Give an SDD to differentiate expressions such as x-3-x-x-x involving the operators and the variable x and constants. Assume that no simplification occurs so that for example 3-x will be translated into 3-1-0-x

5 4 Syntax Directed Translation Schemes

Syntax directed translation schemes are a complementary notation to syntax directed de nitions. All of the applications of syntax directed de nitions in Section 5 3 can be implemented using syntax directed translation schemes.

From Section 2 3 5 a syntax directed translation scheme SDT is a context free grammar with program fragments embedded within production bodies. The program fragments are called semantic actions and can appear at any position within a production body. By convention, we place curly braces around actions if braces are needed as grammar symbols, then we quote them

Any SDT can be implemented by rst building a parse tree and then per forming the actions in a left to right depth—rst order that is during a preorder traversal—An example appears in Section 5 4 3

Typically SDTs are implemented during parsing without building a parse tree. In this section, we focus on the use of SDTs to implement two important classes of SDDs $\,$

- 1 The underlying grammar is LR parsable and the SDD is S attributed
- 2 The underlying grammar is LL parsable and the SDD is L attributed

We shall see how in both these cases the semantic rules in an SDD can be converted into an SDT with actions that are executed at the right time. During parsing an action in a production body is executed as soon as all the grammar symbols to the left of the action have been matched

SDT s that can be implemented during parsing can be characterized by in troducing distinct $marker\ nonterminals$ in place of each embedded action each marker M has only one production M If the grammar with marker non terminals can be parsed by a given method then the SDT can be implemented during parsing

5 4 1 Post x Translation Schemes

By far the simplest SDD implementation occurs when we can parse the grammar bottom up and the SDD is S attributed. In that case, we can construct an SDT in which each action is placed at the end of the production and is executed along with the reduction of the body to the head of that production. SDT s with all actions at the right ends of the production bodies are called $post\ x\ SDT\ s$

Example 5 14 The post x SDT in Fig 5 18 implements the desk calculator SDD of Fig 5 1 with one change the action for the rst production prints a value. The remaining actions are exact counterparts of the semantic rules. Since the underlying grammar is LR and the SDD is S attributed these actions can be correctly performed along with the reduction steps of the parser. \Box

F	E	$\{Fval Eval\}$
F	${f digit}$	$\{ F val \mathbf{digit} \ lexval \ \}$

Figure 5 18 Post x SDT implementing the desk calculator

5 4 2 Parser Stack Implementation of Post x SDT s

Post x SDT s can be implemented during LR parsing by executing the actions when reductions occur. The attribute s of each grammar symbol can be put on the stack in a place where they can be found during the reduction. The best plan is to place the attributes along with the grammar symbols or the LR states that represent these symbols in records on the stack itself.

In Fig 5 19 the parser stack contains records with a eld for a grammar symbol or parser state and below it a eld for an attribute. The three grammar symbols XYZ are on top of the stack perhaps they are about to be reduced according to a production like A XYZ. Here we show Xx as the one attribute of X and so on. In general, we can allow for more attributes either by making the records large enough or by putting pointers to records on the stack. With small attributes it may be simpler to make the records large enough even if some elds go unused some of the time. However, if one or more attributes are of unbounded size—say they are character strings—then it would be better to put a pointer to the attributes value in the stack record and store the actual value in some larger—shared storage area that is not part of the stack

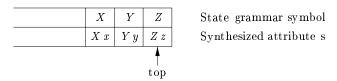

Figure 5 19 Parser stack with a eld for synthesized attributes

If the attributes are all synthesized and the actions occur at the ends of the productions then we can compute the attributes for the head when we reduce the body to the head. If we reduce by a production such as A = XYZ then we have all the attributes of X = Y and Z available at known positions on the stack as in Fig. 5.19. After the action A and its attributes are at the top of the stack in the position of the record for X

Example 5 15 Let us rewrite the actions of the desk calculator SDT of Ex

ample 5 14 so that they manipulate the parser stack explicitly Such stack manipulation is usually done automatically by the parser

Figure 5 20 Implementing the desk calculator on a bottom up parsing stack

Suppose that the stack is kept in an array of records called stack with top a cursor to the top of the stack. Thus $stack\ top$ refers to the top record on the stack $stack\ top$ 1 to the record below that and so on. Also we assume that each record has a eld called val which holds the attribute of whatever grammar symbol is represented in that record. Thus we may refer to the attribute $E\ val$ that appears at the third position on the stack as $stack\ top$ 2 val. The entire SDT is shown in Fig. 5.20

For instance in the second production E E_1 T we go two positions below the top to get the value of E_1 and we not the value of T at the top. The resulting sum is placed where the head E will appear after the reduction that is two positions below the current top. The reason is that after the reduction the three topmost stack symbols are replaced by one. After computing E val we pop two symbols of the top of the stack so the record where we placed E val will now be at the top of the stack

In the third production E-T no action is necessary because the length of the stack does not change and the value of T val at the stack top will simply become the value of E val. The same observation applies to the productions T-F and F \mathbf{digit} Production F-E is slightly different. Although the value does not change two positions are removed from the stack during the reduction so the value has to move to the position after the reduction

Note that we have omitted the steps that manipulate the rst eld of the stack records the eld that gives the LR state or otherwise represents the grammar symbol. If we are performing an LR parse the parsing table tells us what the new state is every time we reduce see Algorithm 4.44. Thus we may

simply place that state in the record for the new top of stack \Box

5 4 3 SDT s With Actions Inside Productions

An action may be placed at any position within the body of a production It is performed immediately after all symbols to its left are processed. Thus if we have a production $B = X \{a\} Y$ the action a is done after we have recognized X if X is a terminal or all the terminals derived from X if X is a nonterminal. More precisely

If the parse is bottom up then we perform action a as soon as this occurrence of X appears on the top of the parsing stack

If the parse is top down we perform a just before we attempt to expand this occurrence of Y if Y a nonterminal or check for Y on the input if Y is a terminal

SDT s that can be implemented during parsing include post x SDT s and a class of SDT s considered in Section 5 5 that implements L attributed de ni tions Not all SDT s can be implemented during parsing as we shall see in the next example

Example 5 16 As an extreme example of a problematic SDT suppose that we turn our desk calculator running example into an SDT that prints the pre $\,$ x form of an expression $\,$ rather than evaluating the expression $\,$ The productions and actions are shown in Fig. 5 21

Figure 5 21 Problematic SDT for in x to pre x translation during parsing

Unfortunately it is impossible to implement this SDT during either top down or bottom up parsing because the parser would have to perform critical actions like printing instances of or long before it knows whether these symbols will appear in its input

Using marker nonterminals M_2 and M_4 for the actions in productions 2 and 4 respectively on input that is a digit a shift reduce parser see Section 4.5.3 has conficts between reducing by M_2 reducing by M_4 and shifting the digit \square

Any SDT can be implemented as follows

- 1 Ignoring the actions parse the input and produce a parse tree as a result
- 2 Then examine each interior node N say one for production A Add additional children to N for the actions in so the children of N from left to right have exactly the symbols and actions of
- 3 Perform a preorder traversal see Section 2 3 4 of the tree and as soon as a node labeled by an action is visited perform that action

For instance Fig 5 22 shows the parse tree for expression 3 5 4 with actions inserted If we visit the nodes in preorder we get the pre x form of the expression 354

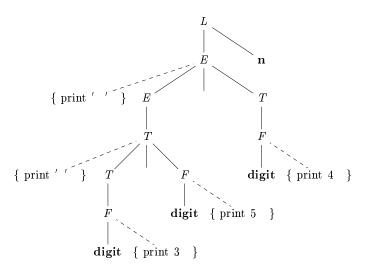

Figure 5 22 Parse tree with actions embedded

5 4 4 Eliminating Left Recursion From SDT s

Since no grammar with left recursion can be parsed deterministically top down we examined left recursion elimination in Section $4\,3\,3\,$ When the grammar is part of an SDT we also need to worry about how the actions are handled

First consider the simple case in which the only thing we care about is the order in which the actions in an SDT are performed. For example, if each action simply prints a string, we care only about the order in which the strings are printed. In this case, the following principle can guide us

When transforming the grammar treat the actions as if they were terminal symbols

5 4 SYNTAX DIRECTED TRANSLATION SCHEMES

This principle is based on the idea that the grammar transformation preserves the order of the terminals in the generated string. The actions are therefore executed in the same order in any left to right parse, top down or bottom up

The trick for eliminating left recursion is to take two productions

$$A - A$$

that generate strings consisting of a $\,$ and any number of $\,$ s and replace them by productions that generate the same strings using a new nonterminal R for remainder $\,$ of the $\,$ rst production

If does not begin with A then A no longer has a left recursive production. In regular definition terms with both sets of productions A is defined by See Section 4.3.3 for the handling of situations where A has more recursive or nonrecursive productions

Example 5 17 Consider the following E productions from an SDT for translating in x expressions into post x notation

If we apply the standard transformation to E the remainder of the left recursive production is

$$T \{ print'' \}$$

and — the body of the other production is T — If we introduce R for the remain der of E —we get the set of productions

When the actions of an SDD compute attributes rather than merely printing output we must be more careful about how we eliminate left recursion from a grammar However if the SDD is S attributed then we can always construct an SDT by placing attribute computing actions at appropriate positions in the new productions

We shall give a general schema for the case of a single recursive production a single nonrecursive production and a single attribute of the left recursive nonterminal the generalization to many productions of each type is not hard but is notationally cumbersome Suppose that the two productions are

Here A a is the synthesized attribute of left recursive nonterminal A and X and Y are single grammar symbols with synthesized attributes X x and Y y respectively. These could represent a string of several grammar symbols each with its own attribute s since the schema has an arbitrary function g computing A g in the recursive production and an arbitrary function g computing g in the second production. In each case g and g take as arguments whatever attributes they are allowed to access if the SDD is g attributed.

We want to turn the underlying grammar into

$$egin{array}{lll} A & & X R \ R & & Y R \end{array}$$

Figure 5 23 suggests what the SDT on the new grammar must do In a we see the e ect of the post x SDT on the original grammar. We apply f once corresponding to the use of production A — X and then apply g as many times as we use the production A — AY — Since R generates a remainder of Y s its translation depends on the string to its left a string of the form XYY — Y Each use of the production R — YR results in an application of g — For R we use an inherited attribute R i to accumulate the result of successively applying g starting with the value of A a

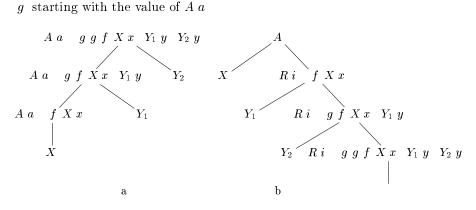

Figure 5 23 Eliminating left recursion from a post x SDT

In addition R has a synthesized attribute R s not shown in Fig. 5.23. This attribute is rst computed when R ends its generation of Y symbols as signaled by the use of production R and R s is then copied up the tree so it can become the value of A a for the entire expression XYY and Y Y The case where XYY is shown in Fig. 5.23 and we see that the value of XYY at the root of XYY is shown in Fig. 5.23 and we see that the value of XYY at the root of XYY is shown in Fig. 5.23 and we see that the value of XYY at the root of XYY is shown in Fig. 5.23 and we see that the value of XYY at the root of XYY is shown in Fig. 5.23 and we see that the value of XYY at the root of XYY is shown in Fig. 5.23 and we see that the value of XYY at the root of XYY is shown in Fig. 5.23 and we see that the value of XYY at the root of XYY is shown in Fig. 5.23 and we see that the value of XYY at the root of XYY is shown in Fig. 5.23 and we see that the value of XYY at the root of XYY is shown in Fig. 5.23 and we see that the value of XYY at the root of XYY is shown in Fig. 5.23 and we see that the value of XYY at the root of XYY is shown in Fig. 5.23 and we see that the value of XYY at the root of XYY is shown in Fig. 5.23 and XYY is show

To accomplish this translation we use the following SDT

5 4 SYNTAX DIRECTED TRANSLATION SCHEMES

Notice that the inherited attribute Ri is evaluated immediately before a use of R in the body while the synthesized attributes Aa and Rs are evaluated at the ends of the productions. Thus whatever values are needed to compute these attributes will be available from what has been computed to the left

5 4 5 SDT s for L Attributed De nitions

In Section 5 4 1 we converted S attributed SDDs into post x SDTs with actions at the right ends of productions. As long as the underlying grammar is LR post x SDTs can be parsed and translated bottom up

Now we consider the more general case of an L attributed SDD We shall assume that the underlying grammar can be parsed top down for if not it is frequently impossible to perform the translation in connection with either an LL or an LR parser. With any grammar, the technique below can be implemented by attaching actions to a parse tree and executing them during preorder traversal of the tree.

The rules for turning an L attributed SDD into an SDT are as follows

- 1 Embed the action that computes the inherited attributes for a nonterminal A immediately before that occurrence of A in the body of the production If several inherited attributes for A depend on one another in an acyclic fashion order the evaluation of attributes so that those needed rst are computed rst
- 2 Place the actions that compute a synthesized attribute for the head of a production at the end of the body of that production

We shall illustrate these principles with two extended examples The rst involves typesetting. It illustrates how the techniques of compiling can be used in language processing for applications other than what we normally think of as programming languages. The second example is about the generation of intermediate code for a typical programming language construct—a form of while statement

Example 5 18 This example is motivated by languages for typesetting math ematical formulas Eqn is an early example of such a language ideas from Eqn are still found in the TEX typesetting system which was used to produce this book

We shall concentrate on only the capability to de ne subscripts subscripts of subscripts and so on ignoring superscripts built up fractions and all other mathematical features. In the Eqn language one writes a sub i sub j to set the expression a_{i_j} . A simple grammar for boxes elements of text bounded by a rectangle is

$$B = B_1 B_2 \mid B_1$$
 sub $B_2 \mid B_1 \mid$ text

Corresponding to these four productions a box can be either

- 1 Two boxes juxtaposed with the rst B_1 to the left of the other B_2
- 2 A box and a subscript box The second box appears in a smaller size lower and to the right of the rst box
- 3 A parenthesized box for grouping of boxes and subscripts Eqn and T_EX both use curly braces for grouping but we shall use ordinary round paren theses to avoid confusion with the braces that surround actions in SDT s
- 4 A text string that is any string of characters

This grammar is ambiguous but we can still use it to parse bottom up if we make subscripting and juxtaposition right associative with **sub** taking precedence over juxtaposition

Expressions will be typeset by constructing larger boxes out of smaller ones In Fig. 5.24 the boxes for E_1 and height are about to be juxtaposed to form the box for E_1 height. The left box for E_1 is itself constructed from the box for E and the subscript 1. The subscript 1 is handled by shrinking its box by about 30. lowering it and placing it after the box for E. Although we shall treat height as a text string the rectangles within its box show how it can be constructed from boxes for the individual letters.

Figure 5 24 Constructing larger boxes from smaller ones

In this example we concentrate on the vertical geometry of boxes only The horizontal geometry—the widths of boxes—is also interesting especially when di erent characters have di erent widths. It may not be readily apparent—but each of the distinct characters in Fig. 5.24 has a di-erent width

The values associated with the vertical geometry of boxes are as follows

a The point size is used to set text within a box. We shall assume that characters not in subscripts are set in 10 point type the size of type in this book. Further we assume that if a box has point size p then its subscript box has the smaller point size 0 7p. Inherited attribute B ps will represent the point size of block B. This attribute must be inherited because the context determines by how much a given box needs to be shrunk due to the number of levels of subscripting

5 4 SYNTAX DIRECTED TRANSLATION SCHEMES

- b Each box has a baseline which is a vertical position that corresponds to the bottoms of lines of text not counting any letters like g that extend below the normal baseline In Fig 5 24 the dotted line represents the baseline for the boxes E height and the entire expression The baseline for the box containing the subscript 1 is adjusted to lower the subscript
- c A box has a height which is the distance from the top of the box to the baseline Synthesized attribute B ht gives the height of box B
- d A box has a depth which is the distance from the baseline to the bottom of the box Synthesized attribute B dp gives the depth of box B

The SDD in Fig 5 25 gives rules for computing point sizes heights and depths Production 1 is used to assign B ps the initial value 10

PRODUCTION		ODUCTION	SEMANTIC RULES
1	S	B	B ps 10
2	В	$B_1 \; B_2$	$egin{array}{cccccccccccccccccccccccccccccccccccc$
3	В	$B_1 \; {f sub} \; B_2$	$\begin{array}{cccccccccccccccccccccccccccccccccccc$
4	B	B_1	$egin{array}{cccccccccccccccccccccccccccccccccccc$
5	В	text	$egin{array}{lll} B & ht & getHt & B & ps & \mathbf{text} & lexval \\ B & dp & getDp & B & ps & \mathbf{text} & lexval \end{array}$

Figure 5 25 SDD for typesetting boxes

Production 2 handles juxtaposition Point sizes are copied down the parse tree that is two sub boxes of a box inherit the same point size from the larger box. Heights and depths are computed up the tree by taking the maximum. That is the height of the larger box is the maximum of the heights of its two components, and similarly for the depth.

Production 3 handles subscripting and is the most subtle In this greatly simplified example we assume that the point size of a subscripted box is 70 of the point size of its parent Reality is much more complex since subscripts cannot shrink inde nitely in practice after a few levels the sizes of subscripts

shrink hardly at all Further we assume that the baseline of a subscript box drops by 25 of the parent s point size again reality is more complex

Production 4 copies attributes appropriately when parentheses are used Fi nally production 5 handles the leaves that represent text boxes. In this matter too the true situation is complicated so we merely show two unspeci ed functions getHt and getDp that examine tables created with each font to determine the maximum height and maximum depth of any characters in the text string. The string itself is presumed to be provided as the attribute lexval of terminal text

Our last task is to turn this SDD into an SDT following the rules for an L attributed SDD which Fig 5 25 is The appropriate SDT is shown in Fig 5 26 For readability since production bodies become long we split them across lines and line up the actions Production bodies therefore consist of the contents of all lines up to the head of the next production \Box

```

```

Figure 5 26 SDT for typesetting boxes

Our next example concentrates on a simple while statement and the gener ation of intermediate code for this type of statement. Intermediate code will be treated as a string valued attribute. Later we shall explore techniques that involve the writing of pieces of a string valued attribute as we parse thus avoid ing the copying of long strings to build even longer strings. The technique was introduced in Example 5.17 where we generated the post x form of an in x

5 4 SYNTAX DIRECTED TRANSLATION SCHEMES

expression on the y rather than computing it as an attribute However in our rst formulation we create a string valued attribute by concatenation

Example 5 19 For this example we only need one production

$$S$$
 while C S_1

Here S is the nonterminal that generates all kinds of statements presumably including if statements assignment statements and others. In this example C stands for a conditional expression—a boolean expression that evaluates to true or false

In this ow of control example the only things we ever generate are labels All the other intermediate code instructions are assumed to be generated by parts of the SDT that are not shown Speci cally we generate explicit instructions of the form ${\bf label}\ L$ where L is an identi er to indicate that L is the label of the instruction that follows. We assume that the intermediate code is like that introduced in Section 2.8.4

The meaning of our while statement is that the conditional C is evaluated If it is true control goes to the beginning of the code for S_1 If false then control goes to the code that follows the while statement s code. The code for S_1 must be designed to jump to the beginning of the code for the while statement when nished the jump to the beginning of the code that evaluates C is not shown in Fig. 5.27

We use the following attributes to generate the proper intermediate code

- 1 The inherited attribute S next labels the beginning of the code that must be executed after S is nished
- 2 The synthesized attribute $S \ code$ is the sequence of intermediate code steps that implements a statement S and ends with a jump to $S \ next$
- 3 The inherited attribute C true labels the beginning of the code that must be executed if C is true
- 4 The inherited attribute C false labels the beginning of the code that must be executed if C is false
- 5 The synthesized attribute C code is the sequence of intermediate code steps that implements the condition C and jumps either to C true or to C false depending on whether C is true or false

The SDD that computes these attributes for the while statement is shown in Fig. 5.27. A number of points merit explanation

The function *new* generates new labels

The variables L1 and L2 hold labels that we need in the code L1 is the beginning of the code for the while statement and we need to arrange

```
S \quad \textbf{while} \quad C \quad S_1 \quad L1 \quad new \\ \quad L2 \quad new \\ \quad S_1 \quad next \quad L1 \\ \quad C \quad false \quad S \quad next \\ \quad C \quad true \quad L2 \\ \quad S \quad code \quad \textbf{label} \parallel L1 \parallel C \quad code \parallel \textbf{label} \parallel L2 \parallel S_1 \quad code \\ \label \parallel L1 \parallel C \quad code \parallel \textbf{label} \parallel L2 \parallel S_1 \quad code \\ \label \parallel L2 \parallel S_1 \quad code \end{pmatrix}
```

Figure 5 27 SDD for while statements

that S_1 jumps there after it nishes. That is why we set S_1 next to L1 L2 is the beginning of the code for S_1 and it becomes the value of C true because we branch there when C is true

Notice that C false is set to S next because when the condition is false we execute whatever code must follow the code for S

We use \parallel as the symbol for concatenation of intermediate code fragments. The value of S code thus begins with the label L1—then the code for condition C—another label L2—and the code for S_1

This SDD is L attributed When we convert it into an SDT the only remaining issue is how to handle the labels L1 and L2 which are variables and not attributes. If we treat actions as dummy nonterminals, then such variables can be treated as the synthesized attributes of dummy nonterminals. Since L1 and L2 do not depend on any other attributes, they can be assigned to the rst action in the production. The resulting SDT with embedded actions that implements this L attributed definition is shown in Fig. 5.28.

Figure 5 28 SDT for while statements

5 4 6 Exercises for Section 5 4

Exercise 5 4 1 We mentioned in Section 5 4 2 that it is possible to deduce from the LR state on the parsing stack what grammar symbol is represented by the state How would we discover this information

Exercise 5 4 2 Rewrite the following SDT

$$egin{array}{lll} A & A & \{a\} & B & | & A & B & \{b\} & | & 0 \\ B & B & \{c\} & A & | & B & A & \{d\} & | & 1 \\ \end{array}$$

5 5 IMPLEMENTING L ATTRIBUTED SDD S

so that the underlying grammar becomes non left recursive. Here a b c and d are actions and 0 and 1 are terminals

Exercise 5 4 3 The following SDT computes the value of a string of 0 s and 1 s interpreted as a positive binary integer

Rewrite this SDT so the underlying grammar is not left recursive and yet the same value of B val is computed for the entire input string

Exercise 5 4 4 Write L attributed SDDs analogous to that of Example 5 19 for the following productions each of which represents a familiar ow of control construct as in the programming language C. You may need to generate a three address statement to jump to a particular label L in which case you should generate ${\bf goto}\ L$

- a S if C S_1 else S_2
- b S do S_1 while C
- c S '{' L '}' L L S |

Note that any statement in the list can have a jump from its middle to the next statement so it is not su cient simply to generate code for each statement in order

Exercise 5 4 5 Convert each of your SDD s from Exercise 5 4 4 to an SDT in the manner of Example 5 19

Exercise 5 4 6 Modify the SDD of Fig 5 25 to include a synthesized attribute B le the length of a box. The length of the concatenation of two boxes is the sum of the lengths of each. Then add your new rules to the proper positions in the SDT of Fig 5 26

Exercise 5 4 7 Modify the SDD of Fig 5 25 to include superscripts denoted by operator \sup between boxes If box B_2 is a superscript of box B_1 then position the baseline of B_2 0 6 times the point size of B_1 above the baseline of B_1 Add the new production and rules to the SDT of Fig 5 26

5 5 Implementing L Attributed SDD s

Since many translation applications can be addressed using L attributed de nitions we shall consider their implementation in more detail in this section The following methods do translation by traversing a parse tree

- 1 Build the parse tree and annotate This method works for any noncircular SDD whatsoever We introduced annotated parse trees in Section 5 1 2
- 2 Build the parse tree add actions and execute the actions in preorder
 This approach works for any L attributed de nition We discussed how
 to turn an L attributed SDD into an SDT in Section 5 4 5 in particular
 we discussed how to embed actions into productions based on the semantic
 rules of such an SDD

In this section we discuss the following methods for translation during parsing

- 3 Use a recursive descent parser with one function for each nonterminal The function for nonterminal A receives the inherited attributes of A as arguments and returns the synthesized attributes of A
- 4 Generate code on the y using a recursive descent parser
- 5 Implement an SDT in conjunction with an LL parser The attributes are kept on the parsing stack and the rules fetch the needed attributes from known locations on the stack
- 6 Implement an SDT in conjunction with an LR parser This method may be surprising since the SDT for an L attributed SDD typically has ac tions in the middle of productions and we cannot be sure during an LR parse that we are even in that production until its entire body has been constructed We shall see however that if the underlying grammar is LL we can always handle both the parsing and translation bottom up

5 5 1 Translation During Recursive Descent Parsing

A recursive descent parser has a function A for each nonterminal A as discussed in Section 4.4.1 We can extend the parser into a translator as follows

- a $\,$ The arguments of function A are the inherited attributes of nonterminal $\,A$
- b The return value of function A is the collection of synthesized attributes of nonterminal A

In the body of function A we need to both parse and handle attributes

- 1 Decide upon the production used to expand A
- 2 Check that each terminal appears on the input when it is required We shall assume that no backtracking is needed but the extension to recur sive descent parsing with backtracking can be done by restoring the input position upon failure as discussed in Section 4 4 1

5 5 IMPLEMENTING L ATTRIBUTED SDD S

- 3 Preserve in local variables the values of all attributes needed to compute inherited attributes for nonterminals in the body or synthesized attributes for the head nonterminal
- 4 Call functions corresponding to nonterminals in the body of the selected production providing them with the proper arguments Since the un derlying SDD is L attributed we have already computed these attributes and stored them in local variables

Example 5 20 Let us consider the SDD and SDT of Example 5 19 for while statements A pseudocode rendition of the relevant parts of the function S appears in Fig. 5 29

```
string S label next {
       string Scode Ccode
                                     local variables holding code fragments
       label L1 L2
                             the local labels
       if current input
                                   token while
                advance input
                check '' is next on the input and advance
                L1
                       new
                L2
                      new
                Ccode C next L2
               check^{\prime} ^{\prime} is next on the input % \left( 1\right) =\left( 1\right) \left( 1\right)  and advance
                Scode S L1
                return label \parallel L1 \parallel Ccode \parallel label \parallel L2 \parallel Scode
       else
                 other statement types
}
```

Figure 5 29 Implementing while statements with a recursive descent parser

We show S as storing and returning long strings. In practice it would be far more e-cient for functions like S and C to return pointers to records that represent these strings. Then the return statement in function S would not physically concatenate the components shown but rather would construct a record or perhaps tree of records expressing the concatenation of the strings represented by Scode and Ccode the labels L1 and L2 and the two occurrences of the literal string. Label.

Example 5 21 Now let us take up the SDT of Fig 5 26 for typesetting boxes First we address parsing since the underlying grammar in Fig 5 26 is ambiguous. The following transformed grammar makes juxtaposition and subscripting right associative with **sub** taking precedence over juxtaposition.

The two new nonterminals T and F are motivated by terms and factors in expressions. Here a factor generated by F is either a parenthesized box or a text string. A term generated by T is a factor with a sequence of subscripts and a box generated by B is a sequence of juxtaposed terms

The attributes of B carry over to T and F since the new nonterminals also denote boxes they were introduced simply to aid parsing. Thus, both T and F have an inherited attribute ps and synthesized attributes ht and dp with semantic actions that can be adapted from the SDT in Fig. 5.26

The grammar is not yet ready for top down parsing since the productions for B and T have common pre xes. Consider T for instance. A top down parser cannot choose between the two productions for T by looking one symbol ahead in the input. Fortunately, we can use a form of left factoring discussed in Section 4.3.4 to make the grammar ready. With SDT is the notion of common pre-x applies to actions as well. Both productions for T begin with the nonterminal F inheriting attribute ps from T

The pseudocode in Fig. 5 30 for T ps folds in the code for F ps After left factoring is applied to T F $\operatorname{sub} T_1 \mid F$ there is only one call to F the pseudocode shows the result of substituting the code for F in place of this call

The function T will be called as T 100 by the function for B which we do not show. It returns a pair consisting of the height and depth of the box generated by nonterminal T in practice it would return a record containing the height and depth

Function T begins by checking for a left parenthesis in which case it must have the production F — B to work with It saves whatever the B inside the parentheses returns but if that B is not followed by a right parenthesis then there is a syntax error which must be handled in a manner not shown

Otherwise if the current input is text then the function T uses getHt and getDp to determine the height and depth of this text

T then decides whether the next box is a subscript and adjusts the point size if so We use the actions associated with the production B B sub B in Fig. 5.26 for the height and depth of the larger box. Otherwise we simply return what F would have returned h1 d1

5 5 2 On The Fly Code Generation

The construction of long strings of code that are attribute values as in Ex ample 5 20 is undesirable for several reasons including the time it could take to copy or move long strings. In common cases such as our running code generation example, we can instead incrementally generate pieces of the code into an array or output the by executing actions in an SDT. The elements we need to make this technique work are

5 5 IMPLEMENTING L ATTRIBUTED SDD S

```
oat T oat ps {
       oat h1 h2 d1 d2
                            locals to hold heights and depths
         start code for F ps
      if current input
            advance input
             h1 d1
                      B ps
                                   syntax error expected ''
            if current input
            advance input
      else if current input
                               text {
            let lexical value text lexval be t
            advance input
            h1
                 getHt ps t
                 qetDp ps t
            d1
      else syntax error expected text or ''
         end code for F ps
      if current input
            advance input
             h2 d2
                      T 07 ps
            return \max h1 \ h2
                                 0.25 ps
                                            \max d1 d2
      return h1 d1
}
```

Figure 5 30 Recursive descent typesetting of boxes

- 1 There is for one or more nonterminals a main attribute. For convenience we shall assume that the main attributes are all string valued. In Example 5 20, the attributes S code and C code are main attributes, the other attributes are not
- 2 The main attributes are synthesized
- 3 The rules that evaluate the main attribute s ensure that
 - a The main attribute is the concatenation of main attributes of non terminals appearing in the body of the production involved perhaps with other elements that are not main attributes such as the string label or the values of labels L1 and L2
 - b The main attributes of nonterminals appear in the rule in the same order as the nonterminals themselves appear in the production body

As a consequence of the above conditions the main attribute can be constructed by emitting the non-main attribute elements of the concatenation. We can rely

The Type of Main Attributes

Our simplifying assumption that main attributes are of string type is really too restrictive. The true requirement is that the type of all the main attributes must have values that can be constructed by concatenation of elements. For instance, a list of objects of any type would be appropriate as long as we represent these lists in a way that allows elements to be elemently appended to the end of the list. Thus, if the purpose of the main attribute is to represent a sequence of intermediate code statements we could produce the intermediate code by writing statements to the end of an array of objects. Of course the requirements stated in Section 5.5.2 still apply to lists for example main attributes must be assembled from other main attributes by concatenation in order

on the recursive calls to the functions for the nonterminals in a production body to emit the value of their main attribute incrementally

Example 5 22 We can modify the function of Fig. 5 29 to emit elements of the main translation S code instead of saving them for concatenation into a return value of S code. The revised function S appears in Fig. 5 31

```
void S label next {
      label L1 L2
                      the local labels
      if current input
                          token while {
            advance input
            check '' is next on the input and advance
            L1
                 new
            L2
                 new
            print label L1
            C next L2
            check '' is next on the input and advance
            print label L2
            S L1
      else
             other statement types
}
```

Figure 5 31 On the y recursive descent code generation for while statements

In Fig 5 31 S and C now have no return value since their only synthesized attributes are produced by printing. Further the position of the print state ments is significant. The order in which output is printed is S rst label S then the code for S which is the same as the value of S rst label S then

5 5 IMPLEMENTING L ATTRIBUTED SDD S

label L2 and nally the code from the recursive call to S which is the same as Scode in Fig. 5.29. Thus the code printed by this call to S is exactly the same as the return value in Fig. 5.29. \Box

Incidentally we can make the same change to the underlying SDT turn the construction of a main attribute into actions that emit the elements of that attribute In Fig 5 32 we see the SDT of Fig 5 28 revised to generate code on the $\,$ v

Figure 5 32 SDT for on the y code generation for while statements

5 5 3 L Attributed SDD s and LL Parsing

Suppose that an L attributed SDD is based on an LL grammar and that we have converted it to an SDT with actions embedded in the productions as described in Section 5 4 5. We can then perform the translation during LL parsing by extending the parser stack to hold actions and certain data items needed for attribute evaluation. Typically, the data items are copies of attributes.

In addition to records representing terminals and nonterminals the parser stack will hold *action records* representing actions to be executed and *synth esize records* to hold the synthesized attributes for nonterminals. We use the following two principles to manage attributes on the stack

The inherited attributes of a nonterminal A are placed in the stack record that represents that nonterminal. The code to evaluate these attributes will usually be represented by an action record immediately above the stack record for A in fact, the conversion of L attributed SDD s to SDT s ensures that the action record will be immediately above A

The synthesized attributes for a nonterminal A are placed in a separate synthesize record that is immediately below the record for A on the stack

This strategy places records of several types on the parsing stack trusting that these variant record types can be managed properly as subclasses of a stack record class. In practice we might combine several records into one but the ideas are perhaps best explained by separating data used for dierent purposes into dierent records.

Action records contain pointers to code to be executed Actions may also appear in synthesize records these actions typically place copies of the synthe sized attribute s in other records further down the stack where the value of

that attribute will be needed after the synthesize record and its attributes are popped o the stack

Let us take a brief look at LL parsing to see the need to make temporary copies of attributes From Section 4 4 4 a table driven LL parser mimics a leftmost derivation. If w is the input that has been matched so far then the stack holds a sequence of grammar symbols such that S w where S is the start symbol. When the parser expands by a production A B C it replaces A on top of the stack by B C

Suppose nonterminal C has an inherited attribute C i With A B C the inherited attribute C i may depend not only on the inherited attributes of A but on all the attributes of B. Thus we may need to process B completely before C i can be evaluated. We therefore save temporary copies of all the attributes needed to evaluate C i in the action record that evaluates C i. Otherwise when the parser replaces A on top of the stack by B C the inherited attributes of A will have disappeared along with its stack record

Since the underlying SDD is L attributed we can be sure that the values of the inherited attributes of A are available when A rises to the top of the stack. The values will therefore be available in time to be copied into the action record that evaluates the inherited attributes of C. Furthermore space for the synthesized attributes of A is not a problem since the space is in the synthesize record for A which remains on the stack below B and C when the parser expands by A and B C

As B is processed we can perform actions through a record just above B on the stack that copy its inherited attributes for use by C as needed and after B is processed the synthesize record for B can copy its synthesized attributes for use by C if needed Likewise synthesized attributes of A may need temporaries to help compute their value and these can be copied to the synthesize record for A as B and then C are processed. The principle that makes all this copying of attributes work is

All copying takes place among the records that are created during one expansion of one nonterminal. Thus each of these records knows how far below it on the stack each other record is and can write values into the records below safely

The next example illustrates the implementation of inherited attributes during LL parsing by diligently copying attribute values. Shortcuts or optimizations are possible particularly with copy rules which simply copy the value of one attribute into another. Shortcuts are deferred until Example 5.24 which also illustrates synthesize records

Example 5 23 This example implements the SDT of Fig 5 32 which gener ates code on the y for the while production This SDT does not have synthe sized attributes except for dummy attributes that represent labels

Figure 5 33 a shows the situation as we are about to use the while production to expand S presumably because the lookahead symbol on the input is

5 5 IMPLEMENTING L ATTRIBUTED SDD S

while The record at the top of stack is for S and it contains only the inherited attribute S next which we suppose has the value x Since we are now parsing top down we show the stack top at the left according to our usual convention

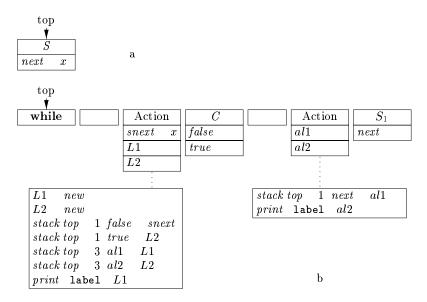

Figure 5 33 Expansion of S according to the while statement production

Figure 5 33 b shows the situation immediately after we have expanded S. There are action records in front of the nonterminals C and S_1 corresponding to the actions in the underlying SDT of Fig. 5 32. The record for C has room for inherited attributes true and false while the record for S_1 has room for attribute next as all S records must. We show values for these elds as because we do not yet know their values

The parser next recognizes **while** and on the input and pops their records of the stack. Now the restriction is at the top and it must be executed. This action record has a fine eld snext which holds a copy of the inherited attribute S next. When S is popped from the stack the value of S next is copied into the fine eld snext for use during the evaluation of the inherited attributes for C. The code for the first action generates new values for E E which we shall suppose are E and E respectively. The next step is to make E the value of E E is written knowing it is only executed when this action record is at the top of stack so E E E refers to the record below it the record for E

The rst action record then copies L1 into eld al1 in the second action where it will be used to evaluate S_1 next It also copies L2 into a eld called al2 of the second action this value is needed for that action record to print its output properly Finally the rst action record prints label y to the output

The situation after completing the rst action and popping its record o

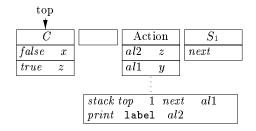

Figure 5 34 After the action above C is performed

the stack is shown in Fig. 5-34. The values of inherited attributes in the record for C have been led in properly as have the temporaries al1 and al2 in the second action record. At this point C is expanded and we presume that the code to implement its test containing jumps to labels x and z as appropriate is generated. When the C record is popped from the stack the record for becomes top and causes the parser to check for on its input

With the action above S_1 at the top of the stack its code sets S_1 next and emits label z. When that is done the record for S_1 becomes the top of stack and as it is expanded we presume it correctly generates code that implements whatever kind of statement it is and then jump to label y.

Example 5 24 Now let us consider the same while statement but with a translation that produces the output S code as a synthesized attribute rather than by on the y generation. In order to follow the explanation it is useful to bear in mind the following invariant or inductive hypothesis which we assume is followed for every nonterminal

Every nonterminal that has code associated with it leaves that code as a string in the synthesize record just below it on the stack

Assuming this statement is true we shall handle the while production so it maintains this statement as an invariant

Figure 5 35 a shows the situation just before S is expanded using the production for while statements. At the top of the stack we see the record for S it has a eld for its inherited attribute S next as in Example 5 23. Immediately below that record is the synthesize record for this occurrence of S. The latter has a eld for S code as all synthesize records for S must have. We also show it with some other elds for local storage and actions since the SDT for the while production in Fig. 5 28 is surely part of a larger SDT.

Our expansion of S is based on the SDT of Fig. 5.28 and it is shown in Fig. 5.35 b. As a shortcut during the expansion, we assume that the inherited attribute S next is assigned directly to C false rather than being placed in the rst action and then copied into the record for C

Let us examine what each record does when it becomes the top of stack First the **while** record causes the token **while** to be matched with the input

5 5 IMPLEMENTING L ATTRIBUTED SDD S

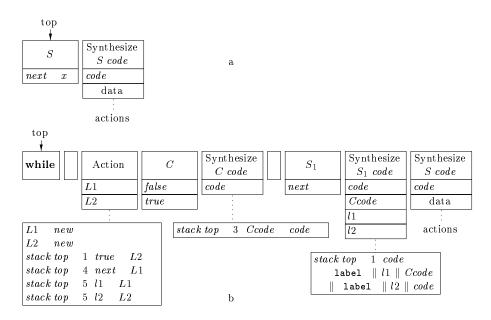

Figure 5 35 Expansion of S with synthesized attribute constructed on the stack

which it must or else we would not have expanded S in this way. After **while** and are popped of the stack the code for the action record is executed. It generates values for L1 and L2 and we take the shortcut of copying them directly to the inherited attributes that need them S_1 next and C true. The last two steps of the action cause L1 and L2 to be copied into the record called Synthesize S_1 code.

The synthesize record for S_1 does double duty not only will it hold the synthesized attribute S_1 code but it will also serve as an action record to complete the evaluation of the attributes for the entire production S while C S_1 In particular when it gets to the top it will compute the synthesized attribute S code and place its value in the synthesize record for the head S

When C becomes the top of the stack it has both its inherited attributes computed. By the inductive hypothesis stated above, we suppose it correctly generates code to execute its condition and jump to the proper label. We also assume that the actions performed during the expansion of C correctly place this code in the record below as the value of synthesized attribute C code

After C is popped the synthesize record for C code becomes the top—Its code is needed in the synthesize record for S_1 code—because that is where we concatenate all the code elements to form S code—The synthesize record for C code therefore has an action to copy C code into the synthesize record for S_1 code—After doing so the record for token—reaches the top of stack—and causes a check for—on the input—Assuming that test succeeds—the record for S_1 becomes the top of stack—By our inductive hypothesis—this nonterminal is

Can We Handle L Attributed SDD s on LR Grammars

In Section 5 4 1 we saw that every S attributed SDD on an LR grammar can be implemented during a bottom up parse From Section 5 5 3 every L attributed SDD on an LL grammar can be parsed top down Since LL grammars are a proper subset of the LR grammars and the S attributed SDD s are a proper subset of the L attributed SDD s can we handle every LR grammar and L attributed SDD bottom up

We cannot as the following intuitive argument shows Suppose we have a production A B C in an LR grammar and there is an inherited attribute B i that depends on inherited attributes of A When we reduce to B we still have not seen the input that C generates so we cannot be sure that we have a body of production A B C Thus we cannot compute B i yet since we are unsure whether to use the rule associated with this production

Perhaps we could wait until we have reduced to C and know that we must reduce B C to A However even then we do not know the inherited attributes of A because even after reduction we may not be sure of the production body that contains this A We could reason that this decision too should be deferred and therefore further defer the computation of B i If we keep reasoning this way we soon realize that we cannot make any decisions until the entire input is parsed Essentially we have reached the strategy of build the parse tree—rst and then perform the translation

expanded and the net e ect is that its code is correctly constructed and placed in the eld for code in the synthesize record for S_1

Now all the data elds of the synthesize record for S_1 have been lled in so when it becomes the top of stack the action in that record can be executed. The action causes the labels and code from C code and S_1 code to be concatenated in the proper order. The resulting string is placed in the record below that is in the synthesize record for S. We have now correctly computed S code and when the synthesize record for S becomes the top-that code is available for placement in another record further down the stack where it will eventually be assembled into a larger string of code implementing a program element of which this S is a part \Box

5 5 4 Bottom Up Parsing of L Attributed SDD s

We can do bottom up every translation that we can do top down More precisely given an L attributed SDD on an LL grammar we can adapt the grammar to compute the same SDD on the new grammar during an LR parse The trick has three parts

5.5 IMPLEMENTING L ATTRIBUTED SDD S

- 1 Start with the SDT constructed as in Section 5 4 5 which places embed ded actions before each nonterminal to compute its inherited attributes and an action at the end of the production to compute synthesized at tributes
- 2 Introduce into the grammar a marker nonterminal in place of each embedded action Each such place gets a distinct marker and there is one production for any marker M namely M
- 3 Modify the action a if marker nonterminal M replaces it in some production A {a} and associate with M an action a' that
 - a Copies as inherited attributes of M any attributes of A or symbols of that action a needs
 - b Computes attributes in the same way as a but makes those at tributes be synthesized attributes of M

This change appears illegal since typically the action associated with production M will have to access attributes belonging to grammar symbols that do not appear in this production. However, we shall implement the actions on the LR parsing stack so the necessary attributes will always be available a known number of positions down the stack

Example 5 25 Suppose that there is a production A = BC in an LL gram mar and the inherited attribute Bi is computed from inherited attribute Ai by some formula Bi = fAi That is the fragment of an SDT we care about is

$$A = \{B i \mid f A i \} B C$$

We introduce marker M with inherited attribute M i and synthesized attribute M s. The former will be a copy of A i and the latter will be B i. The SDT will be written

Notice that the rule for M does not have A i available to it but in fact we shall arrange that every inherited attribute for a nonterminal such as A appears on the stack immediately below where the reduction to A will later take place. Thus when we reduce to M we shall not A i immediately below it from where it may be read. Also the value of M s which is left on the stack along with M is really B i and properly is found right below where the reduction to B will later occur. \Box

Example 5 26 Let us turn the SDT of Fig. 5 28 into an SDT that can operate with an LR parse of the revised grammar. We introduce a marker M before C and a marker N before S_1 so the underlying grammar becomes

Why Markers Work

Markers are nonterminals that derive only and that appear only once among all the bodies of all productions We shall not give a formal proof that when a grammar is LL marker nonterminals can be added at any position in the body and the resulting grammar will still be LR The intuition however is as follows If a grammar is LL then we can determine that a string w on the input is derived from nonterminal A in a derivation that starts with production A by seeing only the rst symbol of w or the following symbol if wThus if we parse w bottom up then the fact that a pre x of w must be reduced to x and then to x is known as soon as the beginning of w appears on the input In particular if we insert markers anywhere in the LR states will incorporate the fact that this marker has to be there and will reduce to the marker at the appropriate point on the input

$$egin{array}{lll} S & & & \mathbf{while} & M & C & N & S_1 \\ M & & & & & \\ N & & & & & \end{array}$$

Before we discuss the actions that are associated with markers M and N let us outline the inductive hypothesis about where attributes are stored

- 1 Below the entire body of the while production—that is below **while** on the stack—will be the inherited attribute *S next*—We may not know the nonterminal or parser state associated with this stack record—but we can be sure that it will have a—eld—in a—xed position of the record—that holds *S next* before we begin to recognize what is derived from this *S*—
- 2 Inherited attributes C true and C false will be just below the stack record for C Since the grammar is presumed to be LL the appearance of **while** on the input assures us that the while production is the only one that can be recognized so we can be sure that M will appear immediately below C on the stack and M s record will hold the inherited attributes of C
- 3 Similarly the inherited attribute S_1 next must appear immediately below S_1 on the stack so we may place that attribute in the record for N
- 4 The synthesized attribute C code will appear in the record for C As always when we have a long string as an attribute value we expect that in practice a pointer to an object representing the string will appear in the record while the string itself is outside the stack
- 5 Similarly the synthesized attribute S_1 code will appear in the record for S_1

5.5 IMPLEMENTING L ATTRIBUTED SDD S

Let us follow the parsing process for a while statement. Suppose that a record holding S next appears on the top of the stack and the next input is the terminal **while**. We shift this terminal onto the stack. It is then certain that the production being recognized is the while production so the LR parser can shift—and determine that its next step must be to reduce—to M—The stack at this time is shown in Fig. 5.36. We also show in that—gure the action that is associated with the reduction to M—We create values for L1 and L2—which live in—elds of the M record. Also in that record are—elds for C true and C false—These attributes must be in the second and third—elds of the record for consistency with other stack records that might appear below C in other contexts and also must provide these attributes for C—The action completes by assigning values to C true and C false—one from the L2 just generated—and the other by reaching down the stack to where we know S next is found

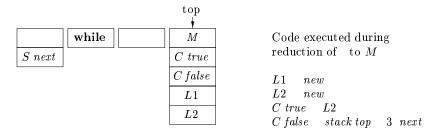

Figure 5 36 LR parsing stack after reduction of to M

We presume that the next inputs are properly reduced to C The synthesized attribute $C\ code$ is therefore placed in the record for C This change to the stack is shown in Fig. 5.37 which also incorporates the next several records that are later placed above C on the stack

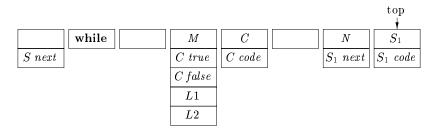

Figure 5 37 Stack just before reduction of the while production body to S

Continuing with the recognition of the while statement the parser should next nd on the input which it pushes onto the stack in a record of its own At that point the parser which knows it is working on a while statement because the grammar is LL will reduce to N. The single piece of data associated with N is the inherited attribute S_1 next. Note that this attribute needs

to be in the record for N because that will be just below the record for S_1 The code that is executed to compute the value of S_1 next is

```
S_1 next stack top 3 L1
```

This action reaches three records below N which is at the top of stack when the code is executed and retrieves the value of L1

Next the parser reduces some pre x of the remaining input to S which we have consistently referred to as S_1 to distinguish it from the S at the head of the production. The value of S_1 code is computed and appears in the stack record for S_1 . This step takes us to the condition that is illustrated in Fig. 5.37.

At this point the parser will reduce everything from while to S_1 to S The code that is executed during this reduction is

That is we construct the value of S code in a variable tempCode That code is the usual consisting of the two labels L1 and L2 the code for C and the code for S_1 The stack is popped so S appears where **while** was The value of the code for S is placed in the code eld of that record where it can be interpreted as the synthesized attribute S code. Note that we do not show in any of this discussion the manipulation of LR states which must also appear on the stack in the eld that we have populated with grammar symbols.

Exercise 5 5 1 Implement each of your SDD s of Exercise 5 4 4 as a recursive descent parser in the style of Section 5 5 1

Exercise 5 5 2 Implement each of your SDD s of Exercise 5 4 4 as a recursive descent parser in the style of Section 5 5 2

Exercise 5 5 3 Implement each of your SDD s of Exercise 5 4 4 with an LL parser in the style of Section 5 5 3 with code generated on the y

Exercise 5 5 4 Implement each of your SDD s of Exercise 5 4 4 with an LL parser in the style of Section 5 5 3 but with code or pointers to the code stored on the stack

Exercise 5 5 5 Implement each of your SDDs of Exercise 5 4 4 with an LR parser in the style of Section 5 5 4

Exercise 5 5 6 Implement your SDD of Exercise 5 2 4 in the style of Section 5 5 1 Would an implementation in the style of Section 5 5 2 be any dier ent

5 6 Summary of Chapter 5

- ◆ Inherited and Synthesized Attributes Syntax directed de nitions may use two kinds of attributes A synthesized attribute at a parse tree node is computed from attributes at its children An inherited attribute at a node is computed from attributes at its parent and or siblings
- ◆ Dependency Graphs Given a parse tree and an SDD we draw edges among the attribute instances associated with each parse tree node to denote that the value of the attribute at the head of the edge is computed in terms of the value of the attribute at the tail of the edge
- ◆ Cyclic De nitions In problematic SDDs we not that there are some parse trees for which it is impossible to not an order in which we can compute all the attributes at all nodes These parse trees have cycles in their associated dependency graphs It is intractable to decide whether an SDD has such circular dependency graphs
- ◆ S Attributed De nitions In an S attributed SDD all attributes are synthesized
- ◆ L Attributed De nitions In an L attributed SDD attributes may be in herited or synthesized However inherited attributes at a parse tree node may depend only on inherited attributes of its parent and on any at tributes of siblings to its left
- ◆ Syntax Trees Each node in a syntax tree represents a construct the chil dren of the node represent the meaningful components of the construct
- → Implementing S Attributed SDD s An S attributed de nition can be implemented by an SDT in which all actions are at the end of the production a post x SDT. The actions compute the synthesized attributes of the production head in terms of synthesized attributes of the symbols in the body. If the underlying grammar is LR then this SDT can be implemented on the LR parser stack.
- ◆ Eliminating Left Recursion From SDT s If an SDT has only side e ects no attributes are computed then the standard left recursion elimination algorithm for grammars allows us to carry the actions along as if they were terminals When attributes are computed we can still eliminate left recursion if the SDT is a post x SDT
- ♦ Implementing L attributed SDD s by Recursive Descent Parsing If we have an L attributed de nition on a top down parsable grammar we can build a recursive descent parser with no backtracking to implement the translation Inherited attributes become arguments of the functions for their nonterminals and synthesized attributes are returned by that function

- → Implementing L Attributed SDD s on an LL Grammar Every L attributed de nition with an underlying LL grammar can be implemented along with the parse Records to hold the synthesized attributes for a non terminal are placed below that nonterminal on the stack while inherited attributes for a nonterminal are stored with that nonterminal on the stack Action records are also placed on the stack to compute attributes at the appropriate time
- → Implementing L Attributed SDD s on an LL Grammar Bottom Up An L attributed de nition with an underlying LL grammar can be converted to a translation on an LR grammar and the translation performed in connection with a bottom up parse The grammar transformation introduces marker nonterminals that appear on the bottom up parser s stack and hold inherited attributes of the nonterminal above it on the stack Synthesized attributes are kept with their nonterminal on the stack

Chapter 6

Intermediate Code Generation

In the analysis synthesis model of a compiler the front end analyzes a source program and creates an intermediate representation from which the back end generates target code. Ideally details of the source language are connected to the front end and details of the target machine to the back end. With a suitably dened intermediate representation a compiler for language i and machine j can then be built by combining the front end for language i with the back end for machine j. This approach to creating suite of compilers can save a considerable amount of e ort m of n compilers can be built by writing just m front ends and n back ends

This chapter deals with intermediate representations static type checking and intermediate code generation. For simplicity, we assume that a compiler front end is organized as in Fig. 6.1 where parsing static checking and intermediate code generation are done sequentially sometimes they can be combined and folded into parsing. We shall use the syntax directed formalisms of Chapters 2 and 5 to specify checking and translation. Many of the translation schemes can be implemented during either bottom up or top down parsing using the techniques of Chapter 5. All schemes can be implemented by creating a syntax tree and then walking the tree.

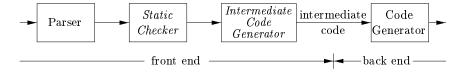

Figure 6.1 Logical structure of a compiler front end

Static checking includes type checking which ensures that operators are applied to compatible operands. It also includes any syntactic checks that remain

after parsing For example static checking assures that a break statement in C is enclosed within a while for or switch statement an error is reported if such an enclosing statement does not exist

The approach in this chapter can be used for a wide range of intermediate representations including syntax trees and three address code both of which were introduced in Section 2.8. The term—three address code—comes from instructions of the general form x-y op z with three addresses—two for the operands y and z and one for the result x

In the process of translating a program in a given source language into code for a given target machine a compiler may construct a sequence of intermediate representations as in Fig 6.2. High level representations are close to the source language and low level representations are close to the target machine. Syntax trees are high level, they depict the natural hierarchical structure of the source program and are well suited to tasks like static type checking.

Figure 6.2 A compiler might use a sequence of intermediate representations

A low level representation is suitable for machine dependent tasks like register allocation and instruction selection. Three address code can range from high to low level depending on the choice of operators. For expressions, the discrences between syntax trees and three address code are supericial as we shall see in Section 6.2.3. For looping statements for example, a syntax tree represents the components of a statement, whereas three address code contains labels and jump instructions to represent the low of control as in machine language.

The choice or design of an intermediate representation varies from compiler to compiler. An intermediate representation may either be an actual language or it may consist of internal data structures that are shared by phases of the compiler. C is a programming language yet it is often used as an intermediate form because it is exible it compiles into expect cient machine code and its compilers are widely available. The original C compiler consisted of a front end that generated C treating a C compiler as a back end

6 1 Variants of Syntax Trees

Nodes in a syntax tree represent constructs in the source program the children of a node represent the meaningful components of a construct. A directed acyclic graph hereafter called a DAG for an expression identities the common subexpressions subexpressions that occur more than once of the expression. As we shall see in this section DAG s can be constructed by using the same techniques that construct syntax trees

6 1 VARIANTS OF SYNTAX TREES

6 1 1 Directed Acyclic Graphs for Expressions

Like the syntax tree for an expression a DAG has leaves corresponding to atomic operands and interior nodes corresponding to operators. The difference is that a node N in a DAG has more than one parent if N represents a common subexpression in a syntax tree, the tree for the common subexpression would be replicated as many times as the subexpression appears in the original expression. Thus, a DAG not only represents expressions more succinctly it gives the compiler important clues regarding the generation of expressions.

Example 6 1 Figure 6 3 shows the DAG for the expression

aa b c b c d

The leaf for a has two parents because a appears twice in the expression More interestingly the two occurrences of the common subexpression b c are represented by one node the node labeled. That node has two parents representing its two uses in the subexpressions a b c and b c d Even though b and c appear twice in the complete expression their nodes each have one parent since both uses are in the common subexpression b c \Box

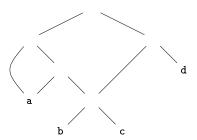

Figure 6.3 Dag for the expression a a b c b c d

The SDD of Fig 6.4 can construct either syntax trees or DAG s. It was used to construct syntax trees in Example 5.11 where functions Leaf and Node created a fresh node each time they were called. It will construct a DAG if before creating a new node these functions are check whether an identical node already exists. If a previously created identical node exists the existing node is returned. For instance, before constructing a new node Node op left right, we check whether there is already a node with label op and children left and right in that order. If so Node returns the existing node otherwise it creates a new node.

Example 6 2 The sequence of steps shown in Fig 6 5 constructs the DAG in Fig 6 3 provided *Node* and *Leaf* return an existing node if possible as

	PRODUCTION		SEMANTIC RULES

13
      p_{13}
```

Figure 6.5 Steps for constructing the DAG of Fig. 6.3

discussed above We assume that entry a points to the symbol table entry for a and similarly for the other identifiers

When the call to *Leaf* id *entry a* is repeated at step 2 the node created by the previous call is returned so p_2-p_1 . Similarly the nodes returned at steps 8 and 9 are the same as those returned at steps 3 and 4 i.e. p_8-p_3 and p_9-p_4 . Hence the node returned at step 10 must be the same at that returned at step 5 i.e. $p_{10}-p_5$.

6 1 2 The Value Number Method for Constructing DAG s

Often the nodes of a syntax tree or DAG are stored in an array of records as suggested by Fig 6 6 Each row of the array represents one record and therefore one node. In each record, the rst eld is an operation code indicating the label of the node. In Fig 6 6 b, leaves have one additional eld which holds the lexical value, either a symbol table pointer or a constant in this case, and

6 1 VARIANTS OF SYNTAX TREES

interior nodes have two additional elds indicating the left and right children

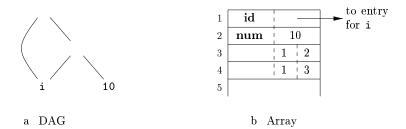

Figure 6.6 Nodes of a DAG for i = 10 allocated in an array

In this array we refer to nodes by giving the integer index of the record for that node within the array. This integer historically has been called the value number for the node or for the expression represented by the node. For instance in Fig. 6.6 the node labeled—has value number 3 and its left and right children have value numbers 1 and 2 respectively. In practice, we could use pointers to records or references to objects instead of integer indexes but we shall still refer to the reference to a node as its value number. If stored in an appropriate data structure value numbers help us construct expression DAG is expression.

Suppose that nodes are stored in an array as in Fig 6.6 and each node is referred to by its value number. Let the *signature* of an interior node be the triple $\langle op \ l \ r \rangle$ where op is the label l its left child s value number and r its right child s value number. A unary operator may be assumed to have r=0

Algorithm 6 3 The value number method for constructing the nodes of a DAG

INPUT Label op node l and node r

OUTPUT The value number of a node in the array with signature $\langle op \ l \ r \rangle$

METHOD Search the array for a node M with label op left child l and right child r If there is such a node return the value number of M If not create in the array a new node N with label op left child l and right child r and return its value number \square

While Algorithm 6.3 yields the desired output—searching the entire array every time we are asked to locate one node is expensive—especially if the array holds expressions from an entire program. A more e—cient approach is to use a hash table in which the nodes are put into—buckets—each of which typically will have only a few nodes—The hash table is one of several data structures that support dictionaries e—ciently ¹ A dictionary is an abstract data type that

 $^{^1{}m See}$ Aho A V J E Hopcroft and J D Ullman *Data Structures and Algorithms* Addison Wesley 1983 for a discussion of data structures supporting dictionaries

allows us to insert and delete elements of a set and to determine whether a given element is currently in the set. A good data structure for dictionaries such as a hash table performs each of these operations in time that is constant or close to constant independent of the size of the set.

To construct a hash table for the nodes of a DAG we need a hash function h that computes the index of the bucket for a signature $\langle op\ l\ r\rangle$ in a way that distributes the signatures across buckets so that it is unlikely that any one bucket will get much more than a fair share of the nodes. The bucket index $h\ op\ l\ r$ is computed deterministically from $op\ l$ and r so that we may repeat the calculation and always get to the same bucket index for node $\langle op\ l\ r\rangle$

The buckets can be implemented as linked lists as in Fig 6.7. An array indexed by hash value holds the *bucket headers* each of which points to the rst cell of a list. Within the linked list for a bucket each cell holds the value number of one of the nodes that hash to that bucket. That is node $\langle op \ l \ r \rangle$ can be found on the list whose header is at index h op l r of the array

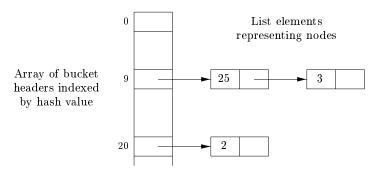

Figure 6 7 Data structure for searching buckets

Thus given the input node $op\ l$ and r we compute the bucket index $h\ op\ l\ r$ and search the list of cells in this bucket for the given input node Typically there are enough buckets so that no list has more than a few cells We may need to look at all the cells within a bucket however and for each value number v found in a cell we must check whether the signature $\langle op\ l\ r\rangle$ of the input node matches the node with value number v in the list of cells as in Fig 6.7. If we indicate a match we return v. If we indicate no match we know no such node can exist in any other bucket so we create a new cell add it to the list of cells for bucket index $h\ op\ l\ r$ and return the value number in that new cell

6 1 3 Exercises for Section 6 1

Exercise 6 1 1 Construct the DAG for the expression

6 2 THREE ADDRESS CODE

Exercise 6 1 2 Construct the DAG and identify the value numbers for the subexpressions of the following expressions assuming associates from the left

6.2 Three Address Code

In three address code there is at most one operator on the right side of an instruction that is no built up arithmetic expressions are permitted. Thus a source language expression like ${\tt x}$ ${\tt y}$ ${\tt z}$ might be translated into the sequence of three address instructions

$$egin{array}{cccc} oldsymbol{\mathsf{t}}_1 & oldsymbol{\mathsf{y}} & oldsymbol{\mathsf{z}} \ oldsymbol{\mathsf{t}}_2 & oldsymbol{\mathsf{x}} & oldsymbol{\mathsf{t}}_1 \end{array}$$

where t_1 and t_2 are compiler generated temporary names. This unraveling of multi operator arithmetic expressions and of nested ow of control statements makes three address code desirable for target code generation and optimization as discussed in Chapters 8 and 9. The use of names for the intermediate values computed by a program allows three address code to be rearranged easily

Example 6 4 Three address code is a linearized representation of a syntax tree or a DAG in which explicit names correspond to the interior nodes of the graph. The DAG in Fig. 6.3 is repeated in Fig. 6.8 together with a corresponding three address code sequence. \Box

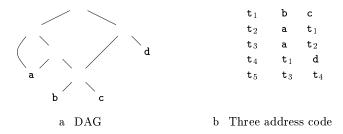

Figure 6.8 A DAG and its corresponding three address code

6 2 1 Addresses and Instructions

Three address code is built from two concepts addresses and instructions. In object oriented terms, these concepts correspond to classes, and the various kinds of addresses and instructions correspond to appropriate subclasses. Alternatively, three address code can be implemented using records with elds for the addresses, records called quadruples and triples are discussed brien y in Section 6.2.2

An address can be one of the following

A name For convenience we allow source program names to appear as addresses in three address code. In an implementation, a source name is replaced by a pointer to its symbol table entry, where all information about the name is kept.

A constant In practice a compiler must deal with many di erent types of constants and variables Type conversions within expressions are considered in Section 6.5.2

A compiler generated temporary It is useful especially in optimizing compilers to create a distinct name each time a temporary is needed. These temporaries can be combined if possible when registers are allocated to variables

We now consider the common three address instructions used in the rest of this book. Symbolic labels will be used by instructions that alter the ow of control. A symbolic label represents the index of a three address instruction in the sequence of instructions. Actual indexes can be substituted for the labels either by making a separate pass or by backpatching discussed in Section 6.7. Here is a list of the common three address instruction forms

- 1 Assignment instructions of the form x y op z where op is a binary arithmetic or logical operation and x y and z are addresses
- 2 Assignments of the form x op y where op is a unary operation Essential unary operations include unary minus logical negation and conversion operators that for example convert an integer to a oating point number
- 3 Copy instructions of the form x y where x is assigned the value of y
- 4 An unconditional jump goto L The three address instruction with label L is the next to be executed
- 5 Conditional jumps of the form if x goto L and ifFalse x goto L These instructions execute the instruction with label L next if x is true and false respectively. Otherwise the following three address instruction in sequence is executed next as usual

6 2 THREE ADDRESS CODE

- 6 Conditional jumps such as if x relop y goto L which apply a relational operator etc to x and y and execute the instruction with label L next if x stands in relation relop to y. If not the three address instruction following if x relop y goto L is executed next in sequence
- 7 Procedure calls and returns are implemented using the following instructions param x for parameters call p n and y call p n for procedure and function calls respectively and return y where y representing a returned value is optional. Their typical use is as the sequence of three address instructions

 $\begin{array}{ll} \operatorname{param} & x_1 \\ \operatorname{param} & x_2 \\ \\ \operatorname{param} & x_n \\ \operatorname{call} & p & n \end{array}$

generated as part of a call of the procedure p x_1 x_2 x_n The in teger n indicating the number of actual parameters in call p n is not redundant because calls can be nested. That is some of the rst param statements could be parameters of a call that comes after p returns its value that value becomes another parameter of the later call. The implementation of procedure calls is outlined in Section 6.9

- 8 Indexed copy instructions of the form x y i and x i y The instruction x y i sets x to the value in the location i memory units beyond location y The instruction x i y sets the contents of the location i units beyond x to the value of y
- 9 Address and pointer assignments of the form x y x y and x y. The instruction x y sets the r value of x to be the location l value of y. Presumably y is a name perhaps a temporary that denotes an expression with an l value such as $\tt A$ i $\tt j$ and x is a pointer name or temporary. In the instruction x y presumably y is a pointer or a temporary whose r value is a location. The r value of x is made equal to the contents of that location. Finally, x y sets the r value of the object pointed to by x to the r value of y

Example 6 5 Consider the statement

do i 1 while a i v

Two possible translations of this statement are shown in Fig 6.9. The translation in Fig 6.9 a uses a symbolic label L attached to the rst instruction

 $^{^2{\}rm From~Section~2~8~3}~l~$ and r values are appropriate on the left and right sides of assign ments respectively

The translation in b shows position numbers for the instructions starting arbitrarily at position 100. In both translations, the last instruction is a conditional jump to the b rst instruction. The multiplication is 8 is appropriate for an array of elements that each take 8 units of space.

Figure 6.9 Two ways of assigning labels to three address statements

The choice of allowable operators is an important issue in the design of an intermediate form. The operator set clearly must be rich enough to implement the operations in the source language. Operators that are close to machine instructions make it easier to implement the intermediate form on a target machine. However if the front end must generate long sequences of instructions for some source language operations, then the optimizer and code generator may have to work harder to rediscover the structure and generate good code for these operations.

6 2 2 Quadruples

The description of three address instructions speci es the components of each type of instruction but it does not specify the representation of these instructions in a data structure. In a compiler, these instructions can be implemented as objects or as records with elds for the operator and the operands. Three such representations are called quadruples triples and indirect triples.

A quadruple or just quad has four elds which we call op arg_1 arg_2 and result The op eld contains an internal code for the operator. For instance the three address instruction x y z is represented by placing in op y in arg_1 z in arg_2 and x in result. The following are some exceptions to this rule

- 1 Instructions with unary operators like x minus y or x y do not use arg_2 Note that for a copy statement like x y op is while for most other operations the assignment operator is implied
- 2 Operators like param use neither arg_2 nor result
- 3 Conditional and unconditional jumps put the target label in result

Example 6 6 Three address code for the assignment a b c b c appears in Fig 6 10 a The special operator minus is used to distinguish the

6 2 THREE ADDRESS CODE

The quadruples in Fig. 6 10 b implement the three address code in a

			op	arg_1	arg_2	result
1	minus c	0	minus	c	l I	t ₁
2	\mathtt{b} \mathtt{t}_1	1		b	t ₁	t 2
3	minus c	2	minus	С	l	t ₃
54	$\mathtt{b} = \mathtt{t}_3$	3		b	t ₃	t ₄
55	$t_2 = t_4$	4		t_2	t ₄	t ₅
a	t_5	5		t ₅	l I	¦ a
			•			

a Three address code

b Quadruples

Figure 6 10 Three address code and its quadruple representation

For readability we use actual identi ers like a b and c in the elds arg_1 arg_2 and result in Fig. 6.10 b instead of pointers to their symbol table entries. Temporary names can either by entered into the symbol table like programmer de ned names or they can be implemented as objects of a class Temp with its own methods

6 2 3 Triples

A triple has only three elds which we call op arg_1 and arg_2 Note that the result eld in Fig 6 10 b is used primarily for temporary names. Using triples we refer to the result of an operation x op y by its position rather than by an explicit temporary name. Thus instead of the temporary t_1 in Fig 6 10 b a triple representation would refer to position 0. Parenthesized numbers represent pointers into the triple structure itself. In Section 6.1.2 positions or pointers to positions were called value numbers.

Triples are equivalent to signatures in Algorithm 6.3. Hence the DAG and triple representations of expressions are equivalent. The equivalence ends with expressions since syntax tree variants and three address code represent control ow quite di-erently.

Example 6 7 The syntax tree and triples in Fig 6 11 correspond to the three address code and quadruples in Fig 6 10 In the triple representation in Fig 6 11 b the copy statement a t_5 is encoded in the triple representation by placing a in the arg_1 eld and 4 in the arg_2 eld \Box

A ternary operation like x i y requires two entries in the triple structure for example we can put x and i in one triple and y in the next—Similarly x y i can implemented by treating it as if it were the two instructions

Why Do We Need Copy Instructions

A simple algorithm for translating expressions generates copy instructions for assignments as in Fig 6 10 a where we copy \mathbf{t}_5 into a rather than assigning \mathbf{t}_2 \mathbf{t}_4 to a directly Each subexpression typically gets its own new temporary to hold its result and only when the assignment operator is processed do we learn where to put the value of the complete expression A code optimization pass perhaps using the DAG of Section 6 1 1 as an intermediate form can discover that \mathbf{t}_5 can be replaced by a

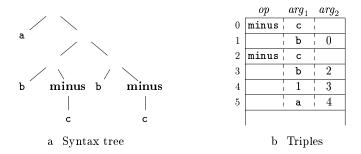

Figure 6 11 Representations of a b c b c

t-y-i and x-t where t is a compiler generated temporary. Note that the temporary t does not actually appear in a triple since temporary values are referred to by their position in the triple structure

A bene t of quadruples over triples can be seen in an optimizing compiler where instructions are often moved around. With quadruples if we move an instruction that computes a temporary t then the instructions that use t require no change. With triples, the result of an operation is referred to by its position so moving an instruction may require us to change all references to that result. This problem does not occur with indirect triples, which we consider next

Indirect triples consist of a listing of pointers to triples rather than a listing of triples themselves. For example, let us use an array instruction to list pointers to triples in the desired order. Then, the triples in Fig. 6.11 b, might be represented as in Fig. 6.12

With indirect triples an optimizing compiler can move an instruction by reordering the *instruction* list without a ecting the triples themselves. When implemented in Java an array of instruction objects is analogous to an indirect triple representation since Java treats the array elements as references to objects

6 2 THREE ADDRESS CODE

ins	structi	on	op	arg_1	arg_2

39	4	4		1	3
40	5	5		a	4

Figure 6 12 Indirect triples representation of three address code

6 2 4 Static Single Assignment Form

Static single assignment form SSA is an intermediate representation that fa cilitates certain code optimizations. Two distinctive aspects distinguish SSA from three address code. The rist is that all assignments in SSA are to variables with distinct names hence the term static single assignment. Figure 6.13 shows the same intermediate program in three address code and in static single assignment form. Note that subscripts distinguish each de nition of variables p and q in the SSA representation.

p	a	b	p_1	a	b
q	p	С	\mathtt{q}_1	p_1	С
p	q	d	\mathtt{p}_2	q_1	d
p	е	p	\mathtt{p}_3	е	p_2
q	p	q	${\tt q}_2$	p_3	q_1

a Three address code b Static single assignment form

Figure 6 13 Intermediate program in three address code and SSA

The same variable may be de ned in two di erent control ow paths in a program For example the source program

has two control ow paths in which the variable x gets de ned If we use di erent names for x in the true part and the false part of the conditional statement then which name should we use in the assignment y x a Here is where the second distinctive aspect of SSA comes into play SSA uses a notational convention called the function to combine the two de nitions of x

Here \mathbf{x}_1 \mathbf{x}_2 has the value \mathbf{x}_1 if the control ow passes through the true part of the conditional and the value \mathbf{x}_2 if the control ow passes through the false part. That is to say the function returns the value of its argument that corresponds to the control ow path that was taken to get to the assignment statement containing the function

```
i a bi cjii ai bc bdiii x fy1 2iv x py
```

Exercise 6 2 3 Show how to transform a three address code sequence into one in which each de ned variable gets a unique variable name

6 3 Types and Declarations

The applications of types can be grouped under checking and translation

Type checking uses logical rules to reason about the behavior of a program at run time. Specifically it ensures that the types of the operands match the type expected by an operator. For example, the coperator in Java expects its two operands to be booleans, the result is also of type boolean.

Translation Applications From the type of a name a compiler can de termine the storage that will be needed for that name at run time Type information is also needed to calculate the address denoted by an array reference to insert explicit type conversions and to choose the right ver sion of an arithmetic operator among other things

63 TYPES AND DECLARATIONS

In this section we examine types and storage layout for names declared within a procedure or a class. The actual storage for a procedure call or an object is allocated at run time, when the procedure is called or the object is created. As we examine local declarations at compile time, we can however lay out *relative addresses*, where the relative address of a name or a component of a data structure is an o-set from the start of a data area.

6 3 1 Type Expressions

Types have structure which we shall represent using *type expressions* a type expression is either a basic type or is formed by applying an operator called a *type constructor* to a type expression. The sets of basic types and constructors depend on the language to be checked

Example 6 8 The array type int 2 3 can be read as array of 2 arrays of 3 integers each and written as a type expression array 2 array 3 integer This type is represented by the tree in Fig. 6 14. The operator array takes two parameters a number and a type \Box

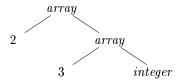

Figure 6 14 Type expression for int 2 3

We shall use the following de nition of type expressions

A basic type is a type expression Typical basic types for a language include boolean char integer oat and void the latter denotes the absence of a value

A type name is a type expression

A type expression can be formed by applying the array type constructor to a number and a type expression

A record is a data structure with named elds A type expression can be formed by applying the *record* type constructor to the eld names and their types Record types will be implemented in Section 6 3 6 by applying the constructor *record* to a symbol table containing entries for the elds

A type expression can be formed by using the type constructor for function types. We write s-t for function from type s to type t. Function types will be useful when type checking is discussed in Section 6.5

Type Names and Recursive Types

Once a class is de ned its name can be used as a type name in C or Java for example consider Node in the program fragment

public class Node

public Node n

Names can be used to de ne recursive types which are needed for data structures such as linked lists The pseudocode for a list element

class Cell int info Cell next

de nes the recursive type Cell as a class that contains a eld info and a eld next of type Cell Similar recursive types can be de ned in C using records and pointers The techniques in this chapter carry over to recursive types

If s and t are type expressions then their Cartesian product s-t is a type expression. Products are introduced for completeness they can be used to represent a list or tuple of types e.g. for function parameters. We assume that associates to the left and that it has higher precedence than

Type expressions may contain variables whose values are type expressions Compiler generated type variables will be used in Section 6 5 4

A convenient way to represent a type expression is to use a graph. The value number method of Section 6.1.2 can be adapted to construct a dag for a type expression with interior nodes for type constructors and leaves for basic types type names and type variables for example see the tree in Fig. 6.14. 3

6 3 2 Type Equivalence

When are two type expressions equivalent Many type checking rules have the form if two type expressions are equal then return a certain type else error Potential ambiguities arise when names are given to type expressions and the names are then used in subsequent type expressions. The key issue is whether a name in a type expression stands for itself or whether it is an abbreviation for another type expression

³Since type names denote type expressions they can set up implicit cycles see the box on Type Names and Recursive Types If edges to type names are redirected to the type expressions denoted by the names then the resulting graph can have cycles due to recursive types

6 3 TYPES AND DECLARATIONS

When type expressions are represented by graphs two types are *structurally* equivalent if and only if one of the following conditions is true

They are the same basic type

They are formed by applying the same constructor to structurally equivalent types

One is a type name that denotes the other

If type names are treated as standing for themselves then the rst two conditions in the above de nition lead to name equivalence of type expressions

Name equivalent expressions are assigned the same value number if we use Algorithm $6\ 3$ Structural equivalence can be tested using the unit cation algorithm in Section $6\ 5\ 5$

6 3 3 Declarations

We shall study types and declarations using a simplified grammar that declares just one name at a time declarations with lists of names can be handled as discussed in Example 5 10. The grammar is

The fragment of the above grammar that deals with basic and array types was used to illustrate inherited attributes in Section 5 3 2. The di erence in this section is that we consider storage layout as well as types

Nonterminal D generates a sequence of declarations. Nonterminal T generates basic array or record types. Nonterminal B generates one of the basic types ${\bf int}$ and ${\bf oat}$ Nonterminal C for component generates strings of zero or more integers each integer surrounded by brackets. An array type consists of a basic type specified by B followed by array components specified by nonterminal C. A record type the second production for T is a sequence of declarations for the fields of the record all surrounded by curly braces.

6 3 4 Storage Layout for Local Names

From the type of a name we can determine the amount of storage that will be needed for the name at run time. At compile time, we can use these amounts to assign each name a relative address. The type and relative address are saved in the symbol table entry for the name. Data of varying length, such as strings or data whose size cannot be determined until run time, such as dynamic arrays is handled by reserving a known axed amount of storage for a pointer to the data. Run time storage management is discussed in Chapter 7.

Address Alignment

The storage layout for data objects is strongly in uenced by the address ing constraints of the target machine. For example, instructions to add integers may expect integers to be aligned that is placed at certain positions in memory such as an address divisible by 4. Although an array of ten characters needs only enough bytes to hold ten characters a compiler may therefore allocate 12 bytes—the next multiple of 4—leaving 2 bytes unused. Space left unused due to alignment considerations is referred to as padding. When space is at a premium—a compiler may pack data so that no padding is left—additional instructions may then need to be executed at run time to position packed data so that it can be operated on as if it were properly aligned.

Suppose that storage comes in blocks of contiguous bytes where a byte is the smallest unit of addressable memory. Typically a byte is eight bits and some number of bytes form a machine word. Multibyte objects are stored in consecutive bytes and given the address of the rst byte.

The width of a type is the number of storage units needed for objects of that type A basic type such as a character integer or oat requires an integral number of bytes. For easy access storage for aggregates such as arrays and classes is allocated in one contiguous block of bytes.

The translation scheme SDT in Fig 6 15 computes types and their widths for basic and array types record types will be discussed in Section 6 3 6. The SDT uses synthesized attributes type and width for each nonterminal and two variables t and w to pass type and width information from a B node in a parse tree to the node for the production C. In a syntax directed de nition t and t would be inherited attributes for t

The body of the T production consists of nonterminal B an action and nonterminal C which appears on the next line. The action between B and C sets t to B type and w to B width. If B int then B type is set to integer and B width is set to 4 the width of an integer. Similarly, if B oat then B type is oat and B width is 8, the width of a oat

The productions for C determine whether T generates a basic type or an array type If C then t becomes C type and w becomes C width

Otherwise C speci es an array component. The action for C num C_1 forms C type by applying the type constructor array to the operands num value and C_1 type. For instance, the result of applying array might be a tree structure such as Fig. 6.14

⁴Storage allocation for pointers in C and C is simpler if all pointers have the same width. The reason is that the storage for a pointer may need to be allocated before we learn the type of the objects it can point to

6 3 TYPES AND DECLARATIONS

```
T
        B
                         \{t \mid B \ type \ w \mid B \ width \}
        C
                         \{T \ type \ C \ type \ T \ width \}
                                                          C \ width \}
                         \{ B \ type \}
B
        int
                                      integer B width
                                                           4 }
                         \{ B \ type \}
                                        oat B width
B
          oat
C
                                      t C width
                         \{ C \ type \}
C
                         \{ C \ type \}
          num
                   C_1
                                      array num value C_1 type
                           C width
                                       num value C_1 width }
```

Figure 6 15 Computing types and their widths

The width of an array is obtained by multiplying the width of an element by the number of elements in the array If addresses of consecutive integers dier by 4 then address calculations for an array of integers will include multiplications by 4 Such multiplications provide opportunities for optimization so it is helpful for the front end to make them explicit In this chapter we ignore other machine dependencies such as the alignment of data objects on word boundaries

Example 6 9 The parse tree for the type int 2 3 is shown by dotted lines in Fig 6 16. The solid lines show how the type and width are passed from B down the chain of C s through variables t and w and then back up the chain as synthesized attributes t and t and t are assigned the values of t and t are assigned the values of t and t are used at the node for t and t are used at the node for t and t are used at the node for t and t are used at the chain of t and t are used at the node for t and t are used at the node fo

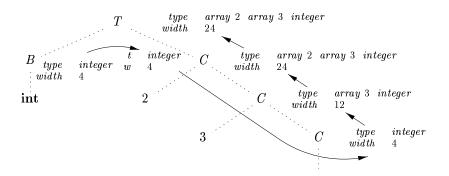

Figure 6 16 Syntax directed translation of array types

6 3 5 Sequences of Declarations

Languages such as C and Java allow all the declarations in a single procedure to be processed as a group. The declarations may be distributed within a Java procedure but they can still be processed when the procedure is analyzed. Therefore we can use a variable say o set to keep track of the next available relative address

The translation scheme of Fig 6 17 deals with a sequence of declarations of the form T id where T generates a type as in Fig 6 15. Before the rst declaration is considered o set is set to 0. As each new name x is seen x is entered into the symbol table with its relative address set to the current value of o set which is then incremented by the width of the type of x

Figure 6 17 Computing the relative addresses of declared names

The semantic action within the production D = T id D_1 creates a symbol table entry by executing top put id lexeme = T type = o set Here top denotes the current symbol table. The method top put creates a symbol table entry for id lexeme with type T type and relative address o set in its data area

The initialization of o set in Fig. 6.17 is more evident if the $\,$ rst production appears on one line as

$$P = \{ o \ set \ 0 \} D$$
 61

Nonterminals generating—called marker nonterminals—can be used to rewrite productions so that all actions appear at the ends of right sides—see Sec tion 5.5.4—Using a marker nonterminal M=6.1—can be restated as

6 3 6 Fields in Records and Classes

The translation of declarations in Fig. 6.17 carries over to elds in records and classes. Record types can be added to the grammar in Fig. 6.15 by adding the following production

$$T$$
 record '' D ''

6 3 TYPES AND DECLARATIONS

The elds in this record type are specified by the sequence of declarations generated by D. The approach of Fig. 6.17 can be used to determine the types and relative addresses of elds provided we are careful about two things

The eld names within a record must be distinct that is a name may appear at most once in the declarations generated by D

The o set or relative address for a eld name is relative to the data area for that record

Example 6 10 The use of a name x for a eld within a record does not con ict with other uses of the name outside the record. Thus the three uses of x in the following declarations are distinct and do not con ict with each other.

```
float x
record float x float y p
record int tag float x float y q
```

A subsequent assignment x p x q x sets variable x to the sum of the elds named x in the records p and q. Note that the relative address of x in p di ers from the relative address of x in q.

For convenience record types will encode both the types and relative ad dresses of their elds using a symbol table for the record type. A record type has the form $record\ t$ where record is the type constructor and t is a symbol table object that holds information about the elds of this record type

The translation scheme in Fig. 6.18 consists of a single production to be added to the productions for T in Fig. 6.15. This production has two semantic actions. The embedded action before D saves the existing symbol table denoted by top and sets top to a fresh symbol table. It also saves the current o set and sets o set to 0. The declarations generated by D will result in types and relative addresses being put in the fresh symbol table. The action after D creates a record type using top before restoring the saved symbol table and o set

Figure 6 18 Handling of eld names in records

For concreteness the actions in Fig. 6.18 give pseudocode for a special complementation. Let class Env implement symbol tables. The call Env push top pushes the current symbol table denoted by top onto a stack. Variable top is then set to a new symbol table. Similarly, o set is pushed onto a stack called Stack. Variable o set is then set to 0.

After the declarations in D have been translated the symbol table top holds the types and relative addresses of the elds in this record. Further o set gives the storage needed for all the elds. The second action sets T type to record top and T width to o set. Variables top and o set are then restored to their pushed values to complete the translation of this record type.

This discussion of storage for record types carries over to classes since no storage is reserved for methods. See Exercise $6\ 3\ 2$

6 3 7 Exercises for Section 6 3

Exercise 6 3 1 Determine the types and relative addresses for the identi ers in the following sequence of declarations

```
float x
record float x float y p
record int tag float x float y c
```

Exercise 6 3 2 Extend the handling of eld names in Fig 6 18 to classes and single inheritance class hierarchies

- a Give an implementation of class Env that allows linked symbol tables so that a subclass can either rede ne a eld name or refer directly to a eld name in a superclass
- b Give a translation scheme that allocates a contiguous data area for the elds in a class including inherited elds Inherited elds must maintain the relative addresses they were assigned in the layout for the superclass

6 4 Translation of Expressions

The rest of this chapter explores issues that arise during the translation of expressions and statements. We begin in this section with the translation of expressions into three address code. An expression with more than one operator like a b c will translate into instructions with at most one operator per in struction. An array reference A i j will expand into a sequence of three address instructions that calculate an address for the reference. We shall consider type checking of expressions in Section 6.5 and the use of boolean expressions to direct the ow of control through a program in Section 6.6

6 4 1 Operations Within Expressions

The syntax directed de nition in Fig. 6.19 builds up the three address code for an assignment statement S using attribute code for S and attributes addr and code for an expression E Attributes S code and E code denote the three address code for S and E respectively Attribute E addr denotes the address that will

6 4 TRANSLATION OF EXPRESSIONS

PRODUCTION	SEMANTIC RULES			
S id E	S code E code gen top get id lexeme ' ' E addr			
$E \hspace{1cm} E_1 \hspace{1cm} E_2$	$egin{array}{cccccccccccccccccccccccccccccccccccc$			
$\mid \hspace{0.5cm} E_1$	$egin{array}{cccccccccccccccccccccccccccccccccccc$			
$\mid \hspace{0.5cm} E_1$	$egin{array}{ccccc} E & addr & E_1 & addr \ E & code & E_1 & code \end{array}$			
id	$egin{array}{cccccccccccccccccccccccccccccccccccc$			

Figure 6 19 Three address code for expressions

hold the value of E Recall from Section 6.2.1 that an address can be a name a constant or a compiler generated temporary

Consider the last production E id in the syntax directed de nition in Fig 6 19 When an expression is a single identifier say x then x itself holds the value of the expression. The semantic rules for this production define E addr to point to the symbol table entry for this instance of id. Let top denote the current symbol table. Function top get retrieves the entry when it is applied to the string representation id lexeme of this instance of id. E code is set to the empty string

When E E_1 the translation of E is the same as that of the subex pression E_1 Hence E addr equals E_1 addr and E code equals E_1 code

The operators and unary in Fig 6 19 are representative of the operators in a typical language. The semantic rules for E E_1 E_2 generate code to compute the value of E from the values of E_1 and E_2 . Values are computed into newly generated temporary names. If E_1 is computed into E_1 addr and E_2 into E_2 addr then E_1 E_2 translates into t E_1 addr E_2 addr where t is a new temporary name. E addr is set to t A sequence of distinct temporary names t_1 t_2 is created by successively executing \mathbf{new} Temp

For convenience we use the notation $gen\ x'\ 'y'\ 'z$ to represent the three address instruction $x\ y\ z$ Expressions appearing in place of variables like $x\ y$ and z are evaluated when passed to gen and quoted strings like ' 'are taken literally ⁵ Other three address instructions will be built up similarly

 $^{^5}$ In syntax directed de nitions gen builds an instruction and returns it. In translation schemes gen builds an instruction and incrementally emits it by putting it into the stream

by applying gen to a combination of expressions and strings

When we translate the production E E_1 E_2 the semantic rules in Fig 6 19 build up E code by concatenating E_1 code E_2 code and an instruction that adds the values of E_1 and E_2 . The instruction puts the result of the addition into a new temporary name for E denoted by E adde

The translation of E E_1 is similar. The rules create a new temporary for E and generate an instruction to perform the unary minus operation

Finally the production S id E generates instructions that assign the value of expression E to the identi er id. The semantic rule for this production uses function $top\ get$ to determine the address of the identi er represented by id as in the rules for E id $S\ code$ consists of the instructions to compute the value of E into an address given by $E\ addr$ followed by an assignment to the address $top\ get$ id lexeme for this instance of id

Example 6 11 The syntax directed de nition in Fig 6 19 translates the as signment statement a b c into the three address code sequence

$$egin{array}{lll} egin{array}{lll} egin{arra$$

6 4 2 Incremental Translation

Code attributes can be long strings so they are usually generated incrementally as discussed in Section 5.5.2. Thus instead of building up E code as in Fig. 6.19 we can arrange to generate only the new three address instructions as in the translation scheme of Fig. 6.20. In the incremental approach gen not only constructs a three address instruction it appends the instruction to the sequence of instructions generated so far. The sequence may either be retained in memory for further processing or it may be output incrementally

The translation scheme in Fig. 6.20 generates the same code as the syntax directed de nition in Fig. 6.19. With the incremental approach the code at tribute is not used since there is a single sequence of instructions that is created by successive calls to gen. For example, the semantic rule for E, E_1 , E_2 in Fig. 6.20 simply calls gen to generate an add instruction, the instructions to compute E_1 into E_1 addr and E_2 into E_2 addr have already been generated

The approach of Fig. 6 20 can also be used to build a syntax tree. The new semantic action for $E=E_1$ and E_2 creates a node by using a constructor as in

$$E \qquad E_1 \quad E_2 \quad \{ \ E \ addr \qquad \mathbf{new} \ \textit{Node'} \quad ' \ E_1 \ addr \ E_2 \ addr \quad \}$$

Here attribute addr represents the address of a node rather than a variable or constant

of generated instructions

6 4 TRANSLATION OF EXPRESSIONS

Figure 6 20 Generating three address code for expressions incrementally

6 4 3 Addressing Array Elements

Array elements can be accessed quickly if they are stored in a block of consecutive locations. In C and Java array elements are numbered 0.1 n 1 for an array with n elements. If the width of each array element is w then the ith element of array A begins in location

$$base \quad i \quad w \qquad \qquad 6 \ 2$$

where base is the relative address of the storage allocated for the array That is base is the relative address of A 0

The formula 6 2 generalizes to two or more dimensions In two dimensions let us write $A i_1 i_2$ as in C for element i_2 in row i_1 Let w_1 be the width of a row and let w_2 be the width of an element in a row The relative address of $A i_1 i_2$ can then be calculated by the formula

base
$$i_1 \ w_1 \ i_2 \ w_2$$
 63

In k dimensions the formula is

$$base \quad i_1 \quad w_1 \quad i_2 \quad w_2 \qquad \qquad i_k \quad w_k \qquad \qquad 6 \ 4$$

where w_i for 1 j k is the generalization of w_1 and w_2 in 6.3

Alternatively the relative address of an array reference can be calculated in terms of the numbers of elements n_j along dimension j of the array and the width $w-w_k$ of a single element of the array. In two dimensions i.e. k-2 and $w-w_2$ —the location for A i_1 — i_2 —is given by

$$base \quad i_1 \quad n_2 \quad i_2 \quad w \qquad \qquad 6.5$$

In k dimensions the following formula calculates the same address as 6.4

base
$$i_1$$
 n_2 i_2 n_3 i_3 n_k i_k w 66

More generally array elements need not be numbered starting at 0. In a one dimensional array the array elements are numbered $low\ low\ 1$ high and base is the relative address of $A\ low$. Formula 6.2 for the address of $A\ i$ is replaced by

$$base i low w$$
 67

The expressions 6 2 and 6 7 can be both be rewritten as i-w-c where the subexpression c-base-low-w can be precalculated at compile time. Note that c-base when low is 0. We assume that c is saved in the symbol table entry for A so the relative address of A i is obtained by simply adding i-w to c

Compile time precalculation can also be applied to address calculations for elements of multidimensional arrays see Exercise 6 4 5. However, there is one situation where we cannot use compile time precalculation, when the arrays size is dynamic. If we do not know the values of low and high or their generalizations in many dimensions, at compile time, then we cannot compute constants such as c. Then formulas like 6.7 must be evaluated as they are written when the program executes

The above address calculations are based on row major layout for arrays which is used in C for example A two dimensional array is normally stored in one of two forms either $row\ major$ row by row or $column\ major$ column by column Figure 6 21 shows the layout of a 2 3 array A in a row major form and b column major form Column major form is used in the Fortran family of languages

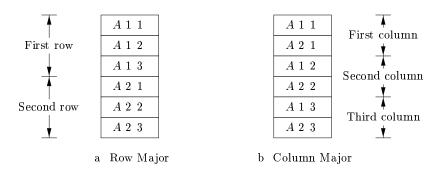

Figure 6 21 Layouts for a two dimensional array

We can generalize row or column major form to many dimensions The generalization of row major form is to store the elements in such a way that as we scan down a block of storage the rightmost subscripts appear to vary fastest like the numbers on an odometer Column major form generalizes to the opposite arrangement with the leftmost subscripts varying fastest

6 4 TRANSLATION OF EXPRESSIONS

6 4 4 Translation of Array References

The chief problem in generating code for array references is to relate the address calculation formulas in Section 6 4 3 to a grammar for array references. Let nonterminal L generate an array name followed by a sequence of index expressions

```
L \qquad L \quad E \quad | \ \mathbf{id} \quad E
```

As in C and Java assume that the lowest numbered array element is 0 Let us calculate addresses based on widths using the formula 6.4 rather than on numbers of elements as in 6.6. The translation scheme in Fig. 6.22 generates three address code for expressions with array references. It consists of the productions and semantic actions from Fig. 6.20 together with productions involving nonterminal L

```
S
                   { gen top get id lexeme ' ' E addr }
       id
           E
                   { gen L array base ' ' L addr ' ' ' ' E addr }
      L E
       E_1 E_2
                   \{ E \ addr \ \mathbf{new} \ Temp \}
                     gen\ E\ addr'\ '\ E_1\ addr'\ '\ E_2\ addr\ \}
                   \{E \ addr
                              top get id lexeme }
      id
      L
                   \{ E \ addr \ \mathbf{new} \ Temp \}
                     gen E addr'' L array base'' L addr'' }
L
       id
           E
                   \{ L \ array \}
                               top get id lexeme
                     L type
                              L\ array\ type\ elem
                     L \ addr
                               new Temp
                     gen L addr' ' E addr' ' L type width }
    L_1 E
                   { L array
                              L_1 \ array
                              L_1 type elem
                     L type
                         new Temp
                               new Temp
                     L \ addr
                     gen t'' E addr'' L type width
                     gen\ L\ addr'\ '\ L_1\ addr''\ t\ \}
```

Figure 6 22 Semantic actions for array references

Nonterminal L has three synthesized attributes

1 L addr denotes a temporary that is used while computing the o set for the array reference by summing the terms i_i w_i in 64

- 2 L array is a pointer to the symbol table entry for the array name The base address of the array say L array base is used to determine the actual l value of an array reference after all the index expressions are analyzed
- 3 L type is the type of the subarray generated by L For any type t we assume that its width is given by t width. We use types as attributes rather than widths since types are needed anyway for type checking. For any array type t suppose that t elem gives the element type

The production S id E represents an assignment to a nonarray variable which is handled as usual. The semantic action for S L E generates an indexed copy instruction to assign the value denoted by expression E to the location denoted by the array reference E Recall that attribute E array gives the symbol table entry for the array. The array E base address—the address of its 0th element—is given by E array base—Attribute E address denotes the temporary that holds the E set for the array reference generated by E. The location for the array reference is therefore E array base E address. The generated instruction copies the E value from address E address into the location for E

Productions E E_1 E_2 and E id are the same as before. The semantic action for the new production E L generates code to copy the value from the location denoted by L into a new temporary. This location is L array base L addr as discussed above for the production S L E Again attribute L array gives the array name and L array base gives its base address. Attribute L addr denotes the temporary that holds the o-set. The code for the array reference places the r-value at the location designated by the base and o-set into a new temporary denoted by E addr

Example 6 12 Let a denote a 2 3 array of integers and let c i and j all denote integers. Then the type of a is $array \ 2 \ array \ 3 \ integer$. Its width w is 24 assuming that the width of an integer is 4. The type of a i is $array \ 3 \ integer$ of width w_1 12. The type of a i j is integer

An annotated parse tree for the expression c a i j is shown in Fig 6 23. The expression is translated into the sequence of three address instructions in Fig 6 24. As usual, we have used the name of each identifier to refer to its symbol table entry. \Box

Figure 6 24 Three address code for expression c a i j

Exercise 6 4 3 Use the translation of Fig 6 22 to translate the following assignments

Exercise 6 4 4 Revise the translation of Fig. 6 22 for array references of the Fortran style that is $id E_1 E_2 E_n$ for an n dimensional array

Exercise 6 4 5 Generalize formula 6 7 to multidimensional arrays and in dicate what values can be stored in the symbol table and used to compute o sets Consider the following cases

a An array A of two dimensions in row major form. The rst dimension has indexes running from l_1 to h_1 and the second dimension has indexes from l_2 to h_2 . The width of a single array element is w

Symbolic Type Widths

The intermediate code should be relatively independent of the target machine so the optimizer does not have to change much if the code generator is replaced by one for a di erent machine. However, as we have described the calculation of type widths an assumption regarding basic types is built into the translation scheme. For instance, Example 6.12 assumes that each element of an integer array takes four bytes. Some intermediate codes e.g., P. code for Pascal leave it to the code generator to all in the size of array elements, so the intermediate code is independent of the size of a machine word. We could have done the same in our translation scheme if we replaced 4 as the width of an integer by a symbolic constant.

- b The same as a but with the array stored in column major form
- c An array A of k dimensions stored in row major form with elements of size w The jth dimension has indexes running from l_i to h_j
- d The same as c but with the array stored in column major form

Exercise 6 4 6 An integer array $A \ i \ j$ stored row major has index i ranging from 1 to 10 and index j ranging from 1 to 20 Integers take 4 bytes each Suppose array A is stored starting at byte 0 Find the location of

a A 4 5 b A 10 8 c A 3 17

Exercise 6 4 7 Repeat Exercise 6 4 6 if A is stored in column major order

Exercise 6 4 8 A real array A i j k has index i ranging from 1 to 4 j ranging from 0 to 4 and k ranging from 5 to 10 Reals take 8 bytes each If A is stored row major starting at byte 0 and the location of

Exercise 6 4 9 Repeat Exercise 6 4 8 if A is stored in column major order

6 5 Type Checking

To do type checking a compiler needs to assign a type expression to each component of the source program. The compiler must then determine that these type expressions conform to a collection of logical rules that is called the type system for the source language.

Type checking has the potential for catching errors in programs In principle any check can be done dynamically if the target code carries the type of an

65 TYPE CHECKING

element along with the value of the element A sound type system eliminates the need for dynamic checking for type errors because it allows us to determine statically that these errors cannot occur when the target program runs An implementation of a language is strongly typed if a compiler guarantees that the programs it accepts will run without type errors

Besides their use for compiling ideas from type checking have been used to improve the security of systems that allow software modules to be imported and executed Java programs compile into machine independent bytecodes that include detailed type information about the operations in the bytecodes Im ported code is checked before it is allowed to execute to guard against both inadvertent errors and malicious misbehavior

6 5 1 Rules for Type Checking

Type checking can take on two forms synthesis and inference Type synthesis builds up the type of an expression from the types of its subexpressions. It requires names to be declared before they are used. The type of E_1 is defined in terms of the types of E_1 and E_2 . A typical rule for type synthesis has the form

if
$$f$$
 has type s t and x has type s then expression f x has type t 6 8

Here f and x denote expressions and s t denotes a function from s to t. This rule for functions with one argument carries over to functions with several arguments. The rule 6.8 can be adapted for E_1 E_2 by viewing it as a function application add E_1 E_2 6

Type inference determines the type of a language construct from the way it is used Looking ahead to the examples in Section 6.5.4 let null be a function that tests whether a list is empty. Then from the usage $null\ x$ we can tell that x must be a list. The type of the elements of x is not known all we know is that x must be a list of elements of some type that is presently unknown

A typical rule for type inference has the form

if
$$f(x)$$
 is an expression then for some and f has type and x has type 69

Type inference is needed for languages like ML which check types but do not require names to be declared

 $^{^6}$ We shall use the term—synthesis—even if some context information is used to determine types—With overloaded functions where the same name is given to more than one function the context of E_1 — E_2 may also need to be considered in some languages

In this section we consider type checking of expressions. The rules for checking statements are similar to those for expressions. For example, we treat the conditional statement if E S as if it were the application of a function if to E and S. Let the special type void denote the absence of a value. Then function if expects to be applied to a boolean and a void, the result of the application is a void.

6 5 2 Type Conversions

Consider expressions like x i where x is of type oat and i is of type integer. Since the representation of integers and oating point numbers is different within a computer and different machine instructions are used for operations on integers and oats the compiler may need to convert one of the operands of to ensure that both operands are of the same type when the addition occurs

Suppose that integers are converted to oats when necessary using a unary operator float For example the integer 2 is converted to a oat in the code for the expression 2 3 14

$$\begin{array}{cccc} \texttt{t}_1 & & \texttt{float} & \texttt{2} \\ \texttt{t}_2 & & \texttt{t}_1 & \texttt{3} & \texttt{14} \end{array}$$

We can extend such examples to consider integer and oat versions of the operators for example int for integer operands and float for oats

Type synthesis will be illustrated by extending the scheme in Section 6 4 2 for translating expressions. We introduce another attribute E type whose value is either integer or oat. The rule associated with E E_1 E_2 builds on the pseudocode

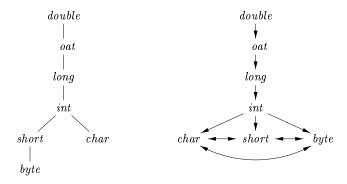

if
$$E_1$$
 type integer and E_2 type integer E type integer else if E_1 type out and E_2 type integer

As the number of types subject to conversion increases the number of cases increases rapidly. Therefore with large numbers of types careful organization of the semantic actions becomes important

Type conversion rules vary from language to language. The rules for Java in Fig. 6.25 distinguish between widening conversions which are intended to preserve information and narrowing conversions which can lose information. The widening rules are given by the hierarchy in Fig. 6.25 a any type lower in the hierarchy can be widened to a higher type. Thus, a char can be widened to an int or to a oat but a char cannot be widened to a short. The narrowing rules are illustrated by the graph in Fig. 6.25 b. a type s can be narrowed to a type t if there is a path from s to t. Note that char short and byte are pairwise convertible to each other

Conversion from one type to another is said to be *implicit* if it is done automatically by the compiler Implicit type conversions also called *coercions*

65 TYPE CHECKING

- a Widening conversions
- b Narrowing conversions

Figure 6 25 Conversions between primitive types in Java

are limited in many languages to widening conversions. Conversion is said to be *explicit* if the programmer must write something to cause the conversion Explicit conversions are also called *casts*

The semantic action for checking $E = E_1 = E_2$ uses two functions

- 1 $max t_1 t_2$ takes two types t_1 and t_2 and returns the maximum or least upper bound of the two types in the widening hierarchy. It declares an error if either t_1 or t_2 is not in the hierarchy e.g. if either type is an array or a pointer type

```
Addr widen Addr a Type t Type w

if t w return a

else if t integer and w oat {

temp new Temp
gen temp''' oat'a
return temp
}
else error
}
```

Figure 6 26 Pseudocode for function widen

The semantic action for E E_1 E_2 in Fig. 6.27 illustrates how type conversions can be added to the scheme in Fig. 6.20 for translating expressions. In the semantic action temporary variable a_1 is either E_1 addr if the type of E_1 does not need to be converted to the type of E or a new temporary variable returned by widen if this conversion is necessary. Similarly, a_2 is either E_2 addr or a new temporary holding the type converted value of E_2 . Neither conversion is needed if both types are integer or both are oat. In general, however, we could not that the only way to add values of two different types is to convert them both to a third type.

```
E \hspace{1cm} E_1 \hspace{1cm} E_2 \hspace{1cm} \set{ E \ type \hspace{1cm} max \ E_1 \ type \ E_2 \ type } \ a_1 \hspace{1cm} widen \ E_1 \ addr \ E_1 \ type \ E \ type \ a_2 \hspace{1cm} widen \ E_2 \ addr \ E_2 \ type \ E \ type \ E \ addr \hspace{1cm} \mathbf{new} \hspace{1cm} Temp \ gen \ E \ addr' \hspace{1cm} ' \hspace{1cm} ' \hspace{1cm} a_2 \hspace{1cm} \}
```

Figure 6 27 Introducing type conversions into expression evaluation

6 5 3 Overloading of Functions and Operators

An overloaded symbol has di erent meanings depending on its context. Over loading is resolved when a unique meaning is determined for each occurrence of a name. In this section, we restrict attention to overloading that can be resolved by looking only at the arguments of a function as in Java.

Example 6 13 The operator in Java denotes either string concatenation or addition depending on the types of its operands. User defined functions can be overloaded as well as in

```
void err
void err String s
```

Note that we can choose between these two versions of a function $\operatorname{\tt err}$ by looking at their arguments \Box

The following is a type synthesis rule for overloaded functions

```
if f can have type s_i t_i for 1 i n where s_i / s_j for i / j and x has type s_k for some 1 k n 6 10 then expression f x has type t_k
```

The value number method of Section 6 1 2 can be applied to type expressions to resolve overloading based on argument types e ciently. In a DAG representing a type expression we assign an integer index called a value number to each node. Using Algorithm 6 3 we construct a signature for a node

6 5 TYPE CHECKING

consisting of its label and the value numbers of its children in order from left to right. The signature for a function consists of the function name and the types of its arguments. The assumption that we can resolve overloading based on the types of arguments is equivalent to saying that we can resolve overloading based on signatures

It is not always possible to resolve overloading by looking only at the arguments of a function. In Ada instead of a single type a subexpression standing alone may have a set of possible types for which the context must provide su cient information to narrow the choice down to a single type see Exercise 6.5.2

6 5 4 Type Inference and Polymorphic Functions

Type inference is useful for a language like ML which is strongly typed but does not require names to be declared before they are used. Type inference ensures that names are used consistently

The term polymorphic refers to any code fragment that can be executed with arguments of di erent types. In this section we consider parametric polymorphism where the polymorphism is characterized by parameters or type variables. The running example is the ML program in Fig. 6.28 which de ness a function length. The type of length can be described as for any type length maps a list of elements of type—to an integer

Figure 6 28 ML program for the length of a list

Example 6 14 In Fig 6 28 the keyword **fun** introduces a function denition functions can be recursive. The program fragment denes function length with one parameter x. The body of the function consists of a conditional expression. The predented function null tests whether a list is empty and the predented function tl short for tail returns the remainder of a list after the rest element is removed.

The function length determines the length or number of elements of a list x. All elements of a list must have the same type but length can be applied to lists whose elements are of any one type. In the following expression length is applied to two different types of lists list elements are enclosed within and

The list of strings has length 3 and the list of integers has length 4 so expres sion 6 11 evaluates to 7 $\;\square$

Using the symbol \forall read as for any type and the type constructor *list* the type of *length* can be written as

$$\forall list integer$$
 6 12

The \forall symbol is the *universal quanti er* and the type variable to which it is applied is said to be *bound* by it Bound variables can be renamed at will provided all occurrences of the variable are renamed. Thus the type expression

$$\forall$$
 list integer

is equivalent to 6.12 A type expression with a \forall symbol in it will be referred to informally as a polymorphic type

Each time a polymorphic function is applied its bound type variables can denote a di erent type. During type checking at each use of a polymorphic type we replace the bound variables by fresh variables and remove the universal quanti ers.

The next example informally infers a type for *length* implicitly using type inference rules like 6 9 which is repeated here

if
$$f(x)$$
 is an expression
then for some and f has type and x has type

Example 6 15 The abstract syntax tree in Fig 6 29 represents the denition of *length* in Fig 6 28. The root of the tree labeled **fun** represents the function denition. The remaining nonleaf nodes can be viewed as function applications. The node labeled represents the application of the operator to a pair of children. Similarly, the node labeled **if** represents the application of an operator **if** to a triple formed by its children for type checking it does not matter that either the **then** or the **else** part will be evaluated but not both

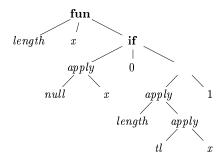

Figure 6 29 Abstract syntax tree for the function de nition in Fig 6 28

From the body of function length we can infer its type Consider the children of the node labeled **if** from left to right Since null expects to be applied to lists x must be a list Let us use variable as a placeholder for the type of the list elements that is x has type list of

Substitutions Instances and Uni cation

If t is a type expression and S is a substitution—a mapping from type variables to type expressions—then we write S t—for the result of consistently replacing all occurrences of each type variable—in t by S—S t—is called an instance of t—For example list integer—is an instance of list—since it is the result of substituting integer for—in list—Note—however that integer—oat is not an instance of—since a substitution must replace all occurrences of—by the same type expression

Substitution S is a uni er of type expressions t_1 and t_2 if S t_1 S t_2 S is the most general uni er of t_1 and t_2 if for any other uni er of t_1 and t_2 say S' it is the case that for any t S' t is an instance of S t In words S' imposes more constraints on t than S does

If $null\ x$ is true then $length\ x$ is 0. Thus the type of length must be function from list of to integer. This inferred type is consistent with the usage of length in the else part $length\ tl\ x$. 1. \Box

Since variables can appear in type expressions we have to re examine the notion of equivalence of types Suppose E_1 of type s s' is applied to E_2 of type t Instead of simply determining the equality of s and t we must unify them Informally we determine whether s and t can be made structurally equivalent by replacing the type variables in s and t by type expressions

A substitution is a mapping from type variables to type expressions. We write S t for the result of applying the substitution S to the variables in type expression t see the box on Substitutions Instances and Uni cation. Two type expressions t_1 and t_2 unify if there exists some substitution S such that S t_1 S t_2 In practice we are interested in the most general uniter which is a substitution that imposes the fewest constraints on the variables in the expressions. See Section 6.5.5 for a unit cation algorithm

Algorithm 6 16 Type inference for polymorphic functions

INPUT A program consisting of a sequence of function de nitions followed by an expression to be evaluated An expression is made up of function applications and names where names can have prede ned polymorphic types

OUTPUT Inferred types for the names in the program

METHOD For simplicity we shall deal with unary functions only. The type of a function f x_1 x_2 with two parameters can be represented by a type expression s_1 s_2 t where s_1 and s_2 are the types of x_1 and x_2 respectively and t is the type of the result f x_1 x_2 . An expression f a b can be checked by matching the type of a with s_1 and the type of b with s_2

Check the function de nitions and the expression in the input sequence Use the inferred type of a function if it is subsequently used in an expression

For a function application E_1 E_2 infer types for E_1 and E_2 Since E_1 is used as a function its type must have the form s s' Technically the type of E_1 must unify with where and are new type variables. Let t be the inferred type of E_2 . Unify s and t If unit cation fails the expression has a type error. Otherwise, the inferred type of E_1 E_2 is s'

For each occurrence of a polymorphic function replace the bound variables in its type by distinct fresh variables and remove the \forall quanti ers. The resulting type expression is the inferred type of this occurrence

For a name that is encountered for the str time introduce a fresh variable for its type

Example 6 17 In Fig 6 30 we infer a type for function length The root of the syntax tree in Fig 6 29 is for a function de nition so we introduce variables and associate the type with function length and the type with x see lines 1 2 of Fig 6 30

At the right child of the root we view **if** as a polymorphic function that is applied to a triple consisting of a boolean and two expressions that represent the **then** and **else** parts. Its type is $\forall boolean$

Each application of a polymorphic function can be to a different type so we make up a fresh variable i where i is from if and remove the \forall see line 3 of Fig 6.30. The type of the left child of **if** must unify with *boolean* and the types of its other two children must unify with i

The prede ned function null has type $\forall list boolean$ We use a fresh type variable n where n is for null in place of the bound variable see line 4. From the application of null to x we infer that the type of x must match $list_n$ see line 5.

At the rst child of **if** the type boolean for $null\ x$ matches the type expected by **if** At the second child the type $_i$ uni es with integer see line 6

Now consider the subexpression $length\ tl\ x$ 1 We make up a fresh variable t where t is for tail for the bound variable in the type of tl see line 8 From the application $tl\ x$ we infer list t list t see line 9

Since $length\ tl\ x$ is an operand of its type must unify with integer see line 10. It follows that the type of length is list n integer. After the

65 TYPE CHECKING

LINE	Expression	Түре				UNIFY		
1	length							
2	x							
3	if	boolean	i i	i				
4	null	$list$ $_{n}$	boolean					
5	null x	boolean			list	n		
6	0	integer				i	integer	
7		integer	integer	integer				
8	tl	$list$ $_t$	$list$ $_t$					
9	tl x	$list$ $_t$			list	t	$list$ $_{n}$	
10	$length\ tl\ x$						integer	
11	1	integer						
12	$length \ tl \ x$ 1	integer						
13	if	integer						

Figure 6 30 Inferring a type for the function length of Fig. 6 28

function de nition is checked the type variable n remains in the type of length Since no assumptions were made about n any type can be substituted for it when the function is used We therefore make it a bound variable and write

$$\forall n \ list n \ integer$$

for the type of length

6 5 5 An Algorithm for Uni cation

Informally uni cation is the problem of determining whether two expressions s and t can be made identical by substituting expressions for the variables in s and t Testing equality of expressions is a special case of uni cation if s and t have constants but no variables then s and t unify if and only if they are identical. The uni cation algorithm in this section extends to graphs with cycles so it can be used to test structural equivalence of circular types t

We shall implement a graph theoretic formulation of unitiation where types are represented by graphs. Type variables are represented by leaves and type constructors are represented by interior nodes. Nodes are grouped into equivalence classes if two nodes are in the same equivalence class then the type expressions they represent must unify. Thus, all interior nodes in the same class must be for the same type constructor, and their corresponding children must be equivalent.

Example 6 18 Consider the two type expressions

 $^{^7}$ In some applications it is an error to unify a variable with an expression containing that variable Algorithm 6 19 permits such substitutions

The following substitution S is the most general uni $\,$ er for these expressions

x	S x
1	1
2	2
3	1
4	2
5	list 2

This substitution maps the two type expressions to the following expression

$$_{1} \qquad _{2} \qquad \mathit{list} \quad _{1} \qquad \mathit{list} \quad _{2}$$

The two expressions are represented by the two nodes labeled $\,$ 1 in Fig. 6 31. The integers at the nodes indicate the equivalence classes that the nodes belong to after the nodes numbered 1 are united $\,$

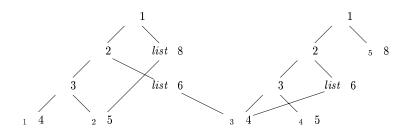

Figure 6 31 Equivalence classes after uni cation

Algorithm 6 19 Uni cation of a pair of nodes in a type graph

INPUT A graph representing a type and a pair of nodes m and n to be united

OUTPUT Boolean value true if the expressions represented by the nodes m and n unify false otherwise

METHOD A node is implemented by a record with elds for a binary operator and pointers to the left and right children. The sets of equivalent nodes are maintained using the set eld. One node in each equivalence class is chosen to be the unique representative of the equivalence class by making its set eld contain a null pointer. The set elds of the remaining nodes in the equivalence class will point possibly indirectly through other nodes in the set to the representative Initially each node n is in an equivalence class by itself with n as its own representative node

The uni cation algorithm shown in Fig 6.32 uses the following two oper ations on nodes

65 TYPE CHECKING

Figure 6 32 Uni cation algorithm

 $nd\ n$ returns the representative node of the equivalence class currently containing node n

union m n merges the equivalence classes containing nodes m and n If one of the representatives for the equivalence classes of m and n is a non variable node union makes that nonvariable node be the representative for the merged equivalence class otherwise union makes one or the other of the original representatives be the new representative. This asymmetry in the speci cation of union is important because a variable cannot be used as the representative for an equivalence class for an expression containing a type constructor or basic type. Otherwise two inequivalent expressions may be uni ed through that variable

The *union* operation on sets is implemented by simply changing the *set* eld of the representative of one equivalence class so that it points to the representative of the other. To indicate the equivalence class that a node belongs to we follow the *set* pointers of nodes until the representative the node with a null pointer in the *set* eld is reached.

Note that the algorithm in Fig. 6-32 uses s-nd-m and t-nd-n rather than m and n respectively. The representative nodes s and t are equal if m and n are in the same equivalence class. If s and t represent the same basic type the call unify-m-n returns true. If s and t are both interior nodes for a binary type constructor we merge their equivalence classes on speculation and recursively check that their respective children are equivalent. By merging rst we decrease the number of equivalence classes before recursively checking the children so the algorithm terminates

The substitution of an expression for a variable is implemented by adding the leaf for the variable to the equivalence class containing the node for that expression Suppose either m or n is a leaf for a variable Suppose also that this leaf has been put into an equivalence class with a node representing an expression with a type constructor or a basic type. Then nd will return a representative that rejects that type constructor or basic type so that a variable cannot be unified with two different expressions.

Example 6 20 Suppose that the two expressions in Example 6 18 are represented by the initial graph in Fig 6 33 where each node is in its own equivalence class. When Algorithm 6 19 is applied to compute unify 1 9 it notes that nodes 1 and 9 both represent the same operator. It therefore merges 1 and 9 into the same equivalence class and calls unify 2 10 and unify 8 14. The result of computing unify 1 9 is the graph previously shown in Fig 6 31.

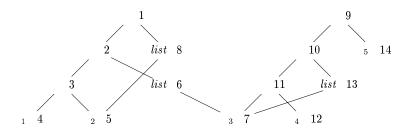

Figure 6 33 Initial graph with each node in its own equivalence class

If Algorithm 6 19 returns true we can construct a substitution S that acts as the uni er as follows. For each variable nd gives the node n that is the representative of the equivalence class of. The expression represented by n is S. For example in Fig. 6 31 we see that the representative for $_3$ is node 4 which represents $_1$. The representative for $_5$ is node 8 which represents $_{1}$. The resulting substitution S is as in Example 6 18

6 5 6 Exercises for Section 6 5

Exercise 6 5 1 Assuming that function widen in Fig 6 26 can handle any of the types in the hierarchy of Fig 6 25 a translate the expressions below Assume that c and d are characters s and t are short integers i and j are integers and x is a oat

axsc bisc

66 CONTROL FLOW

Exercise 6 5 2 As in Ada suppose that each expression must have a unique type but that from a subexpression by itself all we can deduce is a set of possible types. That is the application of function E_1 to argument E_2 represented by E_1 , E_2 has the associated rule

```
E \ type \quad \{ t \mid \text{ for some } s \text{ in } E_2 \ type \ s \quad t \text{ is in } E_1 \ type \}
```

Describe an SDD that determines a unique type for each subexpression by using an attribute *type* to synthesize a set of possible types bottom up and once the unique type of the overall expression is determined proceeds top down to determine attribute *unique* for the type of each subexpression

6 6 Control Flow

The translation of statements such as if else statements and while statements is tied to the translation of boolean expressions. In programming languages boolean expressions are often used to

- 1 Alter the ow of control Boolean expressions are used as conditional expressions in statements that alter the ow of control The value of such boolean expressions is implicit in a position reached in a program For example in **if** E S the expression E must be true if statement S is reached
- 2 Compute logical values A boolean expression can represent true or false as values Such boolean expressions can be evaluated in analogy to arith metic expressions using three address instructions with logical operators

The intended use of boolean expressions is determined by its syntactic context. For example, an expression following the keyword if is used to alter the ow of control while an expression on the right side of an assignment is used to denote a logical value. Such syntactic contexts can be specified in a number of ways, we may use two different nonterminals use inherited attributes or set a finished and approximately we may build a syntax tree and invoke different procedures for the two different uses of boolean expressions.

This section concentrates on the use of boolean expressions to alter the ow of control For clarity we introduce a new nonterminal B for this purpose In Section 6 6 6 we consider how a compiler can allow boolean expressions to represent logical values

6 6 1 Boolean Expressions

Boolean expressions are composed of the boolean operators which we denote and using the C convention for the operators AND OR and NOT respectively applied to elements that are boolean variables or relational ex pressions Relational expressions are of the form E_1 rel E_2 where E_1 and

 E_2 are arithmetic expressions. In this section, we consider boolean expressions generated by the following grammar

```
B \hspace{0.4cm} E \hspace{0.4cm} {
m rel} \hspace{0.4cm} E \hspace{0.4cm} {
m true} \hspace{0.4cm} |\hspace{0.4cm} {
m false}
```

We use the attribute $\operatorname{\mathbf{rel}} \operatorname{\mathbf{\mathit{op}}}$ to indicate which of the six comparison operators or is represented by $\operatorname{\mathbf{rel}}$ As is customary we assume that and are left associative and that has lowest precedence then then

Given the expression B_1 B_2 if we determine that B_1 is true then we can conclude that the entire expression is true without having to evaluate B_2 Similarly given B_1 B_2 if B_1 is false then the entire expression is false

The semantic de nition of the programming language determines whether all parts of a boolean expression must be evaluated. If the language de nition permits or requires portions of a boolean expression to go unevaluated then the compiler can optimize the evaluation of boolean expressions by computing only enough of an expression to determine its value. Thus, in an expression such as $B_1 - B_2$ neither B_1 nor B_2 is necessarily evaluated fully. If either B_1 or B_2 is an expression with side e ects e.g. it contains a function that changes a global variable—then an unexpected answer may be obtained

6 6 2 Short Circuit Code

In *short circuit* or *jumping* code the boolean operators and trans late into jumps. The operators themselves do not appear in the code instead the value of a boolean expression is represented by a position in the code se quence

Example 6 21 The statement

```
if x 100 x 200 x v x 0
```

might be translated into the code of Fig. 6.34. In this translation, the boolean expression is true if control reaches label L_2 . If the expression is false control goes immediately to L_1 skipping L_2 and the assignment $\mathbf{x} = \mathbf{0}$.

Figure 6 34 Jumping code

6 6 3 Flow of Control Statements

We now consider the translation of boolean expressions into three address code in the context of statements such as those generated by the following grammar

$$egin{array}{lll} S & & & \mathbf{if} & B & S_1 \ S & & & \mathbf{if} & B & S_1 & \mathbf{else} & S_2 \ S & & & \mathbf{while} & B & S_1 \ \end{array}$$

In these productions nonterminal B represents a boolean expression and non terminal S represents a statement

This grammar generalizes the running example of while expressions that we introduced in Example 5 19. As in that example both B and S have a synthe sized attribute code which gives the translation into three address instructions. For simplicity, we build up the translations B code and S code as strings us ing syntax directed de nitions. The semantic rules de ning the code attributes could be implemented instead by building up syntax trees and then emitting code during a tree traversal or by any of the approaches outlined in Section 5.5.

The translation of **if** B S_1 consists of B code followed by S_1 code as illustrated in Fig. 6.35 a. Within B code are jumps based on the value of B. If B is true control ows to the rst instruction of S_1 code and if B is false control ows to the instruction immediately following S_1 code

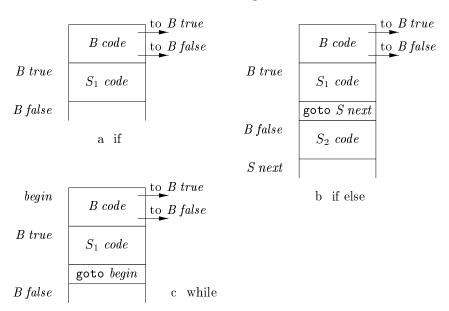

Figure 6 35 Code for if if else and while statements

The labels for the jumps in B code and S code are managed using inherited attributes. With a boolean expression B we associate two labels B true the

label to which control ows if B is true and B false the label to which control ows if B is false. With a statement S we associate an inherited attribute S next denoting a label for the instruction immediately after the code for S. In some cases, the instruction immediately following S code is a jump to some label L. A jump to a jump to L from within S code is avoided using S next.

The syntax directed de $\,$ nition in Fig. 6 36 6 37 produces three address code for boolean expressions in the context of if $\,$ if else $\,$ and while statements

Pro	DUCTION	SEMANTIC RULES		
\overline{P}	S		newlabel	
		$P \ code$	$S\ code\ \ label\ S\ next$	
S	assign	$S\ code$	$\mathbf{assign} \ code$	
S	$\mathbf{if} B S_1$		newlabel	
		B false	$S_1 \ next \qquad S \ next \qquad \qquad$	
		S code	$B \ code \parallel \ label \ B \ true \ \parallel S_1 \ code$	
S	if B S_1 else S_2		newlabel	
		B false	$newlabel \ S_2 \ next \ S \ next \ B \ code$	
		S_1 next	$S_2 \ next \qquad S \ next$	
		$S \ code$	B code	
			$ \ label\ B\ true\ \ S_1\ code$	
			$\parallel gen'goto' S next$	
			$ label B false S_2 code$	
S	while B S_1	begin	newlabel	
		B true	newlabel	
		B false	S next	
		S_1 next	$egin \ label \ begin \ \mid \mid B \ code$	
		$S \ code$		
			$\parallel label \ B \ true \ \parallel S_1 \ code$	
			$\mid\mid gen'$ goto' $begin$	
S	S_1 S_2	S_1 next	newlabel	
		_	$S\ next$	
		$S \ code$	$S_1 \ code \mid\mid label \ S_1 \ next \mid\mid S_2 \ code$	

Figure 6 36 Syntax directed de nition for ow of control statements

We assume that newlabel creates a new label each time it is called and that $label\ L$ attaches label L to the next three address instruction to be generated 8

 $^{^8}$ If implemented literally the semantic rules will generate lots of labels and may attach more than one label to a three address instruction. The backpatching approach of Section 6.7

6 6 CONTROL FLOW

A program consists of a statement generated by P-S The semantic rules associated with this production initialize S next to a new label P code consists of S code followed by the new label S next. Token **assign** in the production S assign is a placeholder for assignment statements. The translation of assignments is as discussed in Section 6.4 for this discussion of control ow S code is simply assign code

In translating S if B S_1 the semantic rules in Fig. 6.36 create a new label B true and attach it to the -rst three address instruction generated for the statement S_1 as illustrated in Fig. 6.35 a. Thus jumps to B true within the code for B will go to the code for S_1 . Further by setting B false to S next we ensure that control will skip the code for S_1 if B evaluates to false

In translating the if else statement S if B S_1 else S_2 the code for the boolean expression B has jumps out of it to the rst instruction of the code for S_1 if B is true and to the rst instruction of the code for S_2 if B is false as illustrated in Fig 6.35 b. Further control ows from both S_1 and S_2 to the three address instruction immediately following the code for S its label is given by the inherited attribute S next. An explicit goto S next appears after the code for S_1 to skip over the code for S_2 . No goto is needed after S_2 since S_2 next is the same as S next.

The code for S while B S_1 is formed from B code and S_1 code as shown in Fig. 6.35 c. We use a local variable begin to hold a new label attached to the rst instruction for this while statement which is also the rst instruction for B. We use a variable rather than an attribute because begin is local to the semantic rules for this production. The inherited label S next marks the instruction that control must ow to if B is false hence B false is set to be S next. A new label B true is attached to the rst instruction for S_1 the code for B generates a jump to this label if B is true. After the code for S_1 we place the instruction goto begin which causes a jump back to the beginning of the code for the boolean expression. Note that S_1 next is set to this label begin so jumps from within S_1 code can go directly to begin

The code for S_1 S_2 consists of the code for S_1 followed by the code for S_2 . The semantic rules manage the labels—the—rst instruction after the code for S_1 is the beginning of the code for S_2 and the instruction after the code for S_2 is also the instruction after the code for S_3 .

We discuss the translation of ow of control statements further in Section 6.7 There we shall see an alternative method called backpatching which emits code for statements in one pass

6 6 4 Control Flow Translation of Boolean Expressions

The semantic rules for boolean expressions in Fig. 6.37 complement the semantic rules for statements in Fig. 6.36. As in the code layout of Fig. 6.35. a boolean expression B is translated into three address instructions that evaluate B using

creates labels only when they are needed Alternatively unnecessary labels can be eliminated during a subsequent optimization phase

conditional and unconditional jumps to one of two labels $\ B \ true$ if $\ B$ is true and $\ B \ false$ if $\ B$ is false

Pro	DUCTION	SEMANTIC RULES					
В	B_1 B_2	$B_1 \ true \ B \ true \ B_1 \ false \ newlabel \ B_2 \ true \ B \ true \ B_2 \ false \ B \ false \ B \ code \ B_1 \ code \ label \ B_1 \ false \ \ B_2 \ code \ B_1 \ false \ B \ false \ B_2 \ true \ B \ true \ B_2 \ false \ B \ false \ B \ code \ B_1 \ code \ label \ B_1 \ true \ \ B_2 \ code \ B_1 \ false \ B \ true \ B \ code \ B_1 \ code \ B_1 \ false \ B \ true \ B \ code \ B_1 \ code \ B_2 \ code \ B_1 \ code \ B_2 \ code \ B_3 \ code \ B_4 \ code \ B_4 \ code \ B_4 \ code \ B_5 \ code \ B_6 \ code \ $

B	false	B code gen 'goto' B false					

Figure 6 37 Generating three address code for booleans

The fourth production in Fig. 6 37 B E_1 rel E_2 is translated directly into a comparison three address instruction with jumps to the appropriate places For instance B of the form a b translates into

$$\begin{array}{ll} \text{if a} & \text{b goto } B \; true \\ \text{goto } B \; false \end{array}$$

The remaining productions for B are translated as follows

1 Suppose B is of the form B_1 B_2 If B_1 is true then we immediately know that B itself is true so B_1 true is the same as B true If B_1 is false then B_2 must be evaluated so we make B_1 false be the label of the rst instruction in the code for B_2 The true and false exits of B_2 are the same as the true and false exits of B respectively

66 CONTROL FLOW

- 2 The translation of B_1 B_2 is similar
- 3 No code is needed for an expression B of the form B_1 just interchange the true and false exits of B to get the true and false exits of B_1
- 4 The constants **true** and **false** translate into jumps to *B true* and *B false* respectively

Example 6 22 Consider again the following statement from Example 6 21

Using the syntax directed de nitions in Figs $6\,36$ and $6\,37$ we would obtain the code in Fig $6\,38$

Figure 6 38 Control ow translation of a simple if statement

The statement 6.13 constitutes a program generated by P S from Fig 6.36. The semantic rules for the production generate a new label L_1 for the instruction after the code for S. Statement S has the form **if** S S where S is S 0. So the rules in Fig 6.36 generate a new label S and attach it to the rst and only in this case instruction in S code which is S 0.

Since has lower precedence than the boolean expression in 6 13 has the form B_1 B_2 where B_1 is x 100 Following the rules in Fig 6 37 B_1 true is L_2 the label of the assignment x 0 B_1 false is a new label L_3 attached to the rst instruction in the code for B_2

Note that the code generated is not optimal in that the translation has three more instructions goto s than the code in Example 6.21. The instruction goto L_3 is redundant since L_3 is the label of the very next instruction. The two goto L_1 instructions can be eliminated by using ifFalse instead of if instructions as in Example 6.21.

6 6 5 Avoiding Redundant Gotos

In Example 6 22 the comparison x = 200 translates into the code fragment

Instead consider the instruction

$$\begin{array}{ccc} & \text{ifFalse x} & 200 \text{ goto } L_1 \\ L_4 & \end{array}$$

This ifFalse instruction takes advantage of the natural ow from one instruction to the next in sequence so control simply falls through to label L_4 if x=200 thereby avoiding a jump

In the code layouts for if and while statements in Fig 6 35 the code for statement S_1 immediately follows the code for the boolean expression B By using a special label fall i.e. don't generate any jump we can adapt the semantic rules in Fig 6 36 and 6 37 to allow control to fall through from the code for B to the code for S_1 . The new rules for S if B S_1 in Fig 6 36 set B true to fall

$$\begin{array}{lll} \textit{B true} & \textit{fall} \\ \textit{B false} & \textit{S}_1 \; \textit{next} & \textit{S next} \\ \textit{S code} & \textit{B code} \mid\mid \textit{S}_1 \; \textit{code} \end{array}$$

Similarly the rules for if else and while statements also set B true to fall

We now adapt the semantic rules for boolean expressions to allow control to fall through whenever possible. The new rules for B E_1 rel E_2 in Fig. 6-39 generate two instructions as in Fig. 6-37 if both B true and B false are explicit labels that is neither equals fall. Otherwise if B true is an explicit label, then B false must be fall so they generate an if instruction that lets control fall through if the condition is false. Conversely, if B false is an explicit label, then they generate an ifFalse instruction. In the remaining case, both B true and B false are fall, so no jump in generated.

In the new rules for B B_1 B_2 in Fig. 6.40 note that the meaning of label fall for B is different from its meaning for B_1 Suppose B true is fall if econtrol falls through B if B evaluates to true. Although B evaluates to true if B_1 does B_1 true must ensure that control jumps over the code for B_2 to get to the next instruction after B.

On the other hand if B_1 evaluates to false the truth value of B is determined by the value of B_2 so the rules in Fig. 6.40 ensure that B_1 false corresponds to control falling through from B_1 to the code for B_2

The semantic rules for B B_1 B_2 are similar to those in Fig. 6.40. We leave them as an exercise

Example 6 23 With the new rules using the special label fall the program 6 13 from Example 6 21

⁹In C and Java expressions may contain assignments within them so code must be gen erated for the subexpressions E_1 and E_2 even if both B true and B false are fall If desired dead code can be eliminated during an optimization phase

66 CONTROL FLOW

```
test
               E_1 addr rel op E_2 addr
               if B true / fall and B false / fall then
                  gen 'if' test 'goto' B true || gen 'goto' B false
               else if B true / fall then gen 'if' test 'goto' B true
               else if B false / fall then gen 'ifFalse' test 'goto' B false
               else ''
    B \ code
               E_1 \ code \parallel E_2 \ code \parallel s
                 Figure 6.39 Semantic rules for B
                                                         E_1 rel E_2
                        if B true / fall then B true else newlabel
             B_1 true
             B_1 false
                        fall
             B_2 true
                        B true
             B_2 false
                        B false
              B \ code
                        if B true / fall then B_1 code || B_2 code
                        else B_1 code || B_2 code || label B_1 true
                 Figure 6 40 Semantic rules for B
                                                         B_1
                                                                 B_2
                if
                          100
                                        200
                                                                  0
translates into the code of Fig 6 41
```

Figure 6 41 If statement translated using the fall through technique

100 goto L_2

200 goto L_1

y goto L_1

if x

 L_2 L_1

ifFalse x ifFalse x

0

As in Example 6 22 the rules for P — S create label L_1 — The difference from Example 6 22 is that the inherited attribute B true is fall when the semantic rules for B — B_1 — B_2 are applied B false is L_1 — The rules in Fig. 6 40 create a new label L_2 to allow a jump over the code for B_2 if B_1 evaluates to true. Thus B_1 true is L_2 and B_1 false is fall since B_2 must be evaluated if B_1 is false.

The production B E_1 rel E_2 that generates x 100 is therefore reached with B true L_2 and B false fall. With these inherited labels, the rules in Fig. 6.39 therefore generate a single instruction if x 100 goto L_2 \square

6 6 6 Boolean Values and Jumping Code

The focus in this section has been on the use of boolean expressions to alter the ow of control in statements A boolean expression may also be evaluated for its value as in assignment statements such as x true or x a b

A clean way of handling both roles of boolean expressions is to syntax tree for expressions using either of the following approaches

- 1 Use two passes Construct a complete syntax tree for the input and then walk the tree in depth—rst order computing the translations speci ed by the semantic rules
- 2 Use one pass for statements but two passes for expressions With this approach we would translate E in **while** E S_1 before S_1 is examined The translation of E however would be done by building its syntax tree and then walking the tree

The following grammar has a single nonterminal E for expressions

Nonterminal E governs the ow of control in S while E S_1 The same nonterminal E denotes a value in S id E and E E

We can handle these two roles of expressions by using separate code generation functions. Suppose that attribute E n denotes the syntax tree node for an expression E and that nodes are objects. Let method jump generate jumping code at an expression node and let method rvalue generate code to compute the value of the node into a temporary

When E appears in S while E S_1 method jump is called at node E n The implementation of jump is based on the rules for boolean expressions in Fig. 6.37. Specifically jumping code is generated by calling E n jump t f where t is a new label for the first instruction of S_1 code and f is the label S next

When E appears in S id E method value is called at node E n If E has the form E_1 E_2 the method call E n value generates code as discussed in Section 6.4 If E has the form E_1 E_2 we rst generate jumping code for E and then assign true or false to a new temporary t at the true and false exits respectively from the jumping code

For example the assignment x a b c d can be implemented by the code in Fig. 6 42

6 6 7 Exercises for Section 6 6

Exercise 6 6 1 Add rules to the syntax directed de nition of Fig 6 36 for the following control ow constructs

a A repeat statement repeat S while B

6 6 CONTROL FLOW

Figure 6 42 Translating a boolean assignment by computing the value of a temporary

```
b A for loop for S_1 B S_2 S_3
```

Exercise 6 6 2 Modern machines try to execute many instructions at the same time including branching instructions. Thus there is a severe cost if the machine speculatively follows one branch when control actually goes another way all the speculative work is thrown away. It is therefore desirable to min imize the number of branches. Notice that the implementation of a while loop in Fig. 6.35 c. has two branches per interation one to enter the body from the condition B and the other to jump back to the code for B. As a result it is usually preferable to implement while B. B as if it were if B are peat B until B. Show what the code layout looks like for this translation and revise the rule for while loops in Fig. 6.36

Exercise 6 6 3 Suppose that there were an exclusive or operator true if and only if exactly one of its two arguments is true in C Write the rule for this operator in the style of Fig 6 37

Exercise 6 6 4 Translate the following expressions using the goto avoiding translation scheme of Section 6 6 5

```
a if a b c d e f x 1
b if a b c d e f x 1
c if a b c d e f x 1
```

Exercise 6 6 5 Give a translation scheme based on the syntax directed de nition in Figs 6 36 and 6 37

Exercise 6 6 6 Adapt the semantic rules in Figs 6 36 and 6 37 to allow control to fall through using rules like the ones in Figs 6 39 and 6 40

Exercise 6 6 7 The semantic rules for statements in Exercise 6 6 6 generate unnecessary labels Modify the rules for statements in Fig 6 36 to create labels as needed using a special label *deferred* to mean that a label has not yet been created Your rules must generate code similar to that in Example 6 21

Exercise 6 6 8 Section 6 6 5 talks about using fall through code to minimize the number of jumps in the generated intermediate code. However, it does not take advantage of the option to replace a condition by its complement e.g. replace if a b goto L_1 goto L_2 by if a b goto L_2 goto L_1 Develop a SDD that does take advantage of this option when needed

6 7 Backpatching

A key problem when generating code for boolean expressions and ow of control statements is that of matching a jump instruction with the target of the jump For example the translation of the boolean expression B in if B S contains a jump for when B is false to the instruction following the code for S In a one pass translation B must be translated before S is examined. What then is the target of the goto that jumps over the code for S. In Section 6.6 we addressed this problem by passing labels as inherited attributes to where the relevant jump instructions were generated. But a separate pass is then needed to bind labels to addresses

This section takes a complementary approach called *backpatching* in which lists of jumps are passed as synthesized attributes. Speci cally when a jump is generated the target of the jump is temporarily left unspeci ed. Each such jump is put on a list of jumps whose labels are to be lied in when the proper label can be determined. All of the jumps on a list have the same target label.

6 7 1 One Pass Code Generation Using Backpatching

Backpatching can be used to generate code for boolean expressions and ow of control statements in one pass. The translations we generate will be of the same form as those in Section 6.6 except for how we manage labels

In this section synthesized attributes truelist and falselist of nonterminal B are used to manage labels in jumping code for boolean expressions. In particular B truelist will be a list of jump or conditional jump instructions into which we must insert the label to which control goes if B is true B falselist likewise is the list of instructions that eventually get the label to which control goes when B is false. As code is generated for B jumps to the true and false exits are left incomplete with the label eld unlled. These incomplete jumps are placed on lists pointed to by B truelist and B falselist as appropriate. Similarly a statement S has a synthesized attribute S nextlist denoting a list of jumps to the instruction immediately following the code for S

For speci city we generate instructions into an instruction array and labels will be indices into this array. To manipulate lists of jumps we use three functions

1 makelist i creates a new list containing only i an index into the array of instructions makelist returns a pointer to the newly created list

6 7 BACKPATCHING

- 2 merge p_1 p_2 concatenates the lists pointed to by p_1 and p_2 and returns a pointer to the concatenated list
- 3 backpatch p i inserts i as the target label for each of the instructions on the list pointed to by p

6 7 2 Backpatching for Boolean Expressions

We now construct a translation scheme suitable for generating code for boolean expressions during bottom up parsing A marker nonterminal M in the gram mar causes a semantic action to pick up at appropriate times the index of the next instruction to be generated. The grammar is as follows

The translation scheme is in Fig 6 43

```
1
     B
                M B_2  { backpatch B_1 falselist M instr
                                B \ true list
                                            merge B_1 truelist B_2 truelist
                                B falselist
                                             B_2 falselist }
                   M B_2  { backpatch B_1 truelist M instr
2
     B
           B_1
                                B\ true list
                                             B_2 truelist
                                B falselist
                                             merge B_1 falselist B_2 falselist 
                             \{ B truelist \}
                                             B_1 falselist
3
     B
                                B falselist
                                             B_1 \ true list \}
            B_1
                             { B truelist
                                             B_1 truelist
     B
                               B falselist
                                               B_1 falselist
           E_1 rel E_2
                             \{ B truelist \}
                                             makelist\ next instr
5
     B
                                B falselist
                                             makelist\ next instr
                                gen'if' E_1 addr rel op E_2 addr'goto \_'
                                gen 'goto _' }
                             \{ \ B \ true list \quad make list \ next in str
6
     B
           true
                                gen 'goto _' }
7
     B
           false
                             \{ B \ falselist \ makelist \ nextinstr \}
                                gen 'goto _' }
                             \{ M instr nextinstr \}
8
     M
```

Figure 6 43 Translation scheme for boolean expressions

Consider semantic action 1 for the production B B_1 MB_2 If B_1 is true then B is also true so the jumps on B_1 truelist become part of B truelist If B_1 is false however we must next test B_2 so the target for the jumps

 B_1 falselist must be the beginning of the code generated for B_2 . This target is obtained using the marker nonterminal M. That nonterminal produces as a synthesized attribute M instr. the index of the next instruction just before B_2 code starts being generated

To obtain that instruction index we associate with the production M the semantic action

$$\{ M instr nextinstr \}$$

The variable nextinstr holds the index of the next instruction to follow. This value will be backpatched onto the B_1 falselist i.e. each instruction on the list B_1 falselist will receive M instr as its target label when we have seen the remainder of the production B B_1 M B_2

Semantic action 2 for B B_1 M B_2 is similar to 1 Action 3 for B swaps the true and false lists Action 4 ignores parentheses

For simplicity semantic action 5 generates two instructions a conditional goto and an unconditional one Neither has its target led in These instructions are put on new lists pointed to by B truelist and B falselist respectively

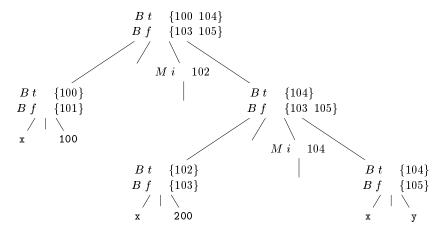

Figure 6 44 Annotated parse tree for x = 100 - x = 200 - x = y

Example 6 24 Consider again the expression

$$x = 100$$
 $x = 200$ $x = y$

An annotated parse tree is shown in Fig. 6.44 for readability attributes tru elist falselist and instr are represented by their initial letters. The actions are performed during a depth—rst traversal of the tree. Since all actions appear at the ends of right sides, they can be performed in conjunction with reductions during a bottom up parse. In response to the reduction of x=100 to B by production 5—the two instructions

6 7 BACKPATCHING

are generated We arbitrarily start instruction numbers at 100 The marker nonterminal M in the production

$$B = B_1 = M B_2$$

records the value of nextinstr which at this time is 102. The reduction of x=200 to B by production 5 generates the instructions

$$102$$
 if x 200 goto $_$ 103 goto $_$

The subexpression x = 200 corresponds to B_1 in the production

$$B B_1 M B_2$$

The marker nonterminal M records the current value of nextinstr which is now 104 Reducing x = y into B by production 5 generates

$$104$$
 if x y goto $_$ 105 goto $_$

We now reduce by B B_1 M B_2 The corresponding semantic action calls backpatch B_1 truelist M instr to bind the true exit of B_1 to the rst instruction of B_2 Since B_1 truelist is $\{102\}$ and M instr is 104 this call to backpatch lls in 104 in instruction 102. The six instructions generated so far are thus as shown in Fig. 6.45 a.

The semantic action associated with the nal reduction by $B = B_1 = M B_2$ calls backpatch $\{101\}\ 102$ which leaves the instructions as in Fig. 6.45 b

The entire expression is true if and only if the gotos of instructions 100 or 104 are reached and is false if and only if the gotos of instructions 103 or 105 are reached. These instructions will have their targets lled in later in the compilation when it is seen what must be done depending on the truth or falsehood of the expression \Box

6 7 3 Flow of Control Statements

We now use backpatching to translate ow of control statements in one pass Consider statements generated by the following grammar

Here S denotes a statement L a statement list A an assignment statement and B a boolean expression. Note that there must be other productions such as

```
100 if x 100 goto _
101 goto _
102 if x 200 goto 104
103 goto _
104 if x y goto _
105 goto _
```

a After backpatching 104 into instruction 102

```
100 if x 100 goto _
101 goto 102
102 if x 200 goto 104
103 goto _
104 if x y goto _
105 goto _
```

b After backpatching 102 into instruction 101

Figure 6 45 Steps in the backpatch process

those for assignment statements. The productions given however are succient to illustrate the techniques used to translate ow of control statements.

The code layout for if if else and while statements is the same as in Section 6.6. We make the tacit assumption that the code sequence in the instruction array rejects the natural ow of control from one instruction to the next. If not then explicit jumps must be inserted to implement the natural sequential ow of control

The translation scheme in Fig. 6.46 maintains lists of jumps that are lled in when their targets are found. As in Fig. 6.43 boolean expressions generated by nonterminal B have two lists of jumps B truelist and B falselist corresponding to the true and false exits from the code for B respectively. Statements generated by nonterminals S and L have a list of unlled jumps given by attribute nextlist that must eventually be completed by backpatching S nextlist is a list of all conditional and unconditional jumps to the instruction following the code for statement S in execution order L nextlist is defined as initially

Consider the semantic action 3 in Fig 6 46 The code layout for production S while B S_1 is as in Fig 6 35 c The two occurrences of the marker nonterminal M in the production

$$S$$
 while M_1 B M_2 S_1

record the instruction numbers of the beginning of the code for B and the beginning of the code for S_1 . The corresponding labels in Fig. 6.35 c. are begin and B true respectively

67 BACKPATCHING

```
1
    S
          if B MS_1 { backpatch B truelist M instr
                           S nextlist

```

Figure 6 46 Translation of statements

Again the only production for M is M. Action 6 in Fig 6 46 sets attribute M instr to the number of the next instruction. After the body S_1 of the while statement is executed control ows to the beginning. Therefore when we reduce **while** M_1 B M_2S_1 to S we backpatch S_1 nextlist to make all targets on that list be M_1 instr. An explicit jump to the beginning of the code for B is appended after the code for S_1 because control may also fall out the bottom. B truelist is backpatched to go to the beginning of S_1 by making jumps on B truelist go to M_2 instr.

A more compelling argument for using S nextlist and L nextlist comes when code is generated for the conditional statement **if** B S_1 **else** S_2 If control falls out the bottom of S_1 as when S_1 is an assignment we must include at the end of the code for S_1 a jump over the code for S_2 We use another marker nonterminal to generate this jump after S_1 Let nonterminal N be this

marker with production N N has attribute N nextlist which will be a list consisting of the instruction number of the jump $goto_-$ that is generated by the semantic action 7 for N

Semantic action 2 in Fig 6 46 deals with if else statements with the syntax

$$S$$
 if B $M_1 S_1 N$ else $M_2 S_2$

We backpatch the jumps when B is true to the instruction M_1 instr the latter is the beginning of the code for S_1 Similarly we backpatch jumps when B is false to go to the beginning of the code for S_2 The list S nextlist includes all jumps out of S_1 and S_2 as well as the jump generated by N Variable temp is a temporary that is used only for merging lists

Semantic actions 8 and 9 handle sequences of statements In

$$L = L_1 M S$$

the instruction following the code for L_1 in order of execution is the beginning of S. Thus the L_1 nextlist list is backpatched to the beginning of the code for S which is given by M instr. In L. S. L nextlist is the same as S nextlist

Note that no new instructions are generated anywhere in these semantic rules except for rules 3 and 7 All other code is generated by the semantic actions associated with assignment statements and expressions. The ow of control causes the proper backpatching so that the assignments and boolean expression evaluations will connect properly

6 7 4 Break Continue and Goto Statements

The most elementary programming language construct for changing the ow of control in a program is the goto statement. In C a statement like goto L sends control to the statement labeled L there must be precisely one statement with label L in this scope. Goto statements can be implemented by maintaining a list of unlled jumps for each label and then backpatching the target when it is known

Java does away with goto statements However Java does permit disciplined jumps called break statements which send control out of an enclosing construct and continue statements which trigger the next iteration of an enclosing loop. The following excerpt from a lexical analyzer illustrates simple break and continue statements

1	for r	eadch					
2	if peek		peek		t	con	tinue
3	else if	peek	\mathbf{n}	line		line	1
4	else bre	ak					
5							

Control jumps from the break statement on line 4 to the next statement after the enclosing for loop—Control jumps from the continue statement on line 2 to code to evaluate readch—and then to the if statement on line 2

6 7 BACKPATCHING

If S is the enclosing loop construct then a break statement is a jump to the rst instruction after the code for S. We can generate code for the break by 1 keeping track of the enclosing loop statement S 2 generating an unlled jump for the break statement and 3 putting this unlled jump on S nextlist where nextlist is as discussed in Section 6.7.3

In a two pass front end that builds syntax trees S nextlist can be imple mented as a eld in the node for S. We can keep track of S by using the symbol table to map a special identifier S by using the symbol table to map a special identifier S by using the symbol table to the node for the enclosing loop statement S. This approach will also handle labeled break statements in Java since the symbol table can be used to map the label to the syntax tree node for the labeled construct

Alternatively instead of using the symbol table to access the node for S we can put a pointer to S nextlist in the symbol table. Now when a break statement is reached we generate an unlled jump look up nextlist through the symbol table and add the jump to the list where it will be backpatched as discussed in Section 6.7.3

Continue statements can be handled in a manner analogous to the break statement. The main dierence between the two is that the target of the generated jump is dierent

6 7 5 Exercises for Section 6 7

Exercise 6 7 1 Using the translation of Fig 6 43 translate each of the fol lowing expressions Show the true and false lists for each subexpression You may assume the address of the rst instruction generated is 100

```
aab cdef
bab cdef
cab cdef
```

Exercise 6 7 2 In Fig 6 47 a is the outline of a program and Fig 6 47 b sketches the structure of the generated three address code using the backpatch ing translation of Fig 6 46 Here i_1 through i_8 are the labels of the generated instructions that begin each of the Code sections When we implement this translation we maintain for each boolean expression B two lists of places in the code for B which we denote by B true and B false. The places on list B true are those places where we eventually put the label of the statement to which control must—ow whenever B is true B false similarly lists the places where we put the label that control—ows to when B is found to be false. Also we maintain for each statement S a list of places where we must put the label to which control—ows when S is nished. Give the value—one of i_1 through i_8 that eventually replaces each place—on each of the following lists

```
a B_3 false b S_2 next c B_4 false d S_1 next e B_2 true
```

Figure 6 47 Control ow structure of program for Exercise 6 7 2

Exercise 6 7 3 When performing the translation of Fig 6 47 using the scheme of Fig 6 46 we create lists S next for each statement starting with the assign ment statements S_1 S_2 and S_3 and proceeding to progressively larger if statements if else statements while statements and statement blocks. There are ve constructed statements of this type in Fig 6 47

```
S_4 while B_3 S_1

S_5 if B_4 S_2

S_6 The block consisting of S_5 and S_3

S_7 The statement if B_2 S_4 else S_6

S_8 The entire program
```

For each of these constructed statements there is a rule that allows us to construct S_i next in terms of other S_j next lists and the lists B_k true and B_k false for the expressions in the program Give the rules for

```
a S_4 next b S_5 next c S_6 next d S_7 next e S_8 next
```

6 8 Switch Statements

The switch or case statement is available in a variety of languages Our switch statement syntax is shown in Fig 6 48. There is a selector expression E which is to be evaluated followed by n constant values V_1 V_2 V_n that the expression might take perhaps including a default value which always matches the expression if no other value does

68 SWITCH STATEMENTS

```
egin{array}{ll} \mathbf{switch} & E & & \mathbf{case} \ V_1 & S_1 & & \mathbf{case} \ V_2 & S_2 & & & \mathbf{case} \ V_{n-1} & S_{n-1} & & \mathbf{default} \ S_n & & & \end{array}
```

Figure 6 48 Switch statement syntax

6 8 1 Translation of Switch Statements

The intended translation of a switch is code to

- 1 Evaluate the expression E
- 2 Find the value V_j in the list of cases that is the same as the value of the expression Recall that the default value matches the expression if none of the values explicitly mentioned in cases does
- 3 Execute the statement S_j associated with the value found

Step 2 is an n way branch which can be implemented in one of several ways. If the number of cases is small say 10 at most then it is reasonable to use a sequence of conditional jumps each of which tests for an individual value and transfers to the code for the corresponding statement

A compact way to implement this sequence of conditional jumps is to create a table of pairs each pair consisting of a value and a label for the corresponding statement s code. The value of the expression itself paired with the label for the default statement is placed at the end of the table at run time. A simple loop generated by the compiler compares the value of the expression with each value in the table being assured that if no other match is found, the last default entry is sure to match

If the number of values exceeds 10 or so it is more e cient to construct a hash table for the values with the labels of the various statements as entries. If no entry for the value possessed by the switch expression is found a jump to the default statement is generated

There is a common special case that can be implemented even more e ciently than by an n way branch. If the values all lie in some small range say min to max and the number of di erent values is a reasonable fraction of max min then we can construct an array of max min buckets where bucket j min contains the label of the statement with value j any bucket that would otherwise remain un lled contains the default label

To perform the switch evaluate the expression to obtain the value j check that it is in the range min to max and transfer indirectly to the table entry at o set j min For example if the expression is of type character a table of

say 128 entries depending on the character set may be created and transferred through with no range testing

6 8 2 Syntax Directed Translation of Switch Statements

The intermediate code in Fig 6 49 is a convenient translation of the switch statement in Fig 6 48. The tests all appear at the end so that a simple code generator can recognize the multiway branch and generate e-cient code for it using the most appropriate implementation suggested at the beginning of this section

```
code to evaluate E into t
         goto test
         code for S_1
L_1
         goto next
         code for S_2
L_2
         goto next
         code for S_{n-1}
L_{n-1}
         goto next
         code for S_n
L_n
         goto next
                  V_1 goto \mathtt{L}_1
         if t
test
         if t V_2 goto L_2
         if t V_{n-1} goto L_{n-1}
         goto L_n
next
```

Figure 6 49 Translation of a switch statement

The more straightforward sequence shown in Fig. 6.50 would require the compiler to do extensive analysis to $\,$ nd the most extensive implementation. Note that it is inconvenient in a one pass compiler to place the branching statements at the beginning because the compiler could not then emit code for each of the statements S_i as it saw them

To translate into the form of Fig. 6.49 when we see the keyword **switch** we generate two new labels **test** and **next** and a new temporary t. Then as we parse the expression E we generate code to evaluate E into t. After processing E we generate the jump goto test

Then as we see each **case** keyword we create a new label L_i and enter it into the symbol table. We place in a queue used only to store cases a value label pair consisting of the value V_i of the case constant and L_i or a pointer to the symbol table entry for L_i . We process each statement **case** V_i . S_i by emitting the label L_i attached to the code for S_i followed by the jump goto next

68 SWITCH STATEMENTS

```
code to evaluate E into t
                    V_1 goto L_1
         code for S_1
         goto next
                   V_2 goto \mathtt{L}_2
         if t
L_1
         code for S_2
         goto next
L_2
         if t
                   V_{n-1} goto L_{n-1}
L_{n-2}
         code for S_{n-1}
         goto next
         code for S_n
next
```

Figure 6 50 Another translation of a switch statement

When the end of the switch is found we are ready to generate the code for the n way branch. Reading the queue of value label pairs, we can generate a sequence of three address statements of the form shown in Fig. 6.51. There t is the temporary holding the value of the selector expression E and L_n is the label for the default statement

```
case t V_1 L_1 case t V_2 L_2 case t V_{n-1} L_{n-1} case t t L_n next
```

Figure 6.51 Case three address code instructions used to translate a switch statement

The case $t V_i L_i$ instruction is a synonym for if $t V_i$ goto L_i in Fig. 6.49 but the case instruction is easier for the nal code generator to detect as a candidate for special treatment. At the code generation phase, these sequences of case statements can be translated into an n way branch of the most excient type depending on how many there are and whether the values fall into a small range

683 Exercises for Section 68

Exercise 6 8 1 In order to translate a switch statement into a sequence of case statements as in Fig 6 51 the translator needs to create the list of value

label pairs as it processes the source code for the switch. We can do so using an additional translation that accumulates just the pairs. Sketch a syntax directed de nition that produces the list of pairs, while also emitting code for the statements S_i that are the actions for each case

6 9 Intermediate Code for Procedures

Procedures and their implementation will be discussed at length in Chapter 7 along with the run time management of storage for names. We use the term function in this section for a procedure that returns a value. We brie y discuss function declarations and three address code for function calls. In three address code a function call is unraveled into the evaluation of parameters in preparation for a call followed by the call itself. For simplicity, we assume that parameters are passed by value parameter passing methods are discussed in Section 1.6.6

Example 6 25 Suppose that a is an array of integers and that f is a function from integers to integers. Then the assignment

n fai

might translate into the following three address code

The rst two lines compute the value of the expression a i into temporary t_2 as discussed in Section 6.4 Line 3 makes t_2 an actual parameter for the call of f on line 4. That line also assigns the return value to temporary t_3 . Line 5 assigns the result of f a i to n.

The productions in Fig 6 52 allow function de nitions and function calls. The syntax generates unwanted commas after the last parameter but is good enough for illustrating translation. Nonterminals D and T generate declarations and types respectively as in Section 6 3. A function de nition generated by D consists of keyword \mathbf{de} \mathbf{ne} a return type the function name formal parameters in parentheses and a function body consisting of a bracketed state ment. Nonterminal F generates zero or more formal parameters where a formal parameter consists of a type followed by an identity or Nonterminals S and E generate statements and expressions respectively. The production for S adds a statement that returns the value of an expression. The production for E adds function calls with actual parameters generated by A. An actual parameter is an expression

6 9 INTERMEDIATE CODE FOR PROCEDURES

Figure 6 52 Adding functions to the source language

Function de nitions and function calls can be translated using concepts that have already been introduced in this chapter

Function types The type of a function must encode the return type and the types of the formal parameters. Let void be a special type that represents no parameter or no return type. The type of a function pop—that returns an integer is therefore—function from void to integer—Function types can be represented by using a constructor fun applied to the return type and an ordered list of types for the parameters

Symbol tables Let s be the top symbol table when the function denition is reached. The function name is entered into s for use in the rest of the program. The formal parameters of a function can be handled in analogy with eld names in a record see Fig. 6.18. In the production for D after seeing \mathbf{de} \mathbf{ne} and the function name, we push s and set up a new symbol table

Call the new symbol table t Note that top is passed as a parameter in **new** Env top so the new symbol table t can be linked to the previous one s The new table t is used to translate the function body. We revert to the previous symbol table s after the function body is translated

Type checking Within expressions a function is treated like any other operator. The discussion of type checking in Section 6.5.2 therefore carries over including the rules for coercions. For example, if f is a function with a parameter of type real, then the integer 2 is coerced to a real in the call f 2.

Function calls When generating three address instructions for a function call $id\ E\ E\ E$ it is su cient to generate the three address instructions for evaluating or reducing the parameters E to addresses followed by a param instruction for each parameter. If we do not want to mix the parameter evaluating instructions with the param instructions the attribute $E\ addr$ for each expression E can be saved in a data structure

such as a queue Once all the expressions are translated the param in structions can be generated as the queue is emptied

The procedure is such an important and frequently used programming construct that it is imperative for a compiler to generate good code for procedure calls and returns. The run time routines that handle procedure parameter passing calls and returns are part of the run time support package. Mechanisms for run time support are discussed in Chapter 7

6 10 Summary of Chapter 6

The techniques in this chapter can be combined to build a simple compiler front end like the one in Appendix A The front end can be built incrementally

- ightharpoonup Pick an intermediate representation An intermediate representation is typically some combination of a graphical notation and three address code As in syntax trees a node in a graphical notation represents a construct the children of a node represent its subconstructs. Three address code takes its name from instructions of the form x-y op z with at most one operator per instruction. There are additional instructions for control ow
- ♦ Translate expressions Expressions with built up operations can be un wound into a sequence of individual operations by attaching actions to each production of the form E E_1 op E_2 The action either creates a node for E with the nodes for E_1 and E_2 as children or it generates a three address instruction that applies op to the addresses for E_1 and E_2 and puts the result into a new temporary name which becomes the address for E
- ♦ Check types The type of an expression E_1 op E_2 is determined by the operator op and the types of E_1 and E_2 A coercion is an implicit type conversion such as from integer to oat Intermediate code contains explicit type conversions to ensure an exact match between operand types and the types expected by an operator
- ◆ Use a symbol table to implement declarations A declaration speci es the type of a name The width of a type is the amount of storage needed for a name with that type Using widths the relative address of a name at run time can be computed as an o set from the start of a data area. The type and relative address of a name are put into the symbol table due to a declaration so the translator can subsequently get them when the name appears in an expression
- ◆ Flatten arrays For quick access array elements are stored in consecutive locations Arrays of arrays are attened so they can be treated as a one

6 11 REFERENCES FOR CHAPTER 6

dimensional array of individual elements The type of an array is used to calculate the address of an array element relative to the base of the array

- ◆ Generate jumping code for boolean expressions In short circuit or jump ing code the value of a boolean expression is implicit in the position reached in the code Jumping code is useful because a boolean expression B is typically used for control ow as in if B S Boolean values can be computed by jumping to t true or t false as appropriate where t is a temporary name Using labels for jumps a boolean expression can be translated by inheriting labels corresponding to its true and false exits The constants true and false translate into a jump to the true and false exits respectively
- ♦ Implement statements using control ow Statements can be translated by inheriting a label next where next marks the rst instruction after the code for this statement. The conditional S if B S_1 can be translated by attaching a new label marking the beginning of the code for S_1 and passing the new label and S next for the true and false exits respectively of B
- ♦ Alternatively use backpatching Backpatching is a technique for generating code for boolean expressions and statements in one pass. The idea is to maintain lists of incomplete jumps where all the jump instructions on a list have the same target. When the target becomes known all the instructions on its list are completed by lling in the target.
- → Implement records Field names in a record or class can be treated as a sequence of declarations A record type encodes the types and relative addresses of the elds A symbol table object can be used for this purpose

6 11 References for Chapter 6

Most of the techniques in this chapter stem from the urry of design and im plementation activity around Algol 60 Syntax directed translation into intermediate code was well established by the time Pascal 11 and C 6 9 were created

UNCOL for Universal Compiler Oriented Language is a mythical universal intermediate language sought since the mid 1950 s. Given an UNCOL compilers could be constructed by hooking a front end for a given source language with a back end for a given target language 10. The bootstrapping techniques given in the report 10 are routinely used to retarget compilers

The UNCOL ideal of mixing and matching front ends with back ends has been approached in a number of ways. A retargetable compiler consists of one front end that can be put together with several back ends to implement a given language on several machines. Neliac was an early example of a language with a retargetable compiler. 5 written in its own language. Another approach is to

retro t a front end for a new language onto an existing compiler Feldman 2 describes the addition of a Fortran 77 front end to the C compilers 6 and 9 GCC the GNU Compiler Collection 3 supports front ends for C C Objective C Fortran Java and Ada

Value numbers and their implementation by hashing are from Ershov 1. The use of type information to improve the security of Java bytecodes is described by Gosling 4.

Type inference by using uni cation to solve sets of equations has been re discovered several times its application to ML is described by Milner 7 See Pierce 8 for a comprehensive treatment of types

Chapter 7

Run Time Environments

A compiler must accurately implement the abstractions embodied in the source language de nition. These abstractions typically include the concepts we discussed in Section 1.6 such as names scopes bindings data types operators procedures parameters and ow of control constructs. The compiler must cooperate with the operating system and other systems software to support these abstractions on the target machine.

To do so the compiler creates and manages a run time environment in which it assumes its target programs are being executed. This environment deals with a variety of issues such as the layout and allocation of storage locations for the objects named in the source program, the mechanisms used by the target program to access variables the linkages between procedures, the mechanisms for passing parameters, and the interfaces to the operating system input output devices, and other programs

The two themes in this chapter are the allocation of storage locations and access to variables and data. We shall discuss memory management in some detail including stack allocation heap management and garbage collection. In the next chapter, we present techniques for generating target code for many common language constructs

7 1 Storage Organization

From the perspective of the compiler writer the executing target program runs in its own logical address space in which each program value has a location. The management and organization of this logical address space is shared between the compiler operating system and target machine. The operating system maps the logical addresses into physical addresses which are usually spread throughout memory.

The run time representation of an object program in the logical address space consists of data and program areas as shown in Fig. 7.1. A compiler for a

language like C on an operating system like Linux might subdivide memory in this way

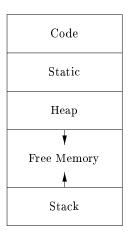

Figure 7.1 Typical subdivision of run time memory into code and data areas

Throughout this book we assume the run time storage comes in blocks of contiguous bytes where a byte is the smallest unit of addressable memory A byte is eight bits and four bytes form a machine word Multibyte objects are stored in consecutive bytes and given the address of the rst byte

As discussed in Chapter 6 the amount of storage needed for a name is de termined from its type. An elementary data type such as a character integer or oat can be stored in an integral number of bytes. Storage for an aggregate type such as an array or structure must be large enough to hold all its components.

The storage layout for data objects is strongly in uenced by the addressing constraints of the target machine. On many machines instructions to add in tegers may expect integers to be aligned that is placed at an address divisible by 4. Although a character array as in C of length 10 needs only enough bytes to hold ten characters a compiler may allocate 12 bytes to get the proper alignment leaving 2 bytes unused. Space left unused due to alignment considerations is referred to as padding. When space is at a premium a compiler may pack data so that no padding is left additional instructions may then need to be executed at run time to position packed data so that it can be operated on as if it were properly aligned.

The size of the generated target code is xed at compile time so the compiler can place the executable target code in a statically determined area *Code* usually in the low end of memory Similarly the size of some program data objects such as global constants and data generated by the compiler such as information to support garbage collection may be known at compile time and these data objects can be placed in another statically determined area called *Static* One reason for statically allocating as many data objects as possible is

7.1 STORAGE ORGANIZATION

that the addresses of these objects can be compiled into the target code In early versions of Fortran all data objects could be allocated statically

To maximize the utilization of space at run time the other two areas *Stack* and *Heap* are at the opposite ends of the remainder of the address space. These areas are dynamic their size can change as the program executes. These areas grow towards each other as needed. The stack is used to store data structures called activation records that get generated during procedure calls

In practice the stack grows towards lower addresses the heap towards higher However throughout this chapter and the next we shall assume that the stack grows towards higher addresses so that we can use positive o sets for notational convenience in all our examples

As we shall see in the next section an activation record is used to store information about the status of the machine such as the value of the program counter and machine registers when a procedure call occurs. When control returns from the call the activation of the calling procedure can be restarted after restoring the values of relevant registers and setting the program counter to the point immediately after the call. Data objects whose lifetimes are contained in that of an activation can be allocated on the stack along with other information associated with the activation

Many programming languages allow the programmer to allocate and deal locate data under program control. For example, C has the functions malloc and free that can be used to obtain and give back arbitrary chunks of stor age. The heap is used to manage this kind of long lived data. Section 7.4 will discuss various memory management algorithms that can be used to maintain the heap.

7 1 1 Static Versus Dynamic Storage Allocation

The layout and allocation of data to memory locations in the run time environment are key issues in storage management. These issues are tricky because the same name in a program text can refer to multiple locations at run time. The two adjectives *static* and *dynamic* distinguish between compile time and run time respectively. We say that a storage allocation decision is static if it can be made by the compiler looking only at the text of the program not at what the program does when it executes. Conversely a decision is dynamic if it can be decided only while the program is running. Many compilers use some combination of the following two strategies for dynamic storage allocation.

- 1 Stack storage Names local to a procedure are allocated space on a stack We discuss the run time stack starting in Section 7.2 The stack supports the normal call return policy for procedures
- 2 Heap storage Data that may outlive the call to the procedure that cre ated it is usually allocated on a heap of reusable storage We discuss heap management starting in Section 7 4 The heap is an area of virtual

memory that allows objects or other data elements to obtain storage when they are created and to return that storage when they are invalidated

To support heap management—garbage collection—enables the run time system to detect useless data elements and reuse their storage—even if the programmer does not return their space explicitly—Automatic garbage collection is an essential feature of many modern languages—despite it being a discult operation to do—e ciently—it may not even be possible for some languages

7 2 Stack Allocation of Space

Almost all compilers for languages that use procedures functions or methods as units of user de ned actions manage at least part of their run time memory as a stack. Each time a procedure is called space for its local variables is pushed onto a stack and when the procedure terminates that space is popped of the stack. As we shall see this arrangement not only allows space to be shared by procedure calls whose durations do not overlap in time but it allows us to compile code for a procedure in such a way that the relative addresses of its nonlocal variables are always the same regardless of the sequence of procedure calls.

7 2 1 Activation Trees

Stack allocation would not be feasible if procedure calls or *activations* of procedures did not nest in time. The following example illustrates nesting of procedure calls

Example 7 1 Figure 7 2 contains a sketch of a program that reads nine integers into an array a and sorts them using the recursive quicksort algorithm

The main function has three tasks It calls readArray sets the sentinels and then calls quicksort on the entire data array Figure 7.3 suggests a sequence of calls that might result from an execution of the program. In this execution the call to partition 1.9 returns 4 so a 1 through a 3 hold elements less than its chosen separator value v while the larger elements are in a 5 through a 9.

In this example as is true in general procedure activations are nested in time. If an activation of procedure p calls procedure q, then that activation of q must end before the activation of p can end. There are three common cases

- 1 The activation of q terminates normally Then in essentially any language control resumes just after the point of p at which the call to q was made
- 2 The activation of q or some procedure q called either directly or indirectly aborts i.e. it becomes impossible for execution to continue. In that case p ends simultaneously with q

 $^{^{1}\}mathrm{Recall}$ we use $\,$ procedure $\,$ as a generic term for function $\,$ procedure $\,$ method or subroutine

7.2 STACK ALLOCATION OF SPACE

```
int a 11
                      Reads 9 integers into a 1
void readArray
                                                a9
    int i
int partition int m int n
       Picks a separator value v and partitions a m n so that
       a m p 1 are less than v a p
                                      v and ap 1 n are
       equal to or greater than v Returns p
void quicksort int m int n
    int i
    if n
            partition m n
        quicksort m i 1
        quicksort i 1 n
main
    readArray
    a 0
            9999
    a 10
            9999
    quicksort 1 9
```

Figure 7.2 Sketch of a quicksort program

3 The activation of q terminates because of an exception that q cannot han dle Procedure p may handle the exception in which case the activation of q has terminated while the activation of p continues although not nec essarily from the point at which the call to q was made. If p cannot handle the exception then this activation of p terminates at the same time as the activation of q and presumably the exception will be handled by some other open activation of a procedure

We therefore can represent the activations of procedures during the running of an entire program by a tree-called an activation tree. Each node corresponds to one activation and the root is the activation of the main-procedure that initiates execution of the program. At a node for an activation of procedure p the children correspond to activations of the procedures called by this activation of p. We show these activations in the order that they are called from left to right. Notice that one child must nish before the activation to its right can begin

A Version of Quicksort

The sketch of a quicksort program in Fig. 7.2 uses two auxiliary functions readArray and partition. The function readArray is used only to load the data into the array a. The rst and last elements of a are not used for data but rather for sentinels set in the main function. We assume a 0 is set to a value lower than any possible data value, and a 10 is set to a value higher than any data value.

The function partition divides a portion of the array delimited by the arguments m and n so the low elements of a m through a n are at the beginning and the high elements are at the end although neither group is necessarily in sorted order. We shall not go into the way partition works except that it may rely on the existence of the sentinels. One possible algorithm for partition is suggested by the more detailed code in Fig. 9.1

Recursive procedure quicksort rst decides if it needs to sort more than one element of the array Note that one element is always sorted so quicksort has nothing to do in that case. If there are elements to sort quicksort rst calls partition which returns an index i to separate the low and high elements. These two groups of elements are then sorted by two recursive calls to quicksort

Example 7 2 One possible activation tree that completes the sequence of calls and returns suggested in Fig. 7 3 is shown in Fig. 7 4. Functions are represented by the rst letters of their names. Remember that this tree is only one possibility since the arguments of subsequent calls and also the number of calls along any branch is in uenced by the values returned by partition.

The use of a run time stack is enabled by several useful relationships between the activation tree and the behavior of the program

- 1 The sequence of procedure calls corresponds to a preorder traversal of the activation tree
- 2 The sequence of returns corresponds to a postorder traversal of the activation tree
- 3 Suppose that control lies within a particular activation of some procedure corresponding to a node N of the activation tree. Then the activations that are currently open live are those that correspond to node N and its ancestors. The order in which these activations were called is the order in which they appear along the path to N starting at the root and they will return in the reverse of that order

7.2 STACK ALLOCATION OF SPACE

```
enter main
enter readArray
leave readArray
enter quicksort 1 9
enter partition 1 9
leave partition 1 9
enter quicksort 1 3
leave quicksort 1 3
enter quicksort 5 9
leave quicksort 5 9
leave quicksort 1 9
```

Figure 7.3 Possible activations for the program of Fig. 7.2

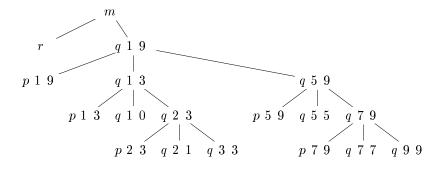

Figure 7.4 Activation tree representing calls during an execution of quicksort

7 2 2 Activation Records

Procedure calls and returns are usually managed by a run time stack called the control stack. Each live activation has an activation record sometimes called a frame on the control stack with the root of the activation tree at the bottom and the entire sequence of activation records on the stack corresponding to the path in the activation tree to the activation where control currently resides. The latter activation has its record at the top of the stack

Example 7 3 If control is currently in the activation q 2 3 of the tree of Fig 7 4 then the activation record for q 2 3 is at the top of the control stack Just below is the activation record for q 1 3 the parent of q 2 3 in the tree Below that is the activation record q 1 9 and at the bottom is the activation record for m the main function and root of the activation tree

We shall conventionally draw control stacks with the bottom of the stack higher than the top so the elements in an activation record that appear lowest on the page are actually closest to the top of the stack

The contents of activation records vary with the language being imple mented. Here is a list of the kinds of data that might appear in an activation record see Fig. 7.5 for a summary and possible order for these elements

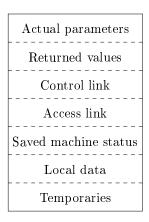

Figure 7 5 A general activation record

- 1 Temporary values such as those arising from the evaluation of expres sions in cases where those temporaries cannot be held in registers
- 2 Local data belonging to the procedure whose activation record this is
- 3 A saved machine status with information about the state of the machine just before the call to the procedure. This information typically includes the return address value of the program counter to which the called procedure must return and the contents of registers that were used by the calling procedure and that must be restored when the return occurs
- 4 An access link may be needed to locate data needed by the called proce dure but found elsewhere e g in another activation record Access links are discussed in Section 7 3 5
- 5 A control link pointing to the activation record of the caller
- 6 Space for the return value of the called function if any Again not all called procedures return a value and if one does we may prefer to place that value in a register for e ciency
- 7 The actual parameters used by the calling procedure Commonly these values are not placed in the activation record but rather in registers when possible for greater e ciency However we show a space for them to be completely general

7.2 STACK ALLOCATION OF SPACE

Example 7 4 Figure 7 6 shows snapshots of the run time stack as control ows through the activation tree of Fig 7 4 Dashed lines in the partial trees go to activations that have ended Since array a is global space is allocated for it before execution begins with an activation of procedure main as shown in Fig 7 6 a

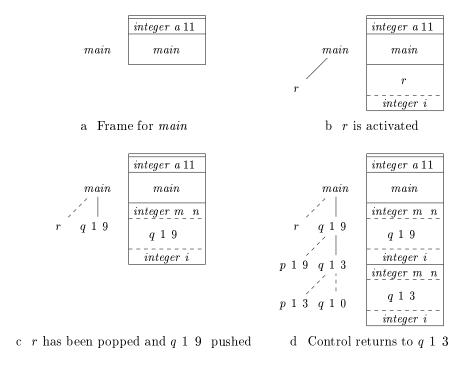

Figure 7.6 Downward growing stack of activation records

When control reaches the rst call in the body of main procedure r is activated and its activation record is pushed onto the stack Fig 7 6 b. The activation record for r contains space for local variable i. Recall that the top of stack is at the bottom of diagrams. When control returns from this activation its record is popped leaving just the record for main on the stack

Control then reaches the call to q quicksort with actual parameters 1 and 9 and an activation record for this call is placed on the top of the stack as in Fig 7.6 c. The activation record for q contains space for the parameters m and n and the local variable i following the general layout in Fig 7.5. Notice that space once used by the call of r is reused on the stack. No trace of data local to r will be available to q 1.9. When q 1.9 returns the stack again has only the activation record for main

Several activations occur between the last two snapshots in Fig 7 6 A recursive call to q 1 3 was made Activations p 1 3 and q 1 0 have begun and ended during the lifetime of q 1 3 leaving the activation record for q 1 3

on top Fig 7 6 d. Notice that when a procedure is recursive it is normal to have several of its activation records on the stack at the same time \Box

7 2 3 Calling Sequences

Procedure calls are implemented by what are known as *calling sequences* which consists of code that allocates an activation record on the stack and enters information into its elds A *return sequence* is similar code to restore the state of the machine so the calling procedure can continue its execution after the call

Calling sequences and the layout of activation records may di er greatly even among implementations of the same language. The code in a calling sequence is often divided between the calling procedure, the caller and the procedure it calls the callee. There is no exact division of run time tasks between caller and callee, the source language the target machine, and the operating system impose requirements that may favor one solution over another. In general, if a procedure is called from n different points, then the portion of the calling sequence assigned to the caller is generated n times. However, the portion assigned to the callee is generated only once. Hence, it is desirable to put as much of the calling sequence into the callee as possible, whatever the callee can be relied upon to know. We shall see however, that the callee cannot know everything

When designing calling sequences and the layout of activation records the following principles are helpful

- 1 Values communicated between caller and callee are generally placed at the beginning of the callee's activation record—so they are as close as possible to the caller's activation record—The motivation is that the caller can compute the values of the actual parameters of the call and place them on top of its own activation record—without having to create the entire activation record of the callee—or even to know the layout of that record Moreover—it allows for the use of procedures that do not always take the same number or type of arguments—such as C s printf function—The callee knows where to place the return value—relative to its own activation record—while however many arguments are present will appear sequentially below that place on the stack
- 2 Fixed length items are generally placed in the middle From Fig 7 5 such items typically include the control link the access link and the machine status elds If exactly the same components of the machine status are saved for each call then the same code can do the saving and restoring for each Moreover if we standardize the machine s status information then programs such as debuggers will have an easier time deciphering the stack contents if an error occurs
- 3 Items whose size may not be known early enough are placed at the end of the activation record Most local variables have a xed length which

7.2 STACK ALLOCATION OF SPACE

can be determined by the compiler by examining the type of the variable However some local variables have a size that cannot be determined until the program executes the most common example is a dynamically sized array where the value of one of the callees parameters determines the length of the array. Moreover, the amount of space needed for temporaries usually depends on how successful the code generation phase is in keeping temporaries in registers. Thus, while the space needed for temporaries is eventually known to the compiler it may not be known when the intermediate code is rst generated.

4 We must locate the top of stack pointer judiciously A common approach is to have it point to the end of the xed length elds in the activation record Fixed length data can then be accessed by xed o sets known to the intermediate code generator relative to the top of stack pointer A consequence of this approach is that variable length elds in the activation records are actually above the top of stack Their o sets need to be calculated at run time but they too can be accessed from the top of stack pointer by using a positive o set

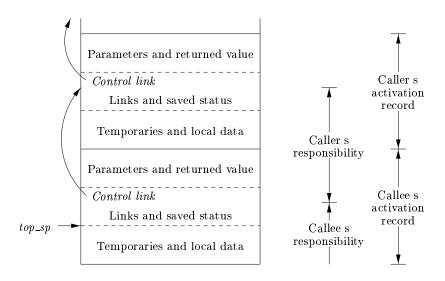

Figure 7.7 Division of tasks between caller and callee

An example of how caller and callee might cooperate in managing the stack is suggested by Fig 7.7. A register top_sp points to the end of the machine status eld in the current top activation record. This position within the callee s activation record is known to the caller so the caller can be made responsible for setting top_sp before control is passed to the callee. The calling sequence and its division between caller and callee are as follows

1 The caller evaluates the actual parameters

- 2 The caller stores a return address and the old value of top_sp into the callee's activation record. The caller then increments top_sp to the position shown in Fig. 7.7 That is top_sp is moved past the caller's local data and temporaries and the callee's parameters and status elds
- 3 The callee saves the register values and other status information
- 4 The callee initializes its local data and begins execution

A suitable corresponding return sequence is

- 1 The callee places the return value next to the parameters as in Fig 7.5
- 2 Using information in the machine status eld the callee restores *top_sp* and other registers and then branches to the return address that the caller placed in the status eld
- 3 Although top_sp has been decremented the caller knows where the return value is relative to the current value of top_sp the caller therefore may use that value

The above calling and return sequences allow the number of arguments of the called procedure to vary from call to call e g as in C s printf function. Note that at compile time the target code of the caller knows the number and types of arguments it is supplying to the callee. Hence the caller knows the size of the parameter area. The target code of the callee however must be prepared to handle other calls as well so it waits until it is called and then examines the parameter eld. Using the organization of Fig. 7.7 information describing the parameters must be placed next to the status eld so the callee can ind it. For example, in the printf function of C, the rist argument describes the remaining arguments so once the rist argument has been located, the callee can individually whatever other arguments there are

7 2 4 Variable Length Data on the Stack

The run time memory management system must deal frequently with the allo cation of space for objects the sizes of which are not known at compile time but which are local to a procedure and thus may be allocated on the stack. In modern languages objects whose size cannot be determined at compile time are allocated space in the heap—the storage structure that we discuss in Section 7.4. However—it is also possible to allocate objects—arrays—or other structures of unknown size on the stack—and we discuss here how to do so—The reason to prefer placing objects on the stack if possible is that we avoid the expense of garbage collecting their space—Note that the stack can be used only for an object if it is local to a procedure and becomes inaccessible when the procedure returns

A common strategy for allocating variable length arrays i e arrays whose size depends on the value of one or more parameters of the called procedure is

7.2 STACK ALLOCATION OF SPACE

shown in Fig 7.8. The same scheme works for objects of any type if they are local to the procedure called and have a size that depends on the parameters of the call

In Fig. 7.8 procedure p has three local arrays whose sizes we suppose cannot be determined at compile time. The storage for these arrays is not part of the activation record for p although it does appear on the stack. Only a pointer to the beginning of each array appears in the activation record itself. Thus when p is executing these pointers are at known o sets from the top of stack pointer so the target code can access array elements through these pointers

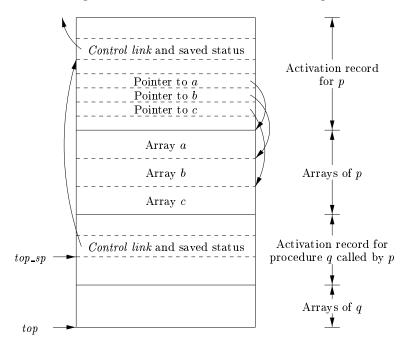

Figure 7 8 Access to dynamically allocated arrays

Also shown in Fig. 7.8 is the activation record for a procedure q called by p. The activation record for q begins after the arrays of p and any variable length arrays of q are located beyond that

Access to the data on the stack is through two pointers top and top_sp Here top marks the actual top of stack it points to the position at which the next activation record will begin. The second top_sp is used to ind local xed length, elds of the top activation record. For consistency with Fig. 7.7 we shall suppose that top_sp points to the end of the machine status, eld. In Fig. 7.8 top_sp points to the end of this eld in the activation record for q. From there we can indicate the control link, eld for q which leads us to the place in the activation record for p where top_sp pointed when p was on top

The code to reposition top and top_sp can be generated at compile time

in terms of sizes that will become known at run time. When q returns top_sp can be restored from the saved control link in the activation record for q. The new value of top is the old unrestored value of top_sp minus the length of the machine status control and access link return value and parameter elds as in Fig. 7.5 in q s activation record. This length is known at compile time to the callee although it may depend on the caller if the number of parameters can vary across calls to q

7 2 5 Exercises for Section 7 2

Exercise 7 2 1 Suppose that the program of Fig. 7 2 uses a partition function that always picks a m as the separator v. Also when the array a m and a n is reordered assume that the order is preserved as much as possible. That is rest come all the elements less than v in their original order, then all elements equal to v and nally all elements greater than v in their original order.

- a Draw the activation tree when the numbers 9 8 7 6 5 4 3 2 1 are sorted
- b What is the largest number of activation records that ever appear together on the stack

Exercise 7 2 2 Repeat Exercise 7 2 1 when the initial order of the numbers is 1 3 5 7 9 2 4 6 8

Exercise 7 2 3 In Fig 7 9 is C code to compute Fibonacci numbers recursively Suppose that the activation record for f includes the following elements in order return value argument n local s local t there will normally be other elements in the activation record as well. The questions below assume that the initial call is f 5

- a Show the complete activation tree
- b What does the stack and its activation records look like the $\$ rst time f 1 is about to return
- c What does the stack and its activation records look like the f 1 is about to return

Exercise 7 2 4 Here is a sketch of two C functions f and g

```
int f int x int i return i 1 int g int y int j f j 1
```

That is function g calls f Draw the top of the stack starting with the activation record for g after g calls f and f is about to return. You can consider only return values parameters control links and space for local variables you do not have to consider stored state or temporary or local values not shown in the code sketch. Answer the following questions

73 ACCESS TO NONLOCAL DATA ON THE STACK

```
int f int n
  int t s
  if n 2 return 1
  s f n 1
  t f n 2
  return s t
```

Figure 7 9 Fibonacci program for Exercise 7 2 3

- a Which function creates the space on the stack for each element
- b Which function writes the value of each element
- c To which activation record does the element belong

Exercise 7 2 5 In a language that passes parameters by reference there is a function f(x, y) that does the following

```
x x 1 y y 2 return x y
```

If a is assigned the value 3 and then f a a is called what is returned

Exercise 7 2 6 The C function f is de ned by

```
int f int x py ppz ppz 1 py 2 x 3 return x py ppz
```

Variable a is a pointer to b variable b is a pointer to c and c is an integer currently with value 4 If we call f c b a what is returned

7 3 Access to Nonlocal Data on the Stack

In this section we consider how procedures access their data. Especially important is the mechanism for anding data used within a procedure p but that does not belong to p. Access becomes more complicated in languages where procedures can be declared inside other procedures. We therefore begin with the simple case of C functions and then introduce a language ML that permits both nested function declarations and functions as a rst class objects that is functions can take functions as arguments and return functions as values. This capability can be supported by modifying the implementation of the run time stack and we shall consider several options for modifying the activation records of Section 7.2

7 3 1 Data Access Without Nested Procedures

In the C family of languages all variables are defined either within a single function or outside any function—globally—Most importantly it is impossible to declare one procedure whose scope is entirely within another procedure Rather a global variable v has a scope consisting of all the functions that follow the declaration of v except where there is a local definition of the identier v Variables declared within a function have a scope consisting of that function only or part of it if the function has nested blocks as discussed in Section 1 6 3

For languages that do not allow nested procedure declarations allocation of storage for variables and access to those variables is simple

- 1 Global variables are allocated static storage. The locations of these variables remain xed and are known at compile time. So to access any variable that is not local to the currently executing procedure, we simply use the statically determined address.
- 2 Any other name must be local to the activation at the top of the stack We may access these variables through the *top_sp* pointer of the stack

An important bene t of static allocation for globals is that declared proce dures may be passed as parameters or returned as results in C a pointer to the function is passed—with no substantial change in the data access strategy With the C static scoping rule—and without nested procedures any name non local to one procedure is nonlocal to all procedures regardless of how they are activated—Similarly if a procedure is returned as a result—then any nonlocal name refers to the storage statically allocated for it

7 3 2 Issues With Nested Procedures

Access becomes far more complicated when a language allows procedure declarations to be nested and also uses the normal static scoping rule that is a procedure can access variables of the procedures whose declarations surround its own declaration following the nested scoping rule described for blocks in Section 1 6 3. The reason is that knowing at compile time that the declaration of p is immediately nested within q does not tell us the relative positions of their activation records at run time. In fact, since either p or q or both may be recursive there may be several activation records of p and or q on the stack

Finding the declaration that applies to a nonlocal name x in a nested procedure p is a static decision it can be done by an extension of the static scope rule for blocks. Suppose x is declared in the enclosing procedure q. Finding the relevant activation of q from an activation of p is a dynamic decision it requires additional run time information about activations. One possible solution to this problem is to use access links—which we introduce in Section 7.3.5

7 3 3 A Language With Nested Procedure Declarations

The C family of languages and many other familiar languages do not support nested procedures so we introduce one that does. The history of nested procedures in languages is long. Algol 60 an ancestor of C had this capability as did its descendant Pascal a once popular teaching language. Of the later languages with nested procedures one of the most in uential is ML and it is this language whose syntax and semantics we shall borrow see the box on More about ML for some of the interesting features of ML

ML is a functional language meaning that variables once declared and initialized are not changed. There are only a few exceptions such as the array whose elements can be changed by special function calls

Variables are de ned and have their unchangeable values initialized by a statement of the form

Functions are de ned using the syntax

For function bodies we shall use let statements of the form

The de nitions are normally val or fun statements. The scope of each such de nition consists of all following de nitions up to the in and all the statements up to the end. Most importantly function de nitions can be nested. For example, the body of a function p can contain a let statement that includes the de nition of another nested function q. Similarly, q can have function de nitions within its own body leading to arbitrarily deep nesting of functions

7 3 4 Nesting Depth

Let us give $nesting\ depth\ 1$ to procedures that are not nested within any other procedure. For example, all C functions are at nesting depth 1. However, if a procedure p is defined immediately within a procedure at nesting depth i, then give p the nesting depth i.

Example 7 5 Figure 7 10 contains a sketch in ML of our running quicksort example. The only function at nesting depth 1 is the outermost function sort which reads an array a of 9 integers and sorts them using the quicksort algorithm. Defined within sort at line 2 is the array a itself. Notice the form

More About ML

In addition to being almost purely functional ML presents a number of other surprises to the programmer who is used to C and its family

ML supports higher order functions That is a function can take functions as arguments and can construct and return other functions Those functions in turn can take functions as arguments to any level

ML has essentially no iteration as in C s for and while statements for instance Rather the e ect of iteration is achieved by recursion. This approach is essential in a functional language since we cannot change the value of an iteration variable like i in for i 0 i 10 i — of C Instead ML would make i a function argument and the function would call itself with progressively higher values of i until the limit was reached

ML supports lists and labeled tree structures as primitive data types

ML does not require declaration of variable types Rather it deduces types at compile time and treats it as an error if it cannot For example val x 1 evidently makes x have integer type and if we also see val y 2 x then we know y is also an integer

of the ML declaration. The rst argument of array says we want the array to have 11 elements all ML arrays are indexed by integers starting with 0 so this array is quite similar to the C array a from Fig. 7.2. The second argument of array says that initially all elements of the array a hold the value 0. This choice of initial value lets the ML compiler deduce that a is an integer array since 0 is an integer so we never have to declare a type for a

Also declared within sort are several functions readArray exchange and quicksort On lines 4 and 6 we suggest that readArray and exchange each access the array a. Note that in ML array accesses can violate the functional nature of the language and both these functions actually change values of a s elements as in the C version of quicksort. Since each of these three functions is defined immediately within a function at nesting depth 1, their nesting depths are all 2.

Lines 7 through 11 show some of the detail of quicksort Local value v the pivot for the partition is declared at line 8 Function partition is de ned at line 9 In line 10 we suggest that partition accesses both the array a and the pivot value v and also calls the function exchange Since partition is de ned immediately within a function at nesting depth 2 it is at depth 3 Line

73 ACCESS TO NONLOCAL DATA ON THE STACK

```
1 fun sort inputFile outputFile
       let
2
                    array 11 0
            val a
3
            fun readArray inputFile
 4
5
            fun exchange i j
 6
 7
            fun quicksort m n
                let
8
                    val v
9
                    fun partition y z
10
                                          exchange
                in
11
                                    partition
                                                   quicksort
                end
       in
12
                                    quicksort
                      readArray
       end
```

Figure 7 10 A version of quicksort in ML style using nested functions

11 suggests that quicksort accesses variables a and v the function partition and itself recursively

Line 12 suggests that the outer function sort accesses a and calls the two procedures readArray and quicksort

7 3 5 Access Links

A direct implementation of the normal static scope rule for nested functions is obtained by adding a pointer called the $access\ link$ to each activation record. If procedure p is nested immediately within procedure q in the source code, then the access link in any activation of p points to the most recent activation of q. Note that the nesting depth of q must be exactly one less than the nesting depth of p. Access links form a chain from the activation record at the top of the stack to a sequence of activations at progressively lower nesting depths. Along this chain are all the activations whose data and procedures are accessible to the currently executing procedure

Suppose that the procedure p at the top of the stack is at nesting depth n_p and p needs to access x which is an element defined within some procedure q that surrounds p and has nesting depth n_q . Note that $n_q = n_p$ with equality only if p and q are the same procedure. To find x we start at the activation record for p at the top of the stack and follow the access link $n_p = n_q$ times from activation record to activation record. Finally, we wind up at an activation record for q and it will always be the most recent.

for q that currently appears on the stack. This activation record contains the element x that we want. Since the compiler knows the layout of activation records x will be found at some x ed x oset from the position in x activation record that we can reach by following the last access link

Example 7 6 Figure 7 11 shows a sequence of stacks that might result from execution of the function sort of Fig 7 10. As before we represent function names by their rst letters and we show some of the data that might appear in the various activation records as well as the access link for each activation. In Fig 7 11 a we see the situation after sort has called readArray to load input into the array a and then called quicksort 1 9 to sort the array. The access link from quicksort 1 9 points to the activation record for sort not because sort called quicksort but because sort is the most closely nested function surrounding quicksort in the program of Fig. 7 10

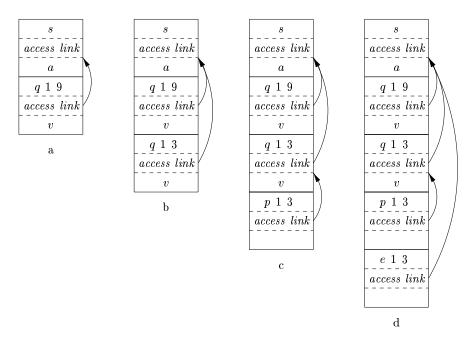

Figure 7 11 Access links for nding nonlocal data

In successive steps of Fig 711 we see a recursive call to quicksort 1 3 followed by a call to partition which calls exchange Notice that quicksort 1 3 s access link points to sort for the same reason that quicksort 1 9 s does

In Fig 7 11 d—the access link for *exchange* bypasses the activation records for *quicksort* and *partition* since *exchange* is nested immediately within *sort* That arrangement is ne since *exchange* needs to access only the array a and the two elements it must swap are indicated by its own parameters i and j \square

7 3 6 Manipulating Access Links

How are access links determined The simple case occurs when a procedure call is to a particular procedure whose name is given explicitly in the procedure call. The harder case is when the call is to a procedure parameter in that case the particular procedure being called is not known until run time, and the nesting depth of the called procedure may differ in different executions of the call. Thus, let us a rst consider what should happen when a procedure q calls procedure p explicitly. There are two cases

- 1 Procedure p is at a higher nesting depth than q Then p must be defined immediately within q or the call by q would not be at a position that is within the scope of the procedure name p. Thus the nesting depth of p is exactly one greater than that of q and the access link from p must lead to q. It is a simple matter for the calling sequence to include a step that places in the access link for p a pointer to the activation record of q. Examples include the call of quicksort by sort to set up Fig. 7.11 a and the call of partition by quicksort to create Fig. 7.11 c.
- 2 The nesting depth n_p of p is less than or equal to the nesting depth n_q of q In order for the call within q to be in the scope of name p procedure q must be nested within some procedure r while p is a procedure de ned immediately within r. The top activation record for r can therefore be found by following the chain of access links starting in the activation record for q for n_q n_p 1 hops. Then the access link for p must go to this activation of r. This case includes recursive calls where p q. In that case the chain of access links is followed for one hop and the access links for p and q are the same. An example is the call of quicksort 1 3 by quicksort 1 9 to set up Fig. 7.11 b. It also includes the case of mutually recursive calls where two or more procedures are defined within a common parent

Example 7 7 For an example of case 3 notice how we go from Fig 7 11 c to Fig 7 11 d. The nesting depth 2 of the called function *exchange* is one less than the depth 3 of the calling function *partition*. Thus we start at the activation record for *partition* and follow 3 2 1 2 access links which takes us from *partition* s activation record to that of *quicksort* 1 3 to that of *sort*. The access link for *exchange* therefore goes to the activation record for *sort* as we see in Fig 7 11 d

An equivalent way to discover this access link is simply to follow access links for n_q n_p hops and copy the access link found in that record. In our example we would go one hop to the activation record for quicksort 1 3 and copy its access link to sort. Notice that this access link is correct for exchange even though exchange is not in the scope of quicksort these being sibling functions nested within sort.

7 3 7 Access Links for Procedure Parameters

When a procedure p is passed to another procedure q as a parameter and q then calls its parameter and therefore calls p in this activation of q it is possible that q does not know the context in which p appears in the program. If so it is impossible for q to know how to set the access link for p. The solution to this problem is as follows when procedures are used as parameters the caller needs to pass along with the name of the procedure parameter the proper access link for that parameter

The caller always knows the link since if p is passed by procedure r as an actual parameter then p must be a name accessible to r and therefore r can determine the access link for p exactly as if p were being called by r directly. That is we use the rules for constructing access links given in Section 7.3.6

Example 7.8 In Fig. 7.12 we see a sketch of an ML function a that has functions b and c nested within it. Function b has a function valued parameter f which it calls. Function c de nes within it a function d and c then calls b with actual parameter d

```
fun a x
let
fun b f
f fun c y
let
fun d z
in
b d
end
in
c 1
end
```

Figure 7 12 Sketch of ML program that uses function parameters

Let us trace what happens when a is executed First a calls c so we place an activation record for c above that for a on the stack. The access link for c points to the record for a since c is defined immediately within a. Then c calls b d. The calling sequence sets up an activation record for b as shown in Fig. 7.13 a

Within this activation record is the actual parameter d and its access link which together form the value of formal parameter f in the activation record for b Notice that c knows about d since d is defined within c and therefore c passes a pointer to its own activation record as the access link. No matter where d was defined in the scope of that definition then one of the three rules of Section 7 3 6 must apply and c can provide the link

73 ACCESS TO NONLOCAL DATA ON THE STACK

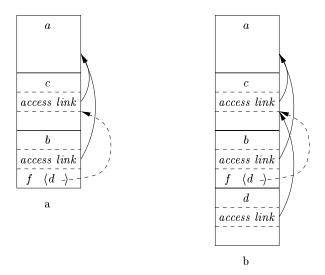

Figure 7 13 Actual parameters carry their access link with them

Now let us look at what b does. We know that at some point it uses its parameter f which has the e ect of calling d. An activation record for d appears on the stack as shown in Fig. 7.13 b. The proper access link to place in this activation record is found in the value for parameter f the link is to the activation record for c since c immediately surrounds the de nition of d. Notice that b is capable of setting up the proper link even though b is not in the scope of c s or d s de nitions. \Box

7 3 8 Displays

One problem with the access link approach to nonlocal data is that if the nesting depth gets large we may have to follow long chains of links to reach the data we need A more e cient implementation uses an auxiliary array d called the display which consists of one pointer for each nesting depth. We arrange that at all times d i is a pointer to the highest activation record on the stack for any procedure at nesting depth i Examples of a display are shown in Fig. 7.14. For instance in Fig. 7.14 d. we see the display d with d 1 holding a pointer to the activation record for sort the highest and only activation record for a function at nesting depth 1. Also d 2 holds a pointer to the activation record for exchange the highest record at depth 2 and d 3 points to partition the highest record at depth 3.

The advantage of using a display is that if procedure p is executing and it needs to access element x belonging to some procedure q we need to look only in d i where i is the nesting depth of q we follow the pointer d i to the activation record for q wherein x is found at a known o set. The compiler knows what i is so it can generate code to access x using d i and the o set of

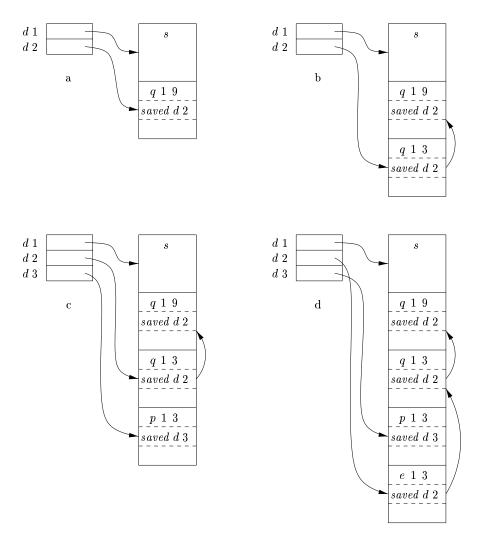

Figure 7 14 Maintaining the display

73 ACCESS TO NONLOCAL DATA ON THE STACK

x from the top of the activation record for q Thus the code never needs to follow a long chain of access links

In order to maintain the display correctly we need to save previous values of display entries in new activation records. If procedure p at depth n_p is called and its activation record is not the first on the stack for a procedure at depth n_p , then the activation record for p needs to hold the previous value of d n_p while d n_p itself is set to point to this activation of p. When p returns and its activation record is removed from the stack, we restore d n_p to have its value prior to the call of p

Example 7 9 Several steps of manipulating the display are illustrated in Fig 7 14 In Fig 7 14 a sort at depth 1 has called quicksort 1 9 at depth 2 The activation record for quicksort has a place to store the old value of d 2 indicated as saved d 2 although in this case since there was no prior activation record at depth 2 this pointer is null

In Fig 714 b quicksort 1 9 calls quicksort 1 3 Since the activation records for both calls are at depth 2 we must store the pointer to quicksort 1 9 which was in d 2 in the record for quicksort 1 3 Then d 2 is made to point to quicksort 1 3

Next partition is called This function is at depth 3 so we use the slot d 3 in the display for the -rst time and make it point to the activation record for partition. The record for partition has a slot for a former value of d 3 but in this case there is none so the pointer remains null. The display and stack at this time are shown in Fig. 7.14 c.

Then partition calls exchange That function is at depth 2 so its activation record stores the old pointer d 2 which goes to the activation record for quicksort 1 3 Notice that the display pointers cross that is d 3 points further down the stack than d 2 does However that is a proper situation exchange can only access its own data and that of sort via d 1 \Box

7 3 9 Exercises for Section 7 3

Exercise 7 3 1 In Fig 7 15 is a ML function main that computes Fibonacci numbers in a nonstandard way Function fib0 will compute the nth Fibonacci number for any n=0 Nested within it is fib1 which computes the nth Fibonacci number on the assumption n=2 and nested within fib1 is fib2 which assumes n=4 Note that neither fib1 nor fib2 need to check for the basis cases Show the stack of activation records that result from a call to main up until the time that the rst call to fib0 1 is about to return Show the access link in each of the activation records on the stack

Exercise 7 3 2 Suppose that we implement the functions of Fig 7 15 using a display Show the display at the moment the rst call to fib0 1 is about to return Also indicate the saved display entry in each of the activation records on the stack at that time

```
fun main
    let
        fun fib0 n
            let
                 fun fib1 n
                     let
                                                     fib1 n 2
                         fun fib2 n
                                        fib1 n 1
                     in
                         if n
                                  4 then fib2 n
                         else fib0 n 1
                                           fib0 n 2
                     end
            in
                 if n
                         2 then fib1 n
                 else 1
            end
    in
        fib0 4
    end
```

7 4 Heap Management

The heap is the portion of the store that is used for data that lives indenitely or until the program explicitly deletes it. While local variables typically become inaccessible when their procedures end many languages enable us to create objects or other data whose existence is not tied to the procedure activation that creates them. For example, both C and Java give the programmer new to create objects that may be passed or pointers to them may be passed from procedure to procedure so they continue to exist long after the procedure that created them is gone. Such objects are stored on a heap

In this section we discuss the *memory manager* the subsystem that allo cates and deallocates space within the heap it serves as an interface between application programs and the operating system. For languages like C or C that deallocate chunks of storage *manually* i.e. by explicit statements of the program such as free or delete—the memory manager is also responsible for implementing deallocation

In Section 7.5 we discuss garbage collection which is the process of nding spaces within the heap that are no longer used by the program and can therefore be reallocated to house other data items. For languages like Java it is the garbage collector that deallocates memory. When it is required the garbage collector is an important subsystem of the memory manager.

7 4 1 The Memory Manager

The memory manager keeps track of all the free space in heap storage at all times It performs two basic functions

Allocation When a program requests memory for a variable or object ² the memory manager produces a chunk of contiguous heap memory of the requested size If possible it satis es an allocation request using free space in the heap if no chunk of the needed size is available it seeks to increase the heap storage space by getting consecutive bytes of virtual memory from the operating system If space is exhausted the memory manager passes that information back to the application program

Deallocation The memory manager returns deallocated space to the pool of free space so it can reuse the space to satisfy other allocation requests Memory managers typically do not return memory to the operating system even if the program s heap usage drops

Memory management would be simpler if a all allocation requests were for chunks of the same size and b storage were released predictably say rst allocated rst deallocated. There are some languages such as Lisp for which condition a holds pure Lisp uses only one data element a two pointer cell—from which all data structures are built—Condition—b—also holds in some situations—the most common being data that can be allocated on the run time stack—However—in most languages—neither—a—nor—b—holds in general—Rather—data elements of di—erent sizes are allocated and there is no good way to predict the lifetimes of all allocated objects

Thus the memory manager must be prepared to service in any order allo cation and deallocation requests of any size ranging from one byte to as large as the program s entire address space

Here are the properties we desire of memory managers

Space E ciency A memory manager should minimize the total heap space needed by a program. Doing so allows larger programs to run in a xed virtual address space. Space e ciency is achieved by minimizing fragmentation discussed in Section 7 4 4

Program E ciency A memory manager should make good use of the memory subsystem to allow programs to run faster. As we shall see in Section 7.4.2 the time taken to execute an instruction can vary widely depending on where objects are placed in memory. Fortunately programs tend to exhibit locality a phenomenon discussed in Section 7.4.3 which refers to the nonrandom clustered way in which typical programs access memory. By attention to the placement of objects in memory the memory manager can make better use of space and hopefully make the program run faster.

 $^{^2}$ In what follows we shall refer to things requiring memory space as objects—even if they are not true objects in the object oriented programming—sense

Low Overhead Because memory allocations and deallocations are fre quent operations in many programs it is important that these operations be as e-cient as possible. That is we wish to minimize the overhead the fraction of execution time spent performing allocation and deallocation. Notice that the cost of allocations is dominated by small requests the overhead of managing large objects is less important because it usu ally can be amortized over a larger amount of computation.

7 4 2 The Memory Hierarchy of a Computer

Memory management and compiler optimization must be done with an aware ness of how memory behaves Modern machines are designed so that program mers can write correct programs without concerning themselves with the details of the memory subsystem. However, the endience of a program is determined not just by the number of instructions executed but also by how long it takes to execute each of these instructions. The time taken to execute an instruction can vary significantly since the time taken to access different parts of memory can vary from nanoseconds to milliseconds. Data intensive programs can there fore benent significantly from optimizations that make good use of the memory subsystem. As we shall see in Section 7.4.3, they can take advantage of the phenomenon of locality.

The large variance in memory access times is due to the fundamental limitation in hardware technology we can build small and fast storage or large and slow storage but not storage that is both large and fast. It is simply impossible today to build gigabytes of storage with nanosecond access times which is how fast high performance processors run. Therefore practically all modern computers arrange their storage as a memory hierarchy. A memory hierarchy as shown in Fig. 7.16 consists of a series of storage elements with the smaller faster ones closer to the processor and the larger slower ones further away.

Typically a processor has a small number of registers whose contents are under software control. Next it has one or more levels of cache usually made out of static RAM that are kilobytes to several megabytes in size. The next level of the hierarchy is the physical main memory made out of hundreds of megabytes or gigabytes of dynamic RAM. The physical memory is then backed up by virtual memory which is implemented by gigabytes of disks. Upon a memory access the machine are tooks for the data in the closest lowest level storage and if the data is not there looks in the next higher level and so on

Registers are scarce so register usage is tailored for the speci-c applications and managed by the code that a compiler generates All the other levels of the hierarchy are managed automatically in this way not only is the programming task simplified but the same program can work electively across machines with different memory configurations. With each memory access the machine searches each level of the memory in succession starting with the lowest level until it locates the data. Caches are managed exclusively in hardware in order to keep up with the relatively fast RAM access times. Because disks are relatively

74 HEAP MANAGEMENT

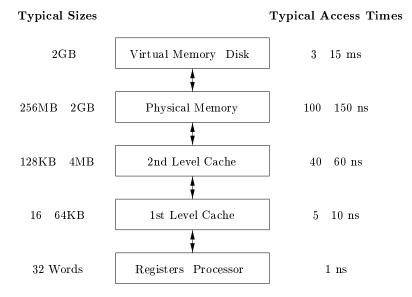

Figure 716 Typical Memory Hierarchy Con gurations

tively slow the virtual memory is managed by the operating system with the assistance of a hardware structure known as the translation lookaside bu er

Data is transferred as blocks of contiguous storage. To amortize the cost of access larger blocks are used with the slower levels of the hierarchy. Be tween main memory and cache data is transferred in blocks known as cache lines which are typically from 32 to 256 bytes long. Between virtual memory disk and main memory data is transferred in blocks known as pages typically between 4K and 64K bytes in size

7 4 3 Locality in Programs

Most programs exhibit a high degree of *locality* that is they spend most of their time executing a relatively small fraction of the code and touching only a small fraction of the data. We say that a program has *temporal locality* if the memory locations it accesses are likely to be accessed again within a short period of time. We say that a program has *spatial locality* if memory locations close to the location accessed are likely also to be accessed within a short period of time.

The conventional wisdom is that programs spend 90 — of their time executing 10 — of the code – Here is why

Programs often contain many instructions that are never executed Programs built with components and libraries use only a small fraction of the provided functionality Also as requirements change and programs evolve legacy systems often contain many instructions that are no longer used

Static and Dynamic RAM

Most random access memory is dynamic which means that it is built of very simple electronic circuits that lose their charge and thus forget the bit they were storing in a short time. These circuits need to be refreshed—that is their bits read and rewritten—periodically—On the other hand static RAM is designed with a more complex circuit for each bit and consequently the bit stored can stay inde nitely until it is changed—Evidently—a chip can store more bits if it uses dynamic RAM circuits than if it uses static RAM circuits so we tend to see large main memories of the dynamic variety while smaller memories like caches are made from static circuits

Only a small fraction of the code that could be invoked is actually executed in a typical run of the program. For example, instructions to handle illegal inputs and exceptional cases, though critical to the correctness of the program, are seldom invoked on any particular run

The typical program spends most of its time executing innermost loops and tight recursive cycles in a program

Locality allows us to take advantage of the memory hierarchy of a modern computer as shown in Fig 7 16 By placing the most common instructions and data in the fast but small storage while leaving the rest in the slow but large storage we can lower the average memory access time of a program signic cantly

It has been found that many programs exhibit both temporal and spatial locality in how they access both instructions and data. Data access patterns however generally show a greater variance than instruction access patterns. Policies such as keeping the most recently used data in the fastest hierarchy work well for common programs but may not work well for some data intensive programs—ones that cycle through very large arrays for example

We often cannot tell just from looking at the code which sections of the code will be heavily used especially for a particular input. Even if we know which instructions are executed heavily the fastest cache often is not large enough to hold all of them at the same time. We must therefore adjust the contents of the fastest storage dynamically and use it to hold instructions that are likely to be used heavily in the near future.

Optimization Using the Memory Hierarchy

The policy of keeping the most recently used instructions in the cache tends to work well in other words the past is generally a good predictor of future memory usage When a new instruction is executed there is a high proba bility that the next instruction also will be executed This phenomenon is an

Cache Architectures

How do we know if a cache line is in a cache. It would be too expensive to check every single line in the cache so it is common practice to restrict the placement of a cache line within the cache. This restriction is known as set associativity. A cache is k way set associative if a cache line can reside only in k locations. The simplest cache is a 1-way associative cache also known as a direct mapped cache. In a direct mapped cache data with memory address n can be placed only in cache address n mod s where s is the size of the cache. Similarly, a k way set associative cache is divided into k sets where a datum with address n can be mapped only to the location n mod s k in each set. Most instruction and data caches have associativity between 1 and 8. When a cache line is brought into the cache and all the possible locations that can hold the line are occupied it is typical to evict the line that has been the least recently used

example of spatial locality. One elective technique to improve the spatial locality of instructions is to have the compiler place basic blocks sequences of instructions that are always executed sequentially that are likely to follow each other contiguously on the same page or even the same cache line if possible. Instructions belonging to the same loop or same function also have a high probability of being executed together ³

We can also improve the temporal and spatial locality of data accesses in a program by changing the data layout or the order of the computation. For example programs that visit large amounts of data repeatedly each time per forming a small amount of computation do not perform well. It is better if we can bring some data from a slow level of the memory hierarchy to a faster level e.g. disk to main memory once and perform all the necessary computations on this data while it resides at the faster level. This concept can be applied recursively to reuse data in physical memory in the caches and in the registers

7 4 4 Reducing Fragmentation

At the beginning of program execution the heap is one contiguous unit of free space. As the program allocates and deallocates memory this space is broken up into free and used chunks of memory and the free chunks need not reside in a contiguous area of the heap. We refer to the free chunks of memory as holes. With each allocation request, the memory manager must place the requested chunk of memory into a large enough hole. Unless a hole of exactly the right size is found, we need to split some hole creating a yet smaller hole.

³ As a machine fetches a word in memory it is relatively inexpensive to *prefetch* the next several contiguous words of memory as well. Thus a common memory hierarchy feature is that a multiword block is fetched from a level of memory each time that level is accessed.

With each deallocation request the freed chunks of memory are added back to the pool of free space. We coalesce contiguous holes into larger holes as the holes can only get smaller otherwise. If we are not careful, the free memory may end up getting fragmented consisting of large numbers of small noncontiguous holes. It is then possible that no hole is large enough to satisfy a future request even though there may be su-cient aggregate free space.

Best Fit and Next Fit Object Placement

We reduce fragmentation by controlling how the memory manager places new objects in the heap. It has been found empirically that a good strategy for mini mizing fragmentation for real life programs is to allocate the requested memory in the smallest available hole that is large enough. This best t algorithm tends to spare the large holes to satisfy subsequent larger requests. An alternative called rst t where an object is placed in the rst lowest address hole in which it to take less time to place objects but has been found inferior to best t in overall performance

To implement best t placement more e ciently we can separate free space chunks into bins according to their sizes. One practical idea is to have many more bins for the smaller sizes because there are usually many more small objects. For example, the Lea memory manager used in the GNU C compiler gcc aligns all chunks to 8 byte boundaries. There is a bin for every multiple of 8 byte chunks from 16 bytes to 512 bytes. Larger sized bins are logarithmically spaced in either minimum size for each bin is twice that of the previous bin and within each of these bins the chunks are ordered by their size. There is always a chunk of free space that can be extended by requesting more pages from the operating system. Called the wilderness chunk this chunk is treated by Lea as the largest sized bin because of its extensibility

Binning makes it easy to nd the best t chunk

If as for small sizes requested from the Lea memory manager there is a bin for chunks of that size only we may take any chunk from that bin

For sizes that do not have a private bin we not the one bin that is allowed to include chunks of the desired size. Within that bin we can use either a rst t or a best t strategy i e we either look for and select the rst chunk that is su ciently large or we spend more time and not the smallest chunk that is su ciently large. Note that when the t is not exact the remainder of the chunk will generally need to be placed in a bin with smaller sizes.

However it may be that the target bin is empty or all chunks in that bin are too small to satisfy the request for space. In that case, we simply repeat the search using the bin for the next larger size s. Eventually, we either and a chunk we can use or we reach the wilderness chunk from which we can surely obtain the needed space possibly by going to the operating system and getting additional pages for the heap

74 HEAP MANAGEMENT

While best t placement tends to improve space utilization it may not be the best in terms of spatial locality. Chunks allocated at about the same time by a program tend to have similar reference patterns and to have similar lifetimes. Placing them close together thus improves the program's spatial locality. One useful adaptation of the best t algorithm is to modify the placement in the case when a chunk of the exact requested size cannot be found. In this case, we use a next t strategy trying to allocate the object in the chunk that has last been split whenever enough space for the new object remains in that chunk Next t also tends to improve the speed of the allocation operation

Managing and Coalescing Free Space

When an object is deallocated manually the memory manager must make its chunk free so it can be allocated again. In some circumstances it may also be possible to combine *coalesce* that chunk with adjacent chunks of the heap to form a larger chunk. There is an advantage to doing so since we can always use a large chunk to do the work of small chunks of equal total size but many small chunks cannot hold one large object as the combined chunk could

If we keep a bin for chunks of one xed size as Lea does for small sizes then we may prefer not to coalesce adjacent blocks of that size into a chunk of double the size. It is simpler to keep all the chunks of one size in as many pages as we need and never coalesce them. Then a simple allocation deallocation scheme is to keep a bitmap with one bit for each chunk in the bin. A 1 indicates the chunk is occupied 0 indicates it is free. When a chunk is deallocated, we change its 1 to a 0. When we need to allocate a chunk we indicates and only chunk with a 0 bit change that bit to a 1 and use the corresponding chunk. If there are no free chunks we get a new page divide it into chunks of the appropriate size and extend the bit vector.

Matters are more complex when the heap is managed as a whole without binning or if we are willing to coalesce adjacent chunks and move the resulting chunk to a di erent bin if necessary. There are two data structures that are useful to support coalescing of adjacent free blocks

Boundary Tags At both the low and high ends of each chunk whether free or allocated we keep vital information. At both ends we keep a free used bit that tells whether or not the block is currently allocated used or available free. Adjacent to each free used bit is a count of the total number of bytes in the chunk

A Doubly Linked Embedded Free List The free chunks but not the allocated chunks are also linked in a doubly linked list. The pointers for this list are within the blocks themselves say adjacent to the boundary tags at either end. Thus no additional space is needed for the free list although its existence does place a lower bound on how small chunks can get they must accommodate two boundary tags and two pointers even if the object is a single byte. The order of chunks on the free list is left

unspeci ed For example the list could be sorted by size thus facilitating best t placement

Example 7 10 Figure 7 17 shows part of a heap with three adjacent chunks $A \ B$ and C Chunk B of size 100 has just been deallocated and returned to the free list. Since we know the beginning left end of B we also know the end of the chunk that happens to be immediately to B s left namely A in this example. The free used bit at the right end of A is currently 0 so A too is free. We may therefore coalesce A and B into one chunk of 300 bytes.

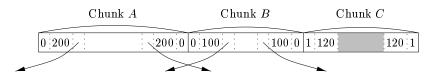

Figure 7 17 Part of a heap and a doubly linked free list

It might be the case that chunk C the chunk immediately to B s right is also free in which case we can combine all of A B and C Note that if we always coalesce chunks when we can then there can never be two adjacent free chunks so we never have to look further than the two chunks adjacent to the one being deallocated. In the current case we indicate the deginning of C by starting at the left end of B which we know and inding the total number of bytes in B which is found in the left boundary tag of B and is 100 bytes. With this information we indicate the right end of B and the beginning of the chunk to its right. At that point we examine the free used bit of C and indicate that it is 1 for used hence C is not available for coalescing

Since we must coalesce A and B we need to remove one of them from the free list. The doubly linked free list structure lets us and the chunks before and after each of A and B. Notice that it should not be assumed that physical neighbors A and B are also adjacent on the free list. Knowing the chunks preceding and following A and B on the free list, it is straightforward to manipulate pointers on the list to replace A and B by one coalesced chunk. \Box

Automatic garbage collection can eliminate fragmentation altogether if it moves all the allocated objects to contiguous storage. The interaction between garbage collection and memory management is discussed in more detail in Section 7.6.4.

7 4 5 Manual Deallocation Requests

We close this section with manual memory management—where the programmer must explicitly arrange for the deallocation of data as in C and C — Ideally any storage that will no longer be accessed should be deleted—Conversely—any storage that may be referenced must not be deleted—Unfortunately it is hard to enforce either of these properties—In addition to considering the di—culties with

74 HEAP MANAGEMENT

manual deallocation we shall describe some of the techniques programmers use to help with the di culties

Problems with Manual Deallocation

Manual memory management is error prone The common mistakes take two forms failing ever to delete data that cannot be referenced is called a *memory leak* error and referencing deleted data is a *dangling pointer dereference* error

It is hard for programmers to tell if a program will never refer to some stor age in the future so the rst common mistake is not deleting storage that will never be referenced. Note that although memory leaks may slow down the exe cution of a program due to increased memory usage they do not a ect program correctness as long as the machine does not run out of memory. Many programs can tolerate memory leaks especially if the leakage is slow. However, for long running programs and especially nonstop programs like operating systems or server code it is critical that they not have leaks

Automatic garbage collection gets rid of memory leaks by deallocating all the garbage Even with automatic garbage collection a program may still use more memory than necessary. A programmer may know that an object will never be referenced even though references to that object exist somewhere. In that case, the programmer must deliberately remove references to objects that will never be referenced so the objects can be deallocated automatically.

Being overly zealous about deleting objects can lead to even worse problems than memory leaks. The second common mistake is to delete some storage and then try to refer to the data in the deallocated storage. Pointers to storage that has been deallocated are known as dangling pointers. Once the freed storage has been reallocated to a new variable any read write or deallocation via the dangling pointer can produce seemingly random elects. We refer to any operation such as read write or deallocate that follows a pointer and tries to use the object it points to as dereferencing the pointer.

Notice that reading through a dangling pointer may return an arbitrary value Writing through a dangling pointer arbitrarily changes the value of the new variable Deallocating a dangling pointer s storage means that the storage of the new variable may be allocated to yet another variable and actions on the old and new variables may conject with each other

Unlike memory leaks dereferencing a dangling pointer after the freed storage is reallocated almost always creates a program error that is hard to debug As a result programmers are more inclined not to deallocate a variable if they are not certain it is unreferencable

A related form of programming error is to access an illegal address. Common examples of such errors include dereferencing null pointers and accessing an out of bounds array element. It is better for such errors to be detected than to have the program silently corrupt the results. In fact, many security violations exploit programming errors of this type, where certain program inputs allow unintended access to data, leading to a hacker, taking control of the program.

An Example Purify

Rational s Purify is one of the most popular commercial tools that helps programmers and memory access errors and memory leaks in programs Purify instruments binary code by adding additional instructions to check for errors as the program executes. It keeps a map of memory to indicate where all the freed and used spaces are Each allocated object is bracketed with extra space accesses to unallocated locations or to spaces between objects are agged as errors. This approach and some dangling pointer references but not when the memory has been reallocated and a valid object is sitting in its place. This approach also and some out of bound array accesses if they happen to land in the space inserted at the end of the objects.

Purify also nds memory leaks at the end of a program execution It searches the contents of all the allocated objects for possible pointer values Any object without a pointer to it is a leaked chunk of memory Purify reports the amount of memory leaked and the locations of the leaked objects. We may compare Purify to a conservative garbage collector which will be discussed in Section 7 8 3

and machine One antidote is to have the compiler insert checks with every access to make sure it is within bounds. The compiler s optimizer can discover and remove those checks that are not really necessary because the optimizer can deduce that the access must be within bounds

Programming Conventions and Tools

We now present a few of the most popular conventions and tools that have been developed to help programmers cope with the complexity in managing memory

Object ownership is useful when an object s lifetime can be statically rea soned about. The idea is to associate an owner with each object at all times. The owner is a pointer to that object presumably belonging to some function invocation. The owner is existence its function is responsible for either deleting the object or for passing the object to another owner. It is possible to have other nonowning pointers to the same object, these pointers can be overwritten any time, and no deletes should ever be applied through them. This convention eliminates memory leaks as well as attempts to delete the same object twice. However, it does not help solve the dangling pointer reference problem, because it is possible to follow a nonowning pointer to an object that has been deleted.

Reference counting is useful when an object s lifetime needs to be determined dynamically The idea is to associate a count with each dynamically

7.5 INTRODUCTION TO GARBAGE COLLECTION

allocated object. Whenever a reference to the object is created we increment the reference count whenever a reference is removed we decrement the reference count. When the count goes to zero, the object can no longer be referenced and can therefore be deleted. This technique however does not catch useless circular data structures where a collection of objects cannot be accessed but their reference counts are not zero, since they refer to each other. For an illustration of this problem, see Example 7.11 Reference counting does eradicate all dangling pointer references since there are no outstanding references to any deleted objects. Reference counting is expensive because it imposes an overhead on every operation that stores a pointer

Region based allocation is useful for collections of objects whose lifetimes are tied to speci c phases in a computation. When objects are created to be used only within some step of a computation we can allocate all such objects in the same region. We then delete the entire region once that computation step completes. This region based allocation technique has limited applicability. However, it is very excient whenever it can be used instead of deallocating objects one at a time it deletes all objects in the region in a wholesale fashion.

7 4 6 Exercises for Section 7 4

Exercise 7 4 1 Suppose the heap consists of seven chunks starting at address 0 The sizes of the chunks in order are 80 30 60 50 70 20 40 bytes When we place an object in a chunk we put it at the high end if there is enough space remaining to form a smaller chunk so that the smaller chunk can easily remain on the linked list of free space However we cannot tolerate chunks of fewer that 8 bytes so if an object is almost as large as the selected chunk we give it the entire chunk and place the object at the low end of the chunk If we request space for objects of the following sizes 32 64 48 16 in that order what does the free space list look like after satisfying the requests if the method of selecting chunks is

a First tb Best t

7 5 Introduction to Garbage Collection

Data that cannot be referenced is generally known as garbage. Many high level programming languages remove the burden of manual memory management from the programmer by o ering automatic garbage collection which deallo cates unreachable data. Garbage collection dates back to the initial implementation of Lisp in 1958. Other signicant languages that o er garbage collection include Java. Perl. ML. Modula 3. Prolog. and Smalltalk.

In this section we introduce many of the concepts of garbage collection. The notion of an object being reachable is perhaps intuitive but we need to be precise the exact rules are discussed in Section 7.5.2. We also discuss in Section 7.5.3 a simple but imperfect method of automatic garbage collection reference counting which is based on the idea that once a program has lost all references to an object it simply cannot and so will not reference the storage

Section 76 covers trace based collectors which are algorithms that discover all the objects that are still useful and then turn all the other chunks of the heap into free space

7 5 1 Design Goals for Garbage Collectors

Garbage collection is the reclamation of chunks of storage holding objects that can no longer be accessed by a program. We need to assume that objects have a type that can be determined by the garbage collector at run time. From the type information, we can tell how large the object is and which components of the object contain references pointers to other objects. We also assume that references to objects are always to the address of the beginning of the object never pointers to places within the object. Thus, all references to an object have the same value and can be identified easily

A user program which we shall refer to as the *mutator* modi es the collection of objects in the heap. The mutator creates objects by acquiring space from the memory manager and the mutator may introduce and drop references to existing objects. Objects become garbage when the mutator program cannot reach them in the sense made precise in Section 7.5.2. The garbage collector nds these unreachable objects and reclaims their space by handing them to the memory manager which keeps track of the free space.

A Basic Requirement Type Safety

Not all languages are good candidates for automatic garbage collection. For a garbage collector to work it must be able to tell whether any given data element or component of a data element is or could be used as a pointer to a chunk of allocated memory space. A language in which the type of any data component can be determined is said to be type safe. There are type safe languages like ML for which we can determine types at compile time. There are other type safe languages like Java whose types cannot be determined at compile time but can be determined at run time. The latter are called dynamically typed languages. If a language is neither statically nor dynamically type safe, then it is said to be unsafe.

Unsafe languages which unfortunately include some of the most important languages such as C and C are bad candidates for automatic garbage collection. In unsafe languages memory addresses can be manipulated arbitrarily arbitrary arithmetic operations can be applied to pointers to create new pointers and arbitrary integers can be cast as pointers. Thus a program

7.5 INTRODUCTION TO GARBAGE COLLECTION

theoretically could refer to any location in memory at any time Consequently no memory location can be considered to be inaccessible and no storage can ever be reclaimed safely

In practice most C and C $\,$ programs do not generate pointers arbitrarily and a theoretically unsound garbage collector that works well empirically has been developed and used $\,$ We shall discuss conservative garbage collection for C and C $\,$ in Section 7.8.3

Performance Metrics

Garbage collection is often so expensive that although it was invented decades ago and absolutely prevents memory leaks it has yet to be adopted by many mainstream programming languages. Many different approaches have been proposed over the years and there is not one clearly best garbage collection algorithm. Before exploring the options let us rest enumerate the performance metrics that must be considered when designing a garbage collector.

Overall Execution Time Garbage collection can be very slow. It is important that it not significantly increase the total run time of an application. Since the garbage collector necessarily must touch a lot of data its performance is determined greatly by how it leverages the memory subsystem.

Space Usage It is important that garbage collection avoid fragmentation and make the best use of the available memory

Pause Time Simple garbage collectors are notorious for causing programs the mutators to pause suddenly for an extremely long time as garbage collection kicks in without warning. Thus besides minimizing the overall execution time it is desirable that the maximum pause time be minimized. As an important special case real time applications require certain computations to be completed within a time limit. We must either suppress garbage collection while performing real time tasks or restrict maximum pause time. Thus, garbage collection is seldom used in real time applications.

Program Locality We cannot evaluate the speed of a garbage collector solely by its running time. The garbage collector controls the placement of data and thus in uences the data locality of the mutator program. It can improve a mutator s temporal locality by freeing up space and reusing it it can improve the mutator s spatial locality by relocating data used together in the same cache or pages

Some of these design goals con ict with one another and tradeo s must be made carefully by considering how programs typically behave Also objects of di erent characteristics may favor di erent treatments requiring a collector to use di erent techniques for di erent kinds of objects

For example the number of objects allocated is dominated by small objects so allocation of small objects must not incur a large overhead. On the other hand consider garbage collectors that relocate reachable objects. Relocation is expensive when dealing with large objects but less so with small objects.

As another example in general the longer we wait to collect garbage in a trace based collector the larger the fraction of objects that can be collected. The reason is that objects often die young so if we wait a while many of the newly allocated objects will become unreachable. Such a collector thus costs less on the average per unreachable object collected. On the other hand infrequent collection increases a program's memory usage decreases its data locality and increases the length of the pauses.

In contrast a reference counting collector by introducing a constant over head to many of the mutator s operations can slow down the overall execution of a program signicantly. On the other hand, reference counting does not at long pauses and it is memory excient because it and garbage as soon as it is produced with the exception of certain cyclic structures discussed in Section 7.5.3

Language design can also a ect the characteristics of memory usage Some languages encourage a programming style that generates a lot of garbage For example programs in functional or almost functional programming languages create more objects to avoid mutating existing objects. In Java all objects other than base types like integers and references are allocated on the heap and not the stack even if their lifetimes are con ned to that of one function invocation. This design frees the programmer from worrying about the lifetimes of variables at the expense of generating more garbage. Compiler optimizations have been developed to analyze the lifetimes of variables and allocate them on the stack whenever possible

7 5 2 Reachability

We refer to all the data that can be accessed directly by a program without having to dereference any pointer as the *root set* For example in Java the root set of a program consists of all the static eld members and all the variables on its stack. A program obviously can reach any member of its root set at any time. Recursively any object with a reference that is stored in the eld members or array elements of any reachable object is itself reachable.

Reachability becomes a bit more complex when the program has been op timized by the compiler. First, a compiler may keep reference variables in registers. These references must also be considered part of the root set. Sec ond even though in a type safe language programmers do not get to manipulate memory addresses directly a compiler often does so for the sake of speeding up the code. Thus, registers in compiled code may point to the middle of an object or an array or they may contain a value to which an o set will be applied to compute a legal address. Here are some things an optimizing compiler can do to enable the garbage collector to and the correct root set.

7.5 INTRODUCTION TO GARBAGE COLLECTION

The compiler can restrict the invocation of garbage collection to only certain code points in the program when no hidden references exist

The compiler can write out information that the garbage collector can use to recover all the references such as specifying which registers contain references or how to compute the base address of an object that is given an internal address

The compiler can assure that there is a reference to the base address of all reachable objects whenever the garbage collector may be invoked

The set of reachable objects changes as a program executes It grows as new objects get created and shrinks as objects become unreachable It is important to remember that once an object becomes unreachable it cannot become reach able again. There are four basic operations that a mutator performs to change the set of reachable objects.

Object Allocations These are performed by the memory manager which returns a reference to each newly allocated chunk of memory This oper ation adds members to the set of reachable objects

Parameter Passing and Return Values References to objects are passed from the actual input parameter to the corresponding formal parameter and from the returned result back to the caller Objects pointed to by these references remain reachable

Reference Assignments Assignments of the form ${\tt u}$ v where u and v are references have two e ects. First u is now a reference to the object referred to by v. As long as u is reachable, the object it refers to is surely reachable. Second the original reference in u is lost. If this reference is the last to some reachable object, then that object becomes unreachable. Any time an object becomes unreachable all objects that are reachable only through references contained in that object also become unreachable.

Procedure Returns As a procedure exits the frame holding its local variables is popped o the stack. If the frame holds the only reachable reference to any object that object becomes unreachable. Again if the now unreachable objects hold the only references to other objects they too become unreachable and so on

In summary new objects are introduced through object allocations Param eter passing and assignments can propagate reachability assignments and ends of procedures can terminate reachability As an object becomes unreachable it can cause more objects to become unreachable

There are two basic ways to nd unreachable objects. Either we catch the transitions as reachable objects turn unreachable or we periodically locate all the reachable objects and then infer that all the other objects are unreachable *Reference counting* introduced in Section 7 4 5 is a well known approximation

Survival of Stack Objects

When a procedure is called a local variable v whose object is allocated on the stack may have pointers to v placed in nonlocal variables. These pointers will continue to exist after the procedure returns yet the space for v disappears resulting in a dangling reference situation. Should we ever allocate a local like v on the stack as C does for example. The answer is that the semantics of many languages requires that local variables cease to exist when their procedure returns. Retaining a reference to such a variable is a programming error, and the compiler is not required to v the bug in the program.

to the $\,$ rst approach. We maintain a count of the references to an object as the mutator performs actions that may change the set of reachable objects. When the count goes to zero, the object becomes unreachable. We discuss this approach in more detail in Section 7.5.3

The second approach computes reachability by tracing all the references transitively A trace based garbage collector starts by labeling—marking—all objects in the root set as reachable—examines iteratively all the references in reachable objects to—nd more reachable objects and labels them as such. This approach must trace all the references before it can determine any object to be unreachable—But once the reachable set is computed—it can—nd many unreachable objects all at once and locate a good deal of free storage at the same time—Because all the references must be analyzed at the same time—we have an option to relocate the reachable objects and thereby reduce fragmentation. There are many di—erent trace based algorithms—and we discuss the options in Sections 7.6 and 7.7.1

7 5 3 Reference Counting Garbage Collectors

We now consider a simple although imperfect garbage collector based on reference counting which identi es garbage as an object changes from being reachable to unreachable the object can be deleted when its count drops to zero. With a reference counting garbage collector, every object must have a eld for the reference count. Reference counts can be maintained as follows.

- 1 Object Allocation The reference count of the new object is set to 1
- 2 Parameter Passing The reference count of each object passed into a procedure is incremented
- 3 Reference Assignments For statement u v where u and v are references the reference count of the object referred to by v goes up by one and the count for the old object referred to by u goes down by one

75 INTRODUCTION TO GARBAGE COLLECTION

- 4 Procedure Returns As a procedure exits objects referred to by the local variables in its activation record have their counts decremented If several local variables hold references to the same object that object s count must be decremented once for each such reference
- 5 Transitive Loss of Reachability Whenever the reference count of an object becomes zero we must also decrement the count of each object pointed to by a reference within the object

Reference counting has two main disadvantages it cannot collect unreach able cyclic data structures and it is expensive. Cyclic data structures are quite plausible data structures often point back to their parent nodes or point to each other as cross references.

Example 7 11 Figure 7 18 shows three objects with references among them but no references from anywhere else. If none of these objects is part of the root set, then they are all garbage but their reference counts are each greater than 0. Such a situation is tantamount to a memory leak if we use reference counting for garbage collection, since then this garbage and any structures like it are never deallocated. \Box

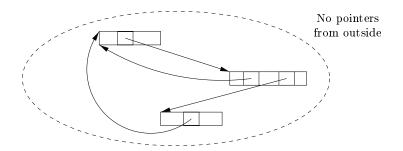

Figure 7 18 An unreachable cyclic data structure

The overhead of reference counting is high because additional operations are introduced with each reference assignment and at procedure entries and exits. This overhead is proportional to the amount of computation in the program and not just to the number of objects in the system. Of particular concern are the updates made to references in the root set of a program. The concept of deferred reference counting has been proposed as a means to eliminate the overhead associated with updating the reference counts due to local stack accesses. That is reference counts do not include references from the root set of the program. An object is not considered to be garbage until the entire root set is scanned and no references to the object are found

The advantage of reference counting on the other hand is that garbage collection is performed in an *incremental* fashion. Even though the total overhead can be large, the operations are spread throughout the mutator's computation

CHAPTER 7 RUN TIME ENVIRONMENTS

Although removing one reference may render a large number of objects un reachable the operation of recursively modifying reference counts can easily be deferred and performed piecemeal across time. Thus reference counting is par ticularly attractive algorithm when timing deadlines must be met as well as for interactive applications where long sudden pauses are unacceptable. Another advantage is that garbage is collected immediately keeping space usage low

7 6 Introduction to Trace Based Collection

Instead of collecting garbage as it is created trace based collectors run periodically to nd unreachable objects and reclaim their space. Typically we run the

7.6 INTRODUCTION TO TRACE BASED COLLECTION

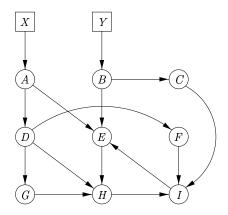

Figure 7 20 Another network of objects

trace based collector whenever the free space is exhausted or its amount drops below some threshold

We begin this section by introducing the simplest mark and sweep gar bage collection algorithm. We then describe the variety of trace based algorithms in terms of four states that chunks of memory can be put in. This section also contains a number of improvements on the basic algorithm including those in which object relocation is a part of the garbage collection function

7 6 1 A Basic Mark and Sweep Collector

Mark and sweep garbage collection algorithms are straightforward stop the world algorithms that and all the unreachable objects and put them on the list of free space. Algorithm 7 12 visits and marks all the reachable objects in the rst tracing step and then sweeps the entire heap to free up unreachable objects. Algorithm 7 14 which we consider after introducing a general framework for trace based algorithms is an optimization of Algorithm 7 12. By using an additional list to hold all the allocated objects it visits the reachable objects only once

Algorithm 7 12 Mark and sweep garbage collection

INPUT A root set of objects a heap and a free list called Free with all the unallocated chunks of the heap. As in Section 7 4 4 all chunks of space are marked with boundary tags to indicate their free used status and size

OUTPUT A modi ed *Free* list after all the garbage has been removed

METHOD The algorithm shown in Fig 7 21 uses several simple data struc tures List *Free* holds objects known to be free A list called *Unscanned* holds objects that we have determined are reached but whose successors we have not yet considered. That is we have not scanned these objects to see what other

```

Figure 7 21 A Mark and Sweep Garbage Collector

objects can be reached through them The Unscanned list is empty initially Additionally each object includes a bit to indicate whether it has been reached the reached bit Before the algorithm begins all allocated objects have the reached bit set to 0

In line 1 of Fig 7.21 we initialize the Unscanned list by placing there all the objects referenced by the root set. The reached bit for these objects is also set to 1. Lines 2 through 7 are a loop in which we in turn examine each object o that is ever placed on the Unscanned list

The for loop of lines 4 through 7 implements the scanning of object o We examine each object o' for which we nd a reference within o If o' has already been reached its reached bit is 1 then there is no need to do anything about o' it either has been scanned previously or it is on the Unscanned list to be scanned later. However if o' was not reached already then we need to set its reached bit to 1 in line 6 and add o' to the Unscanned list in line 7. Figure 7.22 illustrates this process. It shows an Unscanned list with four objects. The rst object on this list corresponding to object o in the discussion above is in the process of being scanned. The dashed lines correspond to the three kinds of objects that might be reached from o

- 1 A previously scanned object that need not be scanned again
- 2 An object currently on the *Unscanned* list
- 3 An item that is reachable but was previously thought to be unreached

76 INTRODUCTION TO TRACE BASED COLLECTION

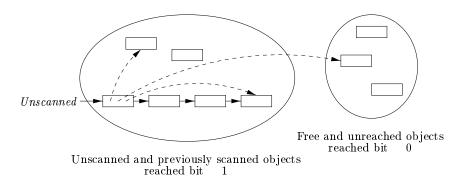

Figure 7 22 The relationships among objects during the marking phase of a mark and sweep garbage collector

Lines 8 through 11 the sweeping phase reclaim the space of all the objects that remain unreached at the end of the marking phase. Note that these will include any objects that were on the *Free* list originally. Because the set of unreached objects cannot be enumerated directly the algorithm sweeps through the entire heap. Line 10 puts free and unreached objects on the *Free* list one at a time. Line 11 handles the reachable objects. We set their reached bit to 0 in order to maintain the proper preconditions for the next execution of the garbage collection algorithm. \Box

7 6 2 Basic Abstraction

All trace based algorithms compute the set of reachable objects and then take the complement of this set Memory is therefore recycled as follows

- a The program or mutator runs and makes allocation requests
- b The garbage collector discovers reachability by tracing
- c The garbage collector reclaims the storage for unreachable objects

This cycle is illustrated in Fig 7 23 in terms of four states for chunks of memory Free Unreached Unscanned and Scanned The state of a chunk might be stored in the chunk itself or it might be implicit in the data structures used by the garbage collection algorithm

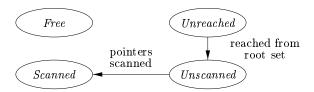

While trace based algorithms may di er in their implementation they can all be described in terms of the following states

- 1 Free A chunk is in the Free state if it is ready to be allocated Thus a Free chunk must not hold a reachable object
- 2 Unreached Chunks are presumed unreachable unless proven reachable by tracing A chunk is in the Unreached state at any point during garbage

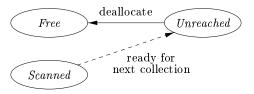

CHAPTER 7 RUN TIME ENVIRONMENTS

a Before tracing action of mutator

b Discovering reachability by tracing

c Reclaiming storage

Figure 7 23 States of memory in a garbage collection cycle

collection if its reachability has not yet been established. Whenever a chunk is allocated by the memory manager its state is set to *Unreached* as illustrated in Fig. 7.23 a. Also after a round of garbage collection the state of a reachable object is reset to *Unreached* to get ready for the next round see the transition from *Scanned* to *Unreached* which is shown dashed to emphasize that it prepares for the next round

- 3 Unscanned Chunks that are known to be reachable are either in state Unscanned or state Scanned A chunk is in the Unscanned state if it is known to be reachable but its pointers have not yet been scanned. The transition to Unscanned from Unreached occurs when we discover that a chunk is reachable see Fig. 7.23 b
- 4 Scanned Every Unscanned object will eventually be scanned and tran sition to the Scanned state To scan an object we examine each of the pointers within it and follow those pointers to the objects to which they refer If a reference is to an Unreached object then that object is put in the Unscanned state When the scan of an object is completed that object is placed in the Scanned state see the lower transition in Fig 7 23 b A Scanned object can only contain references to other Scanned or Unscanned objects and never to Unreached objects

76 INTRODUCTION TO TRACE BASED COLLECTION

When no objects are left in the Unscanned state the computation of reach ability is complete. Objects left in the Unreached state at the end are truly unreachable. The garbage collector reclaims the space they occupy and places the chunks in the Free state as illustrated by the solid transition in Fig. 7.23 c. To get ready for the next cycle of garbage collection objects in the Scanned state are returned to the Unreached state see the dashed transition in Fig. 7.23 c. Again remember that these objects really are reachable right now. The Un reachable state is appropriate because we shall want to start all objects out in this state when garbage collection next begins by which time any of the currently reachable objects may indeed have been rendered unreachable

Example 7 13 Let us see how the data structures of Algorithm 7 12 relate to the four states introduced above Using the reached bit and membership on lists Free and Unscanned we can distinguish among all four states. The table of Fig. 7 24 summarizes the characterization of the four states in terms of the data structure for Algorithm 7 12.

STATE	On Free	On Unscanned	REACHED BIT
Free	Yes	No	0
Unreached	No	No	0
Unscanned	No	Yes	1
Scanned	No	No	1

Figure 7 24 Representation of states in Algorithm 7 12

7 6 3 Optimizing Mark and Sweep

The nal step in the basic mark and sweep algorithm is expensive because there is no easy way to nd only the unreachable objects without examining the entire heap. An improved algorithm due to Baker keeps a list of all allocated objects. To nd the set of unreachable objects which we must return to free space we take the set discrement of the allocated objects and the reached objects.

Algorithm 7 14 Baker's mark and sweep collector

INPUT A root set of objects a heap a free list *Free* and a list of allocated objects which we refer to as *Unreached*

OUTPUT Modi ed lists Free and Unreached which holds allocated objects

METHOD In this algorithm shown in Fig 7 25 the data structure for garbage collection is four lists named *Free Unreached Unscanned* and *Scanned* each of which holds all the objects in the state of the same name. These lists may be implemented by embedded doubly linked lists as was discussed in Section 7 4 4. A reached bit in objects is not used but we assume that each object

contains bits telling which of the four states it is in Initially *Free* is the free list maintained by the memory manager and all allocated objects are on the *Unreached* list also maintained by the memory manager as it allocates chunks to objects

```

Figure 7 25 Baker s mark and sweep algorithm

Lines 1 and 2 initialize Scanned to be the empty list and Unscanned to have only the objects reached from the root set. Note that these objects were presumably on the list Unreached and must be removed from there. Lines 3 through 7 are a straightforward implementation of the basic marking algorithm using these lists. That is the for loop of lines 5 through 7 examines the references in one unscanned object o and if any of those references o' have not yet been reached line 7 changes o' to the Unscanned state

At the end line 8 takes those objects that are still on the Unreached list and deallocates their chunks by moving them to the Free list. Then line 9 takes all the objects in state Scanned which are the reachable objects and reinitializes the Unreached list to be exactly those objects. Presumably as the memory manager creates new objects those too will be added to the Unreached list and removed from the Free list. \Box

In both algorithms of this section we have assumed that chunks returned to the free list remain as they were before deallocation. However, as discussed in Section 7.4.4 it is often advantageous to combine adjacent free chunks into larger chunks. If we wish to do so then every time we return a chunk to the free list either at line 10 of Fig. 7.21 or line 8 of Fig. 7.25 we examine the chunks to its left and right, and merge if one is free

7 6 4 Mark and Compact Garbage Collectors

Relocating collectors move reachable objects around in the heap to eliminate memory fragmentation. It is common that the space occupied by reachable objects is much smaller than the freed space. Thus, after identifying all the holes

76 INTRODUCTION TO TRACE BASED COLLECTION

instead of freeing them individually one attractive alternative is to relocate all the reachable objects into one end of the heap leaving the entire rest of the heap as one free chunk. After all the garbage collector has already analyzed every reference within the reachable objects so updating them to point to the new locations does not require much more work. These plus the references in the root set are all the references we need to change

Having all the reachable objects in contiguous locations reduces fragmen tation of the memory space making it easier to house large objects. Also by making the data occupy fewer cache lines and pages relocation improves a program s temporal and spatial locality since new objects created at about the same time are allocated nearby chunks. Objects in nearby chunks can bene t from prefetching if they are used together. Further the data structure for maintaining free space is simplified instead of a free list all we need is a pointer free to the beginning of the one free block.

Relocating collectors vary in whether they relocate in place or reserve space ahead of time for the relocation

A mark and compact collector described in this section compacts objects in place Relocating in place reduces memory usage

The more e cient and popular *copying collector* in Section 7 6 5 moves objects from one region of memory to another Reserving extra space for relocation allows reachable objects to be moved as they are discovered

The mark and compact collector in Algorithm 7 15 has three phases

- 1 First is a marking phase similar to that of the mark and sweep algorithms described previously
- 2 Second the algorithm scans the allocated section of the heap and computes a new address for each of the reachable objects. New addresses are assigned from the low end of the heap so there are no holes between reach able objects. The new address for each object is recorded in a structure called NewLocation.
- 3 Finally the algorithm copies objects to their new locations updating all references in the objects to point to the corresponding new locations. The needed addresses are found in *NewLocation*

Algorithm 7 15 A mark and compact garbage collector

INPUT A root set of objects a heap and *free* a pointer marking the start of free space

OUTPUT The new value of pointer free

METHOD The algorithm is in Fig 7 26 it uses the following data structures

1 An Unscanned list as in Algorithm 7 12

CHAPTER 7 RUN TIME ENVIRONMENTS

- 2 Reached bits in all objects also as in Algorithm 7 12 To keep our de scription simple we refer to objects as reached or unreached when we mean that their reached bit is 1 or 0 respectively Initially all objects are unreached
- 3 The pointer *free* which marks the beginning of unallocated space in the heap
- 4 The table *NewLocation* This structure could be a hash table search tree or another structure that implements the two operations
 - a Set NewLocation o to a new address for object o
 - b Given object o get the value of NewLocation o

We shall not concern ourselves with the exact structure used although you may assume that *NewLocation* is a hash table and therefore the set and get operations are each performed in average constant time independent of how many objects are in the heap

The rst or marking phase of lines 1 through 7 is essentially the same as the rst phase of Algorithm 7 12. The second phase lines 8 through 12 visits each chunk in the allocated part of the heap from the left or low end. As a result chunks are assigned new addresses that increase in the same order as their old addresses. This ordering is important since when we relocate objects we can do so in a way that assures we only move objects left into space that was formerly occupied by objects we have moved already

Line 8 starts the *free* pointer at the low end of the heap. In this phase we use *free* to indicate the -rst available new address. We create a new address only for those objects o that are marked as reached. Object o is given the next available address at line 10 and at line 11 we increment *free* by the amount of storage that object o requires so *free* again points to the beginning of free space

In the nal phase lines 13 through 17 we again visit the reached objects in the same from the left order as in the second phase. Lines 15 and 16 replace all internal pointers of a reached object o by their proper new values using the NewLocation table to determine the replacement. Then line 17 moves the object o with the revised internal references to its new location. Finally lines 18 and 19 retarget pointers in the elements of the root set that are not themselves heap objects e.g. statically allocated or stack allocated objects. Figure 7.27 suggests how the reachable objects those that are not shaded are moved down the heap while the internal pointers are changed to point to the new locations of the reached objects.

7 6 5 Copying collectors

A copying collector reserves ahead of time space to which the objects can move thus breaking the dependency between tracing and nding free space

Figure 7 26 A Mark and Compact Collector

The memory space is partitioned into two $semispaces\ A$ and B. The mutator allocates memory in one semispace say A until it. Its up at which point the mutator is stopped and the garbage collector copies the reachable objects to the other space say B. When garbage collection completes the roles of the semispaces are reversed. The mutator is allowed to resume and allocate objects in space B and the next round of garbage collection moves reachable objects to space A. The following algorithm is due to C. J. Cheney

Algorithm 7 16 Cheney's copying collector

INPUT A root set of objects and a heap consisting of the *From* semispace containing allocated objects and the *To* semispace all of which is free

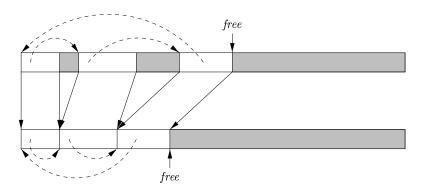

Figure 7 $\overline{27}$ Moving reached objects to the front of the heap—while preserving internal pointers

OUTPUT At the end the *To* semispace holds the allocated objects. A *free* pointer indicates the start of free space remaining in the *To* semispace. The *From* semispace is completely free

METHOD The algorithm is shown in Fig 7 28 Cheney's algorithm and reachable objects in the *From* semispace and copies them as soon as they are reached to the *To* semispace. This placement groups related objects together and may improve spatial locality

Before examining the algorithm itself which is the function CopyingCollec tor in Fig. 7.28 consider the auxiliary function LookupNewLocation in lines. 11 through 16. This function takes an object o and indicate new location for it in the To space if o has no location there yet. All new locations are recorded in a structure NewLocation and a value of NULL indicates o has no assigned location. 4 As in Algorithm 7.15 the exact form of structure NewLocation may vary but it is in eto assume that it is a hash table

If we nd at line 12 that o has no location then it is assigned the beginning of the free space within the To semispace at line 13. Line 14 increments the free pointer by the amount of space taken by o and at line 15 we copy o from the From space to the To space. Thus the movement of objects from one semispace to the other occurs as a side e ect. the rst time we look up the new location for the object. Regardless of whether the location of o was or was not previously established. line 16 returns the location of o in the To space.

Now we can consider the algorithm itself Line 2 establishes that none of the objects in the *From* space have new addresses yet. At line 3 we initialize two pointers *unscanned* and *free* to the beginning of the *To* semispace. Pointer *free* will always indicate the beginning of free space within the *To* space. As we add objects to the *To* space those with addresses below *unscanned* will be in the *Scanned* state while those between *unscanned* and *free* are in the *Unscanned*.

 $^{^4}$ In a typical data structure such as a hash table if o is not assigned a location then there simply would be no mention of it in the structure

                        free
                                sizeof o
14
                  free
15
                  copy o to NewLocation o
16
            return NewLocation o
```

Figure 7 28 A Copying Garbage Collector

state Thus free always leads unscanned and when the latter catches up to the former there are no more Unscanned objects and we are done with the garbage collection. Notice that we do our work within the To space although all references within objects examined at line 8 lead us back to the From space.

Lines 4 and 5 handle the objects reached from the root set. Note that as a side e ect some of the calls to LookupNewLocation at line 5 will increase free as chunks for these objects are allocated within To. Thus the loop of lines 6 through 10 will be entered the first time it is reached unless there are no objects referenced by the root set in which case the entire heap is garbage. This loop then scans each of the objects that has been added to To and is in the Unscanned state. Line 7 takes the next unscanned object of To and lines 8 and 9 each reference within o is translated from its value in the To semispace to its value in the To semispace. Notice that as a side elect if a reference within o is to an object we have not reached previously then the call to LookupNewLocation at line 9 creates space for that object in the To space and moves the object there. Finally line 10 increments unscanned to point to the next object just beyond o in the To space.

7 6 6 Comparing Costs

Cheney's algorithm has the advantage that it does not touch any of the un reachable objects. On the other hand a copying garbage collector must move the contents of all the reachable objects. This process is especially expensive for large objects and for long lived objects that survive multiple rounds of garbage collection. We can summarize the running time of each of the four algorithms described in this section as follows. Each estimate ignores the cost of processing the root set.

Basic Mark and Sweep Algorithm 7 12 Proportional to the number of chunks in the heap

Baker's Mark and Sweep Algorithm 7 14 Proportional to the number of reached objects

Basic Mark and Compact Algorithm 7 15 Proportional to the number of chunks in the heap plus the total size of the reached objects

Cheney s Copying Collector Algorithm 716 Proportional to the total size of the reached objects

7 6 7 Exercises for Section 7 6

Exercise 7 6 1 Show the steps of a mark and sweep garbage collector on

- a Fig 7 19 with the pointer A B deleted
- b Fig 7 19 with the pointer A C deleted
- c Fig 7 20 with the pointer A D deleted
- d Fig 7 20 with the object B deleted

Exercise 7 6 2 The Baker mark and sweep algorithm moves objects among four lists Free Unreached Unscanned and Scanned For each of the object networks of Exercise 7 6 1 indicate for each object the sequence of lists on which it nds itself from just before garbage collection begins until just after it nishes

Exercise 7 6 3 Suppose we perform a mark and compact garbage collection on each of the networks of Exercise 7 6 1 Also suppose that

- i Each object has size 100 bytes and
- ii Initially the nine objects in the heap are arranged in alphabetical order starting at byte 0 of the heap

What is the address of each object after garbage collection

7.7 SHORT PAUSE GARBAGE COLLECTION

Exercise 7 6 4 Suppose we execute Cheney's copying garbage collection al gorithm on each of the networks of Exercise 7 6 1 Also suppose that

- *i* Each object has size 100 bytes
- ii The unscanned list is managed as a queue and when an object has more than one pointer the reached objects are added to the queue in alpha betical order and
- iii The From semispace starts at location 0 and the To semispace starts at location 10 000

What is the value of $NewLocation\ o\$ for each object o that remains after garbage collection

7 7 Short Pause Garbage Collection

Simple trace based collectors do stop the world style garbage collection which may introduce long pauses into the execution of user programs. We can reduce the length of the pauses by performing garbage collection one part at a time. We can divide the work in time by interleaving garbage collection with the mutation or we can divide the work in space by collecting a subset of the garbage at a time. The former is known as incremental collection and the latter is known as partial collection.

An incremental collector breaks up the reachability analysis into smaller units allowing the mutator to run between these execution units. The reachable set changes as the mutator executes so incremental collection is complex. As we shall see in Section 7.7.1 — nding a slightly conservative answer can make tracing more e—cient

The best known of partial collection algorithms is generational garbage col lection it partitions objects according to how long they have been allocated and collects the newly created objects more often because they tend to have a shorter lifetime. An alternative algorithm the train algorithm also collects a subset of garbage at a time and is best applied to more mature objects. These two algorithms can be used together to create a partial collector that handles younger and older objects di erently. We discuss the basic algorithm behind partial collection in Section 7.7.3 and then describe in more detail how the generational and train algorithms work.

Ideas from both incremental and partial collection can be adapted to cre ate an algorithm that collects objects in parallel on a multiprocessor see Sec tion 7.8.1

7 7 1 Incremental Garbage Collection

Incremental collectors are conservative While a garbage collector must not collect objects that are not garbage it does not have to collect all the garbage

CHAPTER 7 RUN TIME ENVIRONMENTS

in each round. We refer to the garbage left behind after collection as oating garbage. Of course it is desirable to minimize oating garbage. In particular an incremental collector should not leave behind any garbage that was not reachable at the beginning of a collection cycle. If we can be sure of such a collection guarantee, then any garbage not collected in one round will be collected in the next, and no memory is leaked because of this approach to garbage collection.

In other words incremental collectors play it safe by overestimating the set of reachable objects. They are process the program stroot set atomically with out interference from the mutator. After anding the initial set of unscanned objects the mutators actions are interleaved with the tracing step. During this period any of the mutators actions that may change reachability are recorded succinctly in a side table so that the collector can make the necessary ad justments when it resumes execution. If space is exhausted before tracing completes the collector completes the tracing process without allowing the mutator to execute. In any event, when tracing is done space is reclaimed atomically

Precision of Incremental Collection

Once an object becomes unreachable it is not possible for the object to become reachable again. Thus as garbage collection and mutation proceed the set of reachable objects can only

- 1 Grow due to new objects allocated after garbage collection starts and
- 2 Shrink by losing references to allocated objects

Let the set of reachable objects at the beginning of garbage collection be R let New be the set of allocated objects during garbage collection and let Lost be the set of objects that have become unreachable due to lost references since tracing began. The set of objects reachable when tracing completes is

It is expensive to reestablish an object s reachability every time a mutator loses a reference to the object so incremental collectors do not attempt to collect all the garbage at the end of tracing Any garbage left behind oating garbage should be a subset of the Lost objects Expressed formally the set S of objects found by tracing must satisfy

$$R$$
 New $Lost$ S R New

Simple Incremental Tracing

We rst describe a straightforward tracing algorithm that nds the upper bound R New The behavior of the mutator is modilled during the tracing as follows

7.7 SHORT PAUSE GARBAGE COLLECTION

All references that existed before garbage collection are preserved that is before the mutator overwrites a reference its old value is remembered and treated like an additional unscanned object containing just that reference

All objects created are considered reachable immediately and are placed in the Unscanned state

This scheme is conservative but correct because it $\operatorname{nds} R$ the set of all the objects reachable before garbage collection plus New the set of all the newly allocated objects. However the cost is high because the algorithm intercepts all write operations and remembers all the overwritten references. Some of this work is unnecessary because it may involve objects that are unreachable at the end of garbage collection. We could avoid some of this work and also improve the algorithm's precision if we could detect when the overwritten references point to objects that are unreachable when this round of garbage collection ends. The next algorithm goes fairly far in these two directions

7 7 2 Incremental Reachability Analysis

If we interleave the mutator with a basic tracing algorithm such as Algorithm 712 then some reachable objects may be misclassi ed as unreachable. The problem is that the actions of the mutator can violate a key invariant of the algorithm namely a Scanned object can only contain references to other Scanned or Unscanned objects never to Unreached objects. Consider the following scenario

- 1 The garbage collector and sobject o_1 reachable and scans the pointers within o_1 thereby putting o_1 in the *Scanned* state
- 2 The mutator stores a reference to an Unreached but reachable object o into the Scanned object o_1 It does so by copying a reference to o from an object o_2 that is currently in the Unreached or Unscanned state
- 3 The mutator loses the reference to o in object o_2 It may have overwrit ten o_2 s reference to o before the reference is scanned or o_2 may have become unreachable and never have reached the *Unscanned* state to have its references scanned

Now o is reachable through object o_1 but the garbage collector may have seen neither the reference to o in o_1 nor the reference to o in o_2

The key to a more precise yet correct incremental trace is that we must note all copies of references to currently unreached objects from an object that has not been scanned to one that has To intercept problematic transfers of references the algorithm can modify the mutator s action during tracing in any of the following ways

CHAPTER 7 RUN TIME ENVIRONMENTS

Write Barriers Intercept writes of references into a Scanned object o_1 when the reference is to an Unreached object o In this case classify o as reachable and place it in the Unscanned set Alternatively place the written object o_1 back in the Unscanned set so we can rescan it

Read Barriers Intercept the reads of references in Unreached or Un scanned objects. Whenever the mutator reads a reference to an object o from an object in either the Unreached or Unscanned state classify o as reachable and place it in the Unscanned set

Transfer Barriers Intercept the loss of the original reference in an Un reached or Unscanned object Whenever the mutator overwrites a reference in an Unreached or Unscanned object save the reference being overwritten classify it as reachable and place the reference itself in the Unscanned set

None of the options above $\,$ nds the smallest set of reachable objects. If the tracing process determines an object to be reachable it stays reachable even though all references to it are overwritten before tracing completes. That is the set of reachable objects found is between $\,R\,$ New $\,$ Lost and $\,R\,$ New

Write barriers are the most e cient of the options outlined above Read barriers are more expensive because typically there are many more reads than there are writes Transfer barriers are not competitive because many objects die young this approach would retain many unreachable objects

Implementing Write Barriers

We can implement write barriers in two ways. The six approach is to remember during a mutation phase all new references written into the Scanned objects. We can place all these references in a list the size of the list is proportional to the number of write operations to Scanned objects unless duplicates are removed from the list. Note that references on the list may later be over written themselves and potentially could be ignored.

The second more e cient approach is to remember the locations where the writes occur. We may remember them as a list of locations written possibly with duplicates eliminated. Note it is not important that we pinpoint the exact locations written as long as all the locations that have been written are rescanned. Thus, there are several techniques that allow us to remember less detail about exactly where the rewritten locations are

Instead of remembering the exact address or the object and eld that is written we can remember just the objects that hold the written elds

We can divide the address space into xed size blocks known as *cards* and use a bit array to remember the cards that have been written into

7.7 SHORT PAUSE GARBAGE COLLECTION

We can choose to remember the pages that contain the written locations. We can simply protect the pages containing *Scanned* objects. Then any writes into *Scanned* objects will be detected without executing any explicit instructions because they will cause a protection violation and the operating system will raise a program exception

In general by coarsening the granularity at which we remember the written locations less storage is needed at the expense of increasing the amount of rescanning performed. In the light references in the modified objects will have to be rescanned regardless of which reference was actually modified. In the last two schemes all reachable objects in the modified cards or modified pages need to be rescanned at the end of the tracing process.

Combining Incremental and Copying Techniques

The above methods are su-cient for mark and sweep garbage collection. Copying collection is slightly more complicated because of its interaction with the mutator. Objects in the *Scanned* or *Unscanned* states have two addresses one in the *From* semispace and one in the *To* semispace. As in Algorithm 7.16 we must keep a mapping from the old address of an object to its relocated address.

There are two choices for how we update the references First we can have the mutator make all the changes in the *From* space and only at the end of garbage collection do we update all the pointers and copy all the contents over to the *To* space Second we can instead make changes to the representation in the *To* space Whenever the mutator dereferences a pointer to the *From* space the pointer is translated to a new location in the *To* space if one exists All the pointers need to be translated to point to the *To* space in the end

7 7 3 Partial Collection Basics

The fundamental fact is that objects typically die young. It has been found that usually between 80 and 98 of all newly allocated objects die within a few million instructions or before another megabyte has been allocated. That is objects often become unreachable before any garbage collection is invoked. Thus is it quite cost elective to garbage collect new objects frequently.

Yet objects that survive a collection once are likely to survive many more collections. With the garbage collectors described so far the same mature objects will be found to be reachable over and over again and in the case of copying collectors copied over and over again in every round of garbage collection. Generational garbage collection works most frequently on the area of the heap that contains the youngest objects so it tends to collect a lot of garbage for relatively little work. The train algorithm on the other hand does not spend a large proportion of time on young objects but it does limit the pauses due to garbage collection. Thus, a good combination of strategies is to use generational collection for young objects, and once an object becomes

su ciently mature to promote it to a separate heap that is managed by the train algorithm

We refer to the set of objects to be collected on one round of partial collection as the *target* set and the rest of the objects as the *stable* set Ideally a partial collector should reclaim all objects in the target set that are unreachable from the program s root set. However, doing so would require tracing all objects which is what we try to avoid in the rst place. Instead, partial collectors conservatively reclaim only those objects that cannot be reached through either the root set of the program or the stable set. Since some objects in the stable set may themselves be unreachable it is possible that we shall treat as reachable some objects in the target set that really have no path from the root set.

We can adapt the garbage collectors described in Sections 7 6 1 and 7 6 4 to work in a partial manner by changing the denition of the root set. Instead of referring to just the objects held in the registers stack and global variables the root set now also includes all the objects in the stable set that point to objects in the target set. References from target objects to other target objects are traced as before to indicate all the reachable objects. We can ignore all pointers to stable objects because these objects are all considered reachable in this round of partial collection.

To identify those stable objects that reference target objects we can adopt techniques similar to those used in incremental garbage collection. In incremental collection, we need to remember all the writes of references from scanned objects to unreached objects during the tracing process. Here we need to remember all the writes of references from the stable objects to the target objects throughout the mutator's execution. Whenever the mutator stores into a stable object a reference to an object in the target set, we remember either the reference or the location of the write. We refer to the set of objects holding references from the stable to the target objects as the remembered set for this set of target objects. As discussed in Section 7.7.2 we can compress the representation of a remembered set by recording only the card or page in which the written object is found.

Partial garbage collectors are often implemented as copying garbage collectors. Noncopying collectors can also be implemented by using linked lists to keep track of the reachable objects. The generational scheme described below is an example of how copying may be combined with partial collection.

7 7 4 Generational Garbage Collection

Generational garbage collection is an e-ective way to exploit the property that most objects die young. The heap storage in generational garbage collection is separated into a series of partitions. We shall use the convention of numbering them 0.1.2 n with the lower numbered partitions holding the younger objects. Objects are rst created in partition 0. When this partition 1 lls up it is garbage collected, and its reachable objects are moved into partition 1. Now with partition 0 empty again, we resume allocating new objects in that

7.7 SHORT PAUSE GARBAGE COLLECTION

partition When partition 0 again $lls ^5$ it is garbage collected and its reachable objects copied into partition 1 where they join the previously copied objects. This pattern repeats until partition 1 also lls up at which point garbage collection is applied to partitions 0 and 1

In general each round of garbage collection is applied to all partitions numbered i or below for some i the proper i to choose is the highest numbered partition that is currently full Each time an object survives a collection i e it is found to be reachable—it is promoted to the next higher partition from the one it occupies—until it reaches the oldest partition—the one numbered n

Using the terminology introduced in Section 7.7.3 when partitions i and below are garbage collected the partitions from 0 through i make up the target set and all partitions above i comprise the stable set. To support inding root sets for all possible partial collections we keep for each partition i a remembered set consisting of all the objects in partitions above i that point to objects in set i. The root set for a partial collection invoked on set i includes the remembered sets for partition i and below

In this scheme all partitions below i are collected whenever we collect i There are two reasons for this policy

- 1 Since younger generations contain more garbage and are collected more often anyway we may as well collect them along with an older generation
- 2 Following this strategy we need to remember only the references pointing from an older generation to a newer generation. That is neither writes to objects in the youngest generation nor promoting objects to the next generation causes updates to any remembered set. If we were to collect a partition without a younger one, the younger generation would become part of the stable set, and we would have to remember references that point from younger to older generations as well

In summary this scheme collects younger generations more often and col lections of these generations are particularly cost e ective since objects die young Garbage collection of older generations takes more time since it in cludes the collection of all the younger generations and collects proportionally less garbage Nonetheless older generations do need to be collected once in a while to remove unreachable objects. The oldest generation holds the most mature objects its collection is expensive because it is equivalent to a full collection. That is generational collectors occasionally require that the full tracing step be performed and therefore can introduce long pauses into a program s execution. An alternative for handling mature objects only is discussed next.

⁵Technically partitions do not ll since they can be expanded with additional disk blocks by the memory manager if desired However there is normally a limit on the size of a partition other than the last We shall refer to reaching this limit as lling the partition

775 The Train Algorithm

While the generational approach is very e cient for the handling of immature objects it is less e cient for the mature objects since mature objects are moved every time there is a collection involving them and they are quite unlikely to be garbage. A dierent approach to incremental collection called the *train algorithm* was developed to improve the handling of mature objects. It can be used for collecting all garbage but it is probably better to use the generational approach for immature objects and only after they have survived a few rounds of collection promote them to another heap managed by the train algorithm. Another advantage to the train algorithm is that we never have to do a complete garbage collection as we do occasionally for generational garbage collection.

To motivate the train algorithm let us look at a simple example of why it is necessary in the generational approach to have occasional all inclusive rounds of garbage collection. Figure 7 29 shows two mutually linked objects in two partitions i and j where j i Since both objects have pointers from outside their partition a collection of only partition i or only partition j could never collect either of these objects. Yet they may in fact be part of a cyclic garbage structure with no links from the outside. In general, the links between the objects shown may involve many objects and long chains of references

Figure 7 29 A cyclic structure across partitions that may be cyclic garbage

In generational garbage collection we eventually collect partition j and since i j we also collect i at that time. Then the cyclic structure will be completely contained in the portion of the heap being collected, and we can tell if it truly is garbage. However, if we never have a round of collection that includes both i and j we would have a problem with cyclic garbage just as we did with reference counting for garbage collection.

The train algorithm uses $\,$ xed length partitions called $\,$ cars $\,$ a car might be a single disk block provided there are no objects larger than disk blocks or the car size could be larger but it is $\,$ xed once and for all $\,$ Cars are organized into $\,$ trains. There is no limit to the number of cars in a train $\,$ and no limit to the number of trains. There is a lexicographic order to cars $\,$ rst order by train number $\,$ and within a train $\,$ order by car number $\,$ as in Fig. 7.30

There are two ways that garbage is collected by the train algorithm

The rst car in lexicographic order that is the rst remaining car of the rst remaining train is collected in one incremental garbage collection step. This step is similar to collection of the rst partition in the gener ational algorithm since we maintain a remembered list of all pointers

7.7 SHORT PAUSE GARBAGE COLLECTION

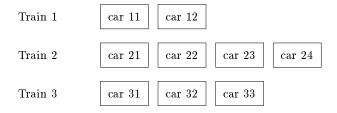

Figure 7 30 Organization of the heap for the train algorithm

from outside the car Here we identify objects with no references at all as well as garbage cycles that are contained completely within this car Reachable objects in the car are always moved to some other car so each garbage collected car becomes empty and can be removed from the train

Sometimes the rst train has no external references. That is there are no pointers from the root set to any car of the train and the remembered sets for the cars contain only references from other cars in the train not from other trains. In this situation the train is a huge collection of cyclic garbage and we delete the entire train

Remembered Sets

We now give the details of the train algorithm Each car has a remembered set consisting of all references to objects in the car from

- a Objects in higher numbered cars of the same train and
- b Objects in higher numbered trains

In addition each train has a remembered set consisting of all references from higher numbered trains. That is the remembered set for a train is the union of the remembered sets for its cars except for those references that are internal to the train. It is thus possible to represent both kinds of remembered sets by dividing the remembered sets for the cars into internal same train and external other trains portions

Note that references to objects can come from anywhere not just from lexicographically higher cars. However, the two garbage collection processes deal with the first car of the first train and the entire first train respectively. Thus, when it is time to use the remembered sets in a garbage collection, there is nothing earlier from which references could come and therefore there is no point in remembering references to higher cars at any time. We must be careful of course to manage the remembered sets properly changing them whenever the mutator modiles references in any object.

Managing Trains

Our objective is to draw out of the rst train all objects that are not cyclic garbage. Then the rst train either becomes nothing but cyclic garbage and is therefore collected at the next round of garbage collection or if the garbage is not cyclic then its cars may be collected one at a time

We therefore need to start new trains occasionally even though there is no limit on the number of cars in one train and we could in principle simply add new cars to a single train every time we needed more space. For example, we could start a new train after every k object creations for some k. That is in general a new object is placed in the last car of the last train if there is room or in a new car that is added to the end of the last train if there is no room. However, periodically, we instead start a new train with one car, and place the new object there

Garbage Collecting a Car

The heart of the train algorithm is how we process the rst car of the rst train during a round of garbage collection. Initially the reachable set is taken to be the objects of that car with references from the root set and those with references in the remembered set for that car. We then scan these objects as in a mark and sweep collector, but we do not scan any reached objects outside the one car being collected. After this tracing some objects in the car may be identified as garbage. There is no need to reclaim their space, because the entire car is going to disappear anyway.

However there are likely to be some reachable objects in the car and these must be moved somewhere else. The rules for moving an object are

If there is a reference in the remembered set from any other train which will be higher numbered than the train of the car being collected then move the object to one of those trains. If there is room the object can go in some existing car of the train from which a reference emanates or it can go in a new last car if there is no room

If there is no reference from other trains but there are references from the root set or from the rst train then move the object to any other car of the same train creating a new last car if there is no room If possible pick a car from which there is a reference to help bring cyclic structures to a single car

After moving all the reachable objects from the rst car we delete that car

Panic Mode

There is one problem with the rules above In order to be sure that all garbage will eventually be collected we need to be sure that every train eventually becomes the rst train and if this train is not cyclic garbage then eventually

7.7 SHORT PAUSE GARBAGE COLLECTION

all cars of that train are removed and the train disappears one car at a time However by rule 2 above collecting the rst car of the rst train can produce a new last car It cannot produce two or more new cars since surely all the objects of the rst car can t in the new last car However could we be in a situation where each collection step for a train results in a new car being added and we never get nished with this train and move on to the other trains

The answer is unfortunately that such a situation is possible. The problem arises if we have a large cyclic nongarbage structure and the mutator manages to change references in such a way that we never see at the time we collect a car any references from higher trains in the remembered set. If even one object is removed from the train during the collection of a car, then we are OK since no new objects are added to the rst train and therefore the rst train will surely run out of objects eventually. However, there may be no garbage at all that we can collect at a stage and we run the risk of a loop where we perpetually garbage collect only the current rst train.

To avoid this problem we need to behave differently whenever we encounter a *futile* garbage collection that is a car from which not even one object can be deleted as garbage or moved to another train. In this panic mode, we make two changes

- 1 When a reference to an object in the rst train is rewritten we maintain the reference as a new member of the root set
- 2 When garbage collecting if an object in the rst car has a reference from the root set including dummy references set up by point 1 then we move that object to another train even if it has no references from other trains. It is not important which train we move it to as long as it is not the rst train.

In this way if there are any references from outside the rst train to objects in the rst train these references are considered as we collect every car and eventually some object will be removed from that train. We can then leave panic mode and proceed normally sure that the current rst train is now smaller than it was

7 7 6 Exercises for Section 7 7

Exercise 7 7 1 Suppose that the network of objects from Fig 7 20 is managed by an incremental algorithm that uses the four lists $Unreached\ Unscanned\ Scanned\ and\ Free\ as$ in Baker's algorithm. To be specification the $Unscanned\ Iist$ is managed as a queue and when more than one object is to be placed on this list due to the scanning of one object, we do so in alphabetical order. Suppose also that we use write barriers to assure that no reachable object is made garbage. Starting with A and B on the $Unscanned\ Iist$ suppose the following events occur

i A is scanned

CHAPTER 7 RUN TIME ENVIRONMENTS

- ii The pointer A D is rewritten to be A H
- iii B is scanned
- iv D is scanned
- v The pointer B C is rewritten to be B I

Simulate the entire incremental garbage collection assuming no more pointers are rewritten. Which objects are garbage. Which objects are placed on the Free list

Exercise 7 7 2 Repeat Exercise 7 7 1 on the assumption that

- a Events ii and v are interchanged in order
- b Events ii and v occur before i iii and iv

Exercise 7 7 3 Suppose the heap consists of exactly the nine cars on three trains shown in Fig. 7 30 i.e. ignore the ellipses. Object o in car 11 has references from cars 12 23 and 32. When we garbage collect car 11 where might o wind up

Exercise 7 7 4 Repeat Exercise 7 7 3 for the cases that o has

- a Only references from cars 22 and 31
- b No references other than from car 11

Exercise 7 7 5 Suppose the heap consists of exactly the nine cars on three trains shown in Fig 7 30 i e ignore the ellipses. We are currently in panic mode Object o_1 in car 11 has only one reference from object o_2 in car 12. That reference is rewritten. When we garbage collect car 11 what could happen to o_1

7 8 Advanced Topics in Garbage Collection

We close our investigation of garbage collection with brief treatments of four additional topics

- 1 Garbage collection in parallel environments
- 2 Partial relocations of objects
- 3 Garbage collection for languages that are not type safe
- 4 The interaction between programmer controlled and automatic garbage collection

781 Parallel and Concurrent Garbage Collection

Garbage collection becomes even more challenging when applied to applications running in parallel on a multiprocessor machine. It is not uncommon for server applications to have thousands of threads running at the same time each of these threads is a mutator. Typically, the heap will consist of gigabytes of memory.

Scalable garbage collection algorithms must take advantage of the presence of multiple processors. We say a garbage collector is *parallel* if it uses multiple threads it is *concurrent* if it runs simultaneously with the mutator

We shall describe a parallel and mostly concurrent collector that uses a concurrent and parallel phase that does most of the tracing work and then a stop the world phase that guarantees all the reachable objects are found and re claims the storage. This algorithm introduces no new basic concepts in garbage collection per secit shows how we can combine the ideas described so far to create a full solution to the parallel and concurrent collection problem. However, there are some new implementation issues that arise due to the nature of parallel execution. We shall discuss how this algorithm coordinates multiple threads in a parallel computation using a rather common work queue model.

To understand the design of the algorithm we must keep in mind the scale of the problem. Even the root set of a parallel application is much larger consisting of every thread s stack register set and globally accessible variables. The amount of heap storage can be very large, and so is the amount of reachable data. The rate at which mutations take place is also much greater.

To reduce the pause time we can adapt the basic ideas developed for in cremental analysis to overlap garbage collection with mutation Recall that an incremental analysis as discussed in Section 7.7 performs the following three steps

- 1 Find the root set This step is normally performed atomically that is with the mutator s stopped
- 2 Interleave the tracing of the reachable objects with the execution of the mutator s In this period every time a mutator writes a reference that points from a Scanned object to an Unreached object we remember that reference As discussed in Section 7.7.2 we have options regarding the granularity with which these references are remembered. In this section we shall assume the card based scheme where we divide the heap into sections called cards and maintain a bit map indicating which cards are dirty have had one or more references within them rewritten
- 3 Stop the mutator s again to rescan all the cards that may hold references to unreached objects

For a large multithreaded application the set of objects reached by the root set can be very large. It is infeasible to take the time and space to visit all such objects while all mutations cease. Also, due to the large heap and the large

CHAPTER 7 RUN TIME ENVIRONMENTS

number of mutation threads many cards may need to be rescanned after all objects have been scanned once. It is thus advisable to scan some of these cards in parallel, while the mutators are allowed to continue to execute concurrently

To implement the tracing of step $\,2\,$ above in parallel we shall use multiple garbage collecting threads concurrently with the mutator threads to trace most of the reachable objects. Then, to implement step $\,3\,$ we stop the mutators and use parallel threads to ensure that all reachable objects are found

The tracing of step 2 is carried out by having each mutator thread per form part of the garbage collection along with its own work. In addition we use threads that are dedicated purely to collecting garbage. Once garbage collection has been initiated whenever a mutator thread performs some memory allocation operation it also performs some tracing computation. The pure garbage collecting threads are put to use only when a machine has idle cycles. As in incremental analysis whenever a mutator writes a reference that points from a Scanned object to an Unreached object the card that holds this reference is marked dirty and needs to be rescanned.

Here is an outline of the parallel concurrent garbage collection algorithm

- 1 Scan the root set for each mutator thread and put all objects directly reachable from that thread into the *Unscanned* state. The simplest incremental approach to this step is to wait until a mutator thread calls the memory manager and have it scan its own root set if that has not already been done. If some mutator thread has not called a memory allocation function but all the rest of tracing is done then this thread must be interrupted to have its root set scanned.
- 2 Scan objects that are in the *Unscanned* state To support parallel computation we use a work queue of xed size work packets each of which holds a number of *Unscanned* objects *Unscanned* objects are placed in work packets as they are discovered Threads looking for work will dequeue these work packets and trace the *Unscanned* objects therein This strategy allows the work to be spread evenly among workers in the tracing process If the system runs out of space and we cannot nd the space to create these work packets we simply mark the cards holding the objects to force them to be scanned The latter is always possible because the bit array holding the marks for the cards has already been allocated
- 3 Scan the objects in dirty cards When there are no more *Unscanned* objects left in the work queue and all threads root sets have been scanned the cards are rescanned for reachable objects. As long as the mutators continue to execute dirty cards continue to be produced. Thus we need to stop the tracing process using some criterion such as allowing cards to be rescanned only once or a xed number of times or when the number of outstanding cards is reduced to some threshold. As a result, this parallel and concurrent step normally terminates before completing the trace which is nished by the nal step below

78 ADVANCED TOPICS IN GARBAGE COLLECTION

4 The nal step guarantees that all reachable objects are marked as reached With all the mutators stopped the root sets for all the threads can now be found quickly using all the processors in the system Because the reachability of most objects has been traced only a small number of objects are expected to be placed in the *Unscanned* state All the threads then participate in tracing the rest of the reachable objects and rescanning all the cards

It is important that we control the rate at which tracing takes place. The tracing phase is like a race. The mutators create new objects and new references that must be scanned, and the tracing tries to scan all the reachable objects and rescan the dirty cards generated in the meanwhile. It is not desirable to start the tracing too much before a garbage collection is needed because that will increase the amount of oating garbage. On the other hand, we cannot wait until the memory is exhausted before the tracing starts because then mutators will not be able to make forward progress and the situation degenerates to that of a stop the world collector. Thus, the algorithm must choose the time to commence the collection and the rate of tracing appropriately. An estimate of the mutation rate from previous cycles of collection can be used to help in the decision. The tracing rate is dynamically adjusted to account for the work performed by the pure garbage collecting threads.

7 8 2 Partial Object Relocation

As discussed starting in Section 7 6 4 copying or compacting collectors are advantageous because they eliminate fragmentation. However these collectors have nontrivial overheads. A compacting collector requires moving all objects and updating all the references at the end of garbage collection. A copying collector gures out where the reachable objects go as tracing proceeds if tracing is performed incrementally we need either to translate a mutator's every reference or to move all the objects and update their references at the end Both options are very expensive especially for a large heap

We can instead use a copying generational garbage collector. It is effective in collecting immature objects and reducing fragmentation but can be expensive when collecting mature objects. We can use the train algorithm to limit the amount of mature data analyzed each time. However, the overhead of the train algorithm is sensitive to the size of the remembered set for each partition.

There is a hybrid collection scheme that uses concurrent tracing to reclaim all the unreachable objects and at the same time moves only a part of the objects. This method reduces fragmentation without incurring the full cost of relocation in each collection cycle

- 1 Before tracing begins choose a part of the heap that will be evacuated
- 2 As the reachable objects are marked also remember all the references pointing to objects in the designated area

- 3 When tracing is complete sweep the storage in parallel to reclaim the space occupied by unreachable objects
- 4 Finally evacuate the reachable objects occupying the designated area and x up the references to the evacuated objects

7 8 3 Conservative Collection for Unsafe Languages

As discussed in Section 751 it is impossible to build a garbage collector that is guaranteed to work for all C and C programs. Since we can always compute an address with arithmetic operations no memory locations in C and C can ever be shown to be unreachable. However, many C or C programs never fabricate addresses in this way. It has been demonstrated that a conservative garbage collector one that does not necessarily discard all garbage can be built to work well in practice for this class of programs.

A conservative garbage collector assumes that we cannot fabricate an ad dress or derive the address of an allocated chunk of memory without an ad dress pointing somewhere in the same chunk. We can indicate all the garbage in programs satisfying such an assumption by treating as a valid address any bit pattern found anywhere in reachable memory as long as that bit pattern may be construed as a memory location. This scheme may classify some data erroneously as addresses. It is correct however since it only causes the collector to be conservative and keep more data than necessary.

Object relocation requiring all references to the old locations be updated to point to the new locations is incompatible with conservative garbage collection. Since a conservative garbage collector does not know if a particular bit pattern refers to an actual address it cannot change these patterns to point to new addresses.

Here is how a conservative garbage collector works. First the memory manager is modi ed to keep a data map of all the allocated chunks of memory. This map allows us to and easily the starting and ending boundary of the chunk of memory that spans a certain address. The tracing starts by scanning the program s root set to and any bit pattern that looks like a memory location without worrying about its type. By looking up these potential addresses in the data map, we can and the starting addresses of those chunks of memory that might be reached and place them in the Unscanned state. We then scan all the unscanned chunks and more presumably reachable chunks of memory and place them on the work list until the work list becomes empty. After tracing is done we sweep through the heap storage using the data map to locate and free all the unreachable chunks of memory.

7 8 4 Weak References

Sometimes programmers use a language with garbage collection but also wish to manage memory or parts of memory themselves. That is a programmer may know that certain objects are never going to be accessed again even though

78 ADVANCED TOPICS IN GARBAGE COLLECTION

references to the objects remain An example from compiling will suggest the problem

Example 7 17 We have seen that the lexical analyzer often manages a symbol table by creating an object for each identi er it sees. These objects may appear as lexical values attached to leaves of the parse tree representing those identi ers for instance. However, it is also useful to create a hash table keyed by the identi ers string to locate these objects. That table makes it easier for the lexical analyzer to and the object when it encounters a lexeme that is an identi er.

When the compiler passes the scope of an identi er I its symbol table object no longer has any references from the parse tree or probably any other intermediate structure used by the compiler. However, a reference to the object is still sitting in the hash table. Since the hash table is part of the root set of the compiler, the object cannot be garbage collected. If another identifier with the same lexeme as I is encountered, then it will be discovered that I is out of scope and the reference to its object will be deleted. However, if no other identifier with this lexeme is encountered, then I is object may remain as uncollectable yet useless throughout compilation. \Box

If the problem suggested by Example 7 17 is important then the compiler writer could arrange to delete from the hash table all references to objects as soon as their scope ends. However, a technique known as weak references allows the programmer to rely on automatic garbage collection, and yet not have the heap burdened with reachable yet truly unused objects. Such a system allows certain references to be declared, weak. An example would be all the references in the hash table we have been discussing. When the garbage collector scans an object it does not follow weak references within that object and does not make the objects they point to reachable. Of course, such an object may still be reachable if there is another reference to it that is not weak.

7 8 5 Exercises for Section 7 8

Exercise 7 8 1 In Section 7 8 3 we suggested that it was possible to garbage collect for C programs that do not fabricate expressions that point to a place within a chunk unless there is an address that points somewhere within that same chunk Thus we rule out code like

p 12345 x p

because while p might point to some chunk accidentally there could be no other pointer to that chunk. On the other hand with the code above it is more likely that p points nowhere and executing that code will result in a segmentation fault. However, in C it is possible to write code such that a variable like p is guaranteed to point to some chunk, and yet there is no pointer to that chunk. Write such a program

7 9 Summary of Chapter 7

- ◆ Run Time Organization To implement the abstractions embodied in the source language a compiler creates and manages a run time environment in concert with the operating system and the target machine The run time environment has static data areas for the object code and the static data objects created at compile time It also has dynamic stack and heap areas for managing objects created and destroyed as the target program executes
- igspace Control Stack Procedure calls and returns are usually managed by a run time stack called the control stack. We can use a stack because procedure calls or activations nest in time that is if p calls q then this activation of q is nested within this activation of p
- → Stack Allocation Storage for local variables can be allocated on a run time stack for languages that allow or require local variables to become inaccessible when their procedures end For such languages each live activation has an activation record or frame on the control stack with the root of the activation tree at the bottom and the entire sequence of activation records on the stack corresponding to the path in the activation tree to the activation where control currently resides The latter activation has its record at the top of the stack
- ◆ Access to Nonlocal Data on the Stack For languages like C that do not allow nested procedure declarations the location for a variable is either global or found in the activation record on top of the run time stack For languages with nested procedures we can access nonlocal data on the stack through access links which are pointers added to each activation record The desired nonlocal data is found by following a chain of access links to the appropriate activation record A display is an auxiliary array used in conjunction with access links that provides an e-cient short cut alternative to a chain of access links
- ♦ Heap Management The heap is the portion of the store that is used for data that can live inde nitely or until the program deletes it explicitly The memory manager allocates and deallocates space within the heap Garbage collection and spaces within the heap that are no longer in use and can therefore be reallocated to house other data items. For languages that require it the garbage collector is an important subsystem of the memory manager.
- ◆ Exploiting Locality By making good use of the memory hierarchy memory managers can in uence the run time of a program The time taken to access dierent parts of memory can vary from nanoseconds to milliseconds Fortunately most programs spend most of their time executing a relatively small fraction of the code and touching only a small fraction of

79 SUMMARY OF CHAPTER 7

the data A program has temporal locality if it is likely to access the same memory locations again soon it has spatial locality if it is likely to access nearby memory locations soon

- ♦ Reducing Fragmentation As the program allocates and deallocates mem ory the heap may get fragmented or broken into large numbers of small noncontiguous free spaces or holes. The best t strategy allocate the smallest available hole that satis es a request—has been found empirically to work well. While best—t tends to improve space utilization it may not be best for spatial locality. Fragmentation can be reduced by combining or coalescing adjacent holes.
- ◆ Manual Deallocation Manual memory management has two common failings not deleting data that can not be referenced is a memory leak error and referencing deleted data is a dangling pointer dereference error
- ◆ Reachability Garbage is data that cannot be referenced or reached There are two basic ways of nding unreachable objects either catch the tran sition as a reachable object turns unreachable or periodically locate all reachable objects and infer that all remaining objects are unreachable
- ◆ Reference Counting Collectors maintain a count of the references to an object when the count transitions to zero the object becomes unreachable Such collectors introduce the overhead of maintaining references and can fail to nd cyclic garbage which consists of unreachable objects that reference each other perhaps through a chain of references
- ◆ Trace Based Garbage Collectors iteratively examine or trace all references to nd reachable objects starting with the root set consisting of objects that can be accessed directly without having to dereference any pointers
- ◆ Mark and Sweep Collectors visit and mark all reachable objects in a rst tracing step and then sweep the heap to free up unreachable objects
- ♦ Mark and Compact Collectors improve upon mark and sweep they relocate reachable objects in the heap to eliminate memory fragmentation
- igspace Copying Collectors break the dependency between tracing and nding free space. They partition the memory into two semispaces A and B. Allocation requests are satisfied from one semispace say A until it. Ils up at which point the garbage collector takes over copies the reachable objects to the other space say B and reverses the roles of the semispaces.
- ◆ Incremental Collectors Simple trace based collectors stop the user program while garbage is collected Incremental collectors interleave the actions of the garbage collector and the mutator or user program The mutator can interfere with incremental reachability analysis since it can

change the references within previously scanned objects Incremental collectors therefore play it safe by overestimating the set of reachable objects any oating garbage can be picked up in the next round of collection

◆ Partial Collectors also reduce pauses they collect a subset of the garbage at a time. The best known of partial collection algorithms generational garbage collection partitions objects according to how long they have been allocated and collects the newly created objects more often because they tend to have shorter lifetimes. An alternative algorithm the train algorithm uses xed length partitions called cars that are collected into trains. Each collection step is applied to the rst remaining car of the rst remaining train. When a car is collected reachable objects are moved out to other cars so this car is left with garbage and can be removed from the train. These two algorithms can be used together to create a partial collector that applies the generational algorithm to younger objects and the train algorithm to more mature objects.

Chapter 8

Code Generation

The nal phase in our compiler model is the code generator. It takes as input the intermediate representation IR produced by the front end of the compiler along with relevant symbol table information and produces as output a semantically equivalent target program as shown in Fig. 8.1.

The requirements imposed on a code generator are severe. The target program must preserve the semantic meaning of the source program and be of high quality, that is it must make elective use of the available resources of the target machine. Moreover, the code generator itself must run elecitly

The challenge is that mathematically the problem of generating an optimal target program for a given source program is undecidable many of the subproblems encountered in code generation such as register allocation are computationally intractable. In practice we must be content with heuristic techniques that generate good but not necessarily optimal code. Fortunately heuristics have matured enough that a carefully designed code generator can produce code that is several times faster than code produced by a naive one

Compilers that need to produce e cient target programs include an optimization phase prior to code generation. The optimizer maps the IR into IR from which more e cient code can be generated. In general, the code optimization and code generation phases of a compiler often referred to as the back end may make multiple passes over the IR before generating the target program. Code optimization is discussed in detail in Chapter 9. The techniques presented in this chapter can be used whether or not an optimization phase occurs before code generation.

A code generator has three primary tasks instruction selection register

Figure 8.1 Position of code generator

allocation and assignment and instruction ordering. The importance of these tasks is outlined in Section 8.1 Instruction selection involves choosing appropriate target machine instructions to implement the IR statements. Register allocation and assignment involves deciding what values to keep in which registers. Instruction ordering involves deciding in what order to schedule the execution of instructions.

This chapter presents algorithms that code generators can use to trans late the IR into a sequence of target language instructions for simple register machines. The algorithms will be illustrated by using the machine model in Section 8.2. Chapter 10 covers the problem of code generation for complex modern machines that support a great deal of parallelism within a single instruction.

After discussing the broad issues in the design of a code generator we show what kind of target code a compiler needs to generate to support the abstrac tions embodied in a typical source language. In Section 8.3 we outline imple mentations of static and stack allocation of data areas and show how names in the IR can be converted into addresses in the target code.

Many code generators partition IR instructions into basic blocks which consist of sequences of instructions that are always executed together. The partitioning of the IR into basic blocks is the subject of Section 8.4. The following section presents simple local transformations that can be used to transform basic blocks into modi ed basic blocks from which more elicient code can be generated. These transformations are a rudimentary form of code optimization although the deeper theory of code optimization will not be taken up until Chapter 9. An example of a useful local transformation is the discovery of common subexpressions at the level of intermediate code and the resultant replacement of arithmetic operations by simpler copy operations.

Section 8 6 presents a simple code generation algorithm that generates code for each statement in turn keeping operands in registers as long as possible. The output of this kind of code generator can be readily improved by peephole optimization techniques such as those discussed in the following Section 8 7.

The remaining sections explore instruction selection and register allocation

8 1 Issues in the Design of a Code Generator

While the details are dependent on the speci cs of the intermediate representation the target language and the run time system tasks such as instruction selection register allocation and assignment and instruction ordering are encountered in the design of almost all code generators

The most important criterion for a code generator is that it produce cor rect code Correctness takes on special signi cance because of the number of special cases that a code generator might face Given the premium on correct ness designing a code generator so it can be easily implemented tested and maintained is an important design goal

8 1 1 Input to the Code Generator

The input to the code generator is the intermediate representation of the source program produced by the front end along with information in the symbol table that is used to determine the run time addresses of the data objects denoted by the names in the IR

The many choices for the IR include three address representations such as quadruples triples indirect triples virtual machine representations such as bytecodes and stack machine code linear representations such as post x no tation and graphical representations such as syntax trees and DAG s Many of the algorithms in this chapter are couched in terms of the representations considered in Chapter 6 three address code trees and DAG s The techniques we discuss can be applied however to the other intermediate representations as well

In this chapter we assume that the front end has scanned parsed and translated the source program into a relatively low level IR so that the values of the names appearing in the IR can be represented by quantities that the target machine can directly manipulate such as integers and oating point numbers. We also assume that all syntactic and static semantic errors have been detected that the necessary type checking has taken place and that type conversion operators have been inserted wherever necessary. The code generator can therefore proceed on the assumption that its input is free of these kinds of errors

8 1 2 The Target Program

The instruction set architecture of the target machine has a signi cant im pact on the di-culty of constructing a good code generator that produces high quality machine code. The most common target machine architectures are RISC—reduced instruction set computer—CISC—complex instruction set computer—and stack based

A RISC machine typically has many registers three address instructions simple addressing modes and a relatively simple instruction set architecture In contrast a CISC machine typically has few registers two address instructions a variety of addressing modes several register classes variable length instructions and instructions with side e ects

In a stack based machine operations are done by pushing operands onto a stack and then performing the operations on the operands at the top of the stack. To achieve high performance the top of the stack is typically kept in registers. Stack based machines almost disappeared because it was felt that the stack organization was too limiting and required too many swap and copy operations.

However stack based architectures were revived with the introduction of the Java Virtual Machine JVM The JVM is a software interpreter for Java bytecodes an intermediate language produced by Java compilers The inter preter provides software compatibility across multiple platforms a major factor in the success of Java

To overcome the high performance penalty of interpretation which can be on the order of a factor of 10 *just in time* JIT Java compilers have been created. These JIT compilers translate bytecodes during run time to the native hardware instruction set of the target machine. Another approach to improving Java performance is to build a compiler that compiles directly into the machine instructions of the target machine bypassing the Java bytecodes entirely

Producing an absolute machine language program as output has the advantage that it can be placed in a xed location in memory and immediately executed Programs can be compiled and executed quickly

Producing a relocatable machine language program often called an *object module* as output allows subprograms to be compiled separately. A set of relocatable object modules can be linked together and loaded for execution by a linking loader. Although we must pay the added expense of linking and loading if we produce relocatable object modules we gain a great deal of exibility in being able to compile subroutines separately and to call other previously compiled programs from an object module. If the target machine does not handle relocation automatically the compiler must provide explicit relocation information to the loader to link the separately compiled program modules

Producing an assembly language program as output makes the process of code generation somewhat easier. We can generate symbolic instructions and use the macro facilities of the assembler to help generate code. The price paid is the assembly step after code generation.

In this chapter we shall use a very simple RISC like computer as our target machine. We add to it some CISC like addressing modes so that we can also discuss code generation techniques for CISC machines. For readability, we use assembly code as the target language. As long as addresses can be calculated from o sets and other information stored in the symbol table, the code generator can produce relocatable or absolute addresses for names just as easily as symbolic addresses.

8 1 3 Instruction Selection

The code generator must map the IR program into a code sequence that can be executed by the target machine—The complexity of performing this mapping is determined by factors such as

the level of the IR

the nature of the instruction set architecture

the desired quality of the generated code

If the IR is high level the code generator may translate each IR statement into a sequence of machine instructions using code templates. Such statement by statement code generation however often produces poor code that needs

8 1 ISSUES IN THE DESIGN OF A CODE GENERATOR

further optimization If the IR re ects some of the low level details of the un derlying machine then the code generator can use this information to generate more e cient code sequences

The nature of the instruction set of the target machine has a strong e ect on the di-culty of instruction selection. For example, the uniformity and completeness of the instruction set are important factors. If the target machine does not support each data type in a uniform manner, then each exception to the general rule requires special handling. On some machines, for example oating point operations are done using separate registers.

Instruction speeds and machine idioms are other important factors. If we do not care about the e-ciency of the target program instruction selection is straightforward. For each type of three address statement, we can design a code skeleton that do not the target code to be generated for that construct. For example, every three address statement of the form $\mathbf{x} \cdot \mathbf{y} \cdot \mathbf{z}$ where $\mathbf{x} \cdot \mathbf{y}$ and \mathbf{z} are statically allocated, can be translated into the code sequence

LD	RO	У		RO	У		load y into register RO
\mathtt{ADD}	RO	RO	z	RO	RO	Z	$\operatorname{add} \mathbf{z} ext{ to RO}$
ST	x	RO		х	RO		store RO into x

This strategy often produces redundant loads and stores For example the sequence of three address statements

would be translated into

LD	RO	b		RO	b	
\mathtt{ADD}	RO	RO	С	RO	RO	С
ST	a	RO		a	RO	
LD	RO	a		RO	a	
ADD	RO	RO	е	RO	RO	е
ST	d	R.O		d	RO	

Here the fourth statement is redundant since it loads a value that has just been stored and so is the third if a is not subsequently used

The quality of the generated code is usually determined by its speed and size. On most machines a given IR program can be implemented by many di erent code sequences with significant cost di erences between the di erent implementations. A naive translation of the intermediate code may therefore lead to correct but unacceptably inesseries cient target code.

For example if the target machine has an increment instruction INC then the three address statement a a 1 may be implemented more e ciently by the single instruction INC a rather than by a more obvious sequence that loads a into a register adds one to the register and then stores the result back into a

LD RO a RO a
ADD RO RO 1 RO RO 1
ST a RO a RO

We need to know instruction costs in order to design good code sequences but unfortunately accurate cost information is often di cult to obtain De ciding which machine code sequence is best for a given three address construct may also require knowledge about the context in which that construct appears

In Section 8.9 we shall see that instruction selection can be modeled as a tree pattern matching process in which we represent the IR and the machine instructions as trees. We then attempt to tile an IR tree with a set of subtrees that correspond to machine instructions. If we associate a cost with each machine instruction subtree, we can use dynamic programming to generate optimal code sequences. Dynamic programming is discussed in Section 8.11

8 1 4 Register Allocation

A key problem in code generation is deciding what values to hold in what registers Registers are the fastest computational unit on the target machine but we usually do not have enough of them to hold all values Values not held in registers need to reside in memory Instructions involving register operands are invariably shorter and faster than those involving operands in memory so e cient utilization of registers is particularly important

The use of registers is often subdivided into two subproblems

- 1 Register allocation during which we select the set of variables that will reside in registers at each point in the program
- 2 Register assignment during which we pick the speci c register that a variable will reside in

Finding an optimal assignment of registers to variables is di-cult even with single register machines. Mathematically the problem is NP complete. The problem is further complicated because the hardware and or the operating system of the target machine may require that certain register usage conventions be observed.

Example 8 1 Certain machines require register pairs an even and next odd numbered register for some operands and results For example on some machines integer multiplication and integer division involve register pairs The multiplication instruction is of the form

where x the multiplicand is the odd register of an even odd register pair and y the multiplier can be anywhere. The product occupies the entire even odd register pair. The division instruction is of the form

81 ISSUES IN THE DESIGN OF A CODE GENERATOR

D x y

where the dividend occupies an even odd register pair whose even register is x the divisor is y After division the even register holds the remainder and the odd register the quotient

Now consider the two three address code sequences in Fig. 8.2 in which the only di erence in a and b is the operator in the second statement. The shortest assembly code sequences for a and b are given in Fig. 8.3.

t	a	b		t	a	b
t	t	С		t	t	С
t	t	d		t	t	d
	a				b	

Figure 8 2 Two three address code sequences

L	R1	a		L	RO	a
Α	R1	b		A	RO	b
M	RO	С		A	RO	С
D	R0	d		${\tt SRDA}$	RO	32
ST	R1	t		D	RO	d
				ST	R1	t
	a			b		

Figure 8 3 Optimal machine code sequences

Ri stands for register i SRDA stands for Shift Right Double Arithmetic and SRDA RO 32 shifts the dividend into R1 and clears RO so all bits equal its sign bit L ST and A stand for load store and add respectively. Note that the optimal choice for the register into which a is to be loaded depends on what will ultimately happen to t

Strategies for register allocation and assignment are discussed in Section 8 8 Section 8 10 shows that for certain classes of machines we can construct code sequences that evaluate expressions using as few registers as possible

8 1 5 Evaluation Order

The order in which computations are performed can a ect the e-ciency of the target code. As we shall see some computation orders require fewer registers to hold intermediate results than others. However, picking a best order in the general case is a di-cult NP complete problem. Initially we shall avoid

the problem by generating code for the three address statements in the order in which they have been produced by the intermediate code generator. In Chapter 10 we shall study code scheduling for pipelined machines that can execute several operations in a single clock cycle

8 2 The Target Language

Familiarity with the target machine and its instruction set is a prerequisite for designing a good code generator. Unfortunately in a general discussion of code generation it is not possible to describe any target machine in su-cient detail to generate good code for a complete language on that machine. In this chapter we shall use as a target language assembly code for a simple computer that is representative of many register machines. However, the code generation techniques presented in this chapter can be used on many other classes of machines as well

8 2 1 A Simple Target Machine Model

Our target computer models a three address machine with load and store oper ations computation operations jump operations and conditional jumps. The underlying computer is a byte addressable machine with n general purpose registers R0 R1 Rn 1 A full edged assembly language would have scores of instructions. To avoid hiding the concepts in a myriad of details we shall use a very limited set of instructions and assume that all operands are integers. Most instructions consists of an operator followed by a target followed by a list of source operands. A label may precede an instruction. We assume the following kinds of instructions are available.

Load operations The instruction LD dst addr loads the value in location addr into location dst This instruction denotes the assignment dst addr The most common form of this instruction is LD r x which loads the value in location x into register r An instruction of the form LD r_1 r_2 is a register to register copy in which the contents of register r_2 are copied into register r_1

Store operations The instruction ST x r stores the value in register r into the location x This instruction denotes the assignment x r

Computation operations of the form OP dst src_1 src_2 where OP is a operator like ADD or SUB and dst src_1 and src_2 are locations not necessarily distinct. The elect of this machine instruction is to apply the operation represented by OP to the values in locations src_1 and src_2 and place the result of this operation in location dst. For example, SUB r_1 , r_2 , r_3 computes r_1 , r_2 , r_3 . Any value formerly stored in r_1 is lost but if r_1 is r_2 or r_3 , the old value is read a rst. Unary operators that take only one operand do not have a src_2

8 2 THE TARGET LANGUAGE

Unconditional jumps The instruction BR L causes control to branch to the machine instruction with label L BR stands for branch

Conditional jumps of the form $\operatorname{Bcond} r$ L where r is a register L is a label and cond stands for any of the common tests on values in the register r. For example BLTZ r L causes a jump to label L if the value in register r is less than zero and allows control to pass to the next machine instruction if not

We assume our target machine has a variety of addressing modes

In instructions a location can be a variable name x referring to the mem ory location that is reserved for x that is the l value of x

A location can also be an indexed address of the form $a\ r$ where a is a variable and r is a register. The memory location denoted by $a\ r$ is computed by taking the l value of a and adding to it the value in register r. For example, the instruction LD R1 a R2 has the elect of setting R1 contents a contents R2 where contents x denotes the contents of the register or memory location represented by x. This addressing mode is useful for accessing arrays where a is the base address of the array that is the address of the rst element, and r holds the number of bytes past that address we wish to go to reach one of the elements of array a

A memory location can be an integer indexed by a register For ex ample LD R1 100 R2 has the e ect of setting R1 contents 100 contents R2 that is of loading into R1 the value in the memory location obtained by adding 100 to the contents of register R2 This feature is useful for following pointers as we shall see in the example below

We also allow two indirect addressing modes r means the memory location found in the location represented by the contents of register r and 100 r means the memory location found in the location obtained by adding 100 to the contents of r For example LD R1 100 R2 has the e ect of setting R1 contents contents 100 contents R2 that is of loading into R1 the value in the memory location stored in the memory location obtained by adding 100 to the contents of register R2

Finally we allow an immediate constant addressing mode The constant is pre xed by The instruction LD R1 100 loads the integer 100 into register R1 and ADD R1 R1 100 adds the integer 100 into register R1

Comments at the end of instructions are preceded by

Example 8 2 The three address statement x y z can be implemented by the machine instructions

CHAPTER 8 CODE GENERATION

```
LD
    R1
                         R1
                               У
         У
LD
    R2
                         R2
         z
                               7.
SUB R1
        R1
             R2
                         R1
                               R1
                                     R2
ST
    x R1
                              R1
                         х
```

We can do better perhaps One of the goals of a good code generation algorithm is to avoid using all four of these instructions whenever possible For example y and or z may have been computed in a register and if so we can avoid the LD step s Likewise we might be able to avoid ever storing x if its value is used within the register set and is not subsequently needed

Suppose a is an array whose elements are 8 byte values perhaps real numbers. Also assume elements of a are indexed starting at 0. We may execute the three address instruction b a i by the machine instructions

LD	R1	i	R1	i	
MUL	R1	R1 8	R1	R1 8	
LD	R2	a R1	R2	contents a	contents R1
ST	b	R2	b	R2	

That is the second step computes 8i and the third step places in register R2 the value in the ith element of a — the one found in the location that is 8i bytes past the base address of the array a

Similarly the assignment into the array a represented by three address in struction a j c is implemented by

```
LD
   R1
LD
   R2
        j
                       R2
MUL R2
                                 8
            8
                       R2
                            R2
ST a R2
                                                       R1
           R1
                       contents a
                                      contents R2
```

To implement a simple pointer indirection such as the three address state ment \mathbf{x} \mathbf{p} we can use machine instructions like

```
LD R1 p R1 p

LD R2 0 R1 R2 contents 0 contents R1

ST x R2 x R2
```

The assignment through a pointer p y is similarly implemented in machine code by

```
LD R1 p R1 p R2 y R2 y ST 0 R1 R2 contents 0 contents R1 R2
```

Finally consider a conditional jump three address instruction like

```
if x y goto L
```

82 THE TARGET LANGUAGE

The machine code equivalent would be something like

LD	R1	x		R1	x				
LD	R2	У		R2	У				
SUB	R1	R1	R2	R1	R1		R2		
BLTZ	R1	M		if	R1	0	jump	to	М

Here M is the label that represents the $\,$ rst machine instruction generated from the three address instruction that has label L. As for any three address instruction we hope that we can save some of these machine instructions because the needed operands are already in registers or because the result need never be stored. \Box

8 2 2 Program and Instruction Costs

We often associate a cost with compiling and running a program Depending on what aspect of a program we are interested in optimizing some common cost measures are the length of compilation time and the size running time and power consumption of the target program

Determining the actual cost of compiling and running a program is a complex problem. Finding an optimal target program for a given source program is an undecidable problem in general and many of the subproblems involved are NP hard. As we have indicated in code generation we must often be content with heuristic techniques that produce good but not necessarily optimal target programs

For the remainder of this chapter we shall assume each target language instruction has an associated cost. For simplicity we take the cost of an in struction to be one plus the costs associated with the addressing modes of the operands. This cost corresponds to the length in words of the instruction Addressing modes involving registers have zero additional cost while those in volving a memory location or constant in them have an additional cost of one because such operands have to be stored in the words following the instruction Some examples

The instruction LD RO R1 copies the contents of register R1 into register R0 This instruction has a cost of one because no additional memory words are required

The instruction LD RO M loads the contents of memory location M into register RO The cost is two since the address of memory location M is in the word following the instruction

The instruction LD R1 100 R2 loads into register R1 the value given by *contents contents* 100 *contents* R2 The cost is two because the constant 100 is stored in the word following the instruction

CHAPTER 8 CODE GENERATION

In this chapter we assume the cost of a target language program on a given input is the sum of costs of the individual instructions executed when the program is run on that input Good code generation algorithms seek to minimize the sum of the costs of the instructions executed by the generated target program on typical inputs We shall see that in some situations we can actually generate optimal code for expressions on certain classes of register machines

8 2 3 Exercises for Section 8 2

Exercise 8 2 1 Generate code for the following three address statements as suming all variables are stored in memory locations

- a x 1
- b x a
- c x a 1

```

8 3 Addresses in the Target Code

In this section we show how names in the IR can be converted into addresses in the target code by looking at code generation for simple procedure calls and returns using static and stack allocation. In Section 7.1 we described how each executing program runs in its own logical address space that was partitioned into four code and data areas.

- 1 A statically determined area *Code* that holds the executable target code. The size of the target code can be determined at compile time
- 2 A statically determined data area *Static* for holding global constants and other data generated by the compiler. The size of the global constants and compiler data can also be determined at compile time
- 3 A dynamically managed area *Heap* for holding data objects that are allo cated and freed during program execution. The size of the *Heap* cannot be determined at compile time
- 4 A dynamically managed area Stack for holding activation records as they are created and destroyed during procedure calls and returns. Like the Heap the size of the Stack cannot be determined at compile time

8 3 1 Static Allocation

To illustrate code generation for simpli ed procedure calls and returns we shall focus on the following three address statements

```
return
halt
action which is a placeholder for other three address statements
```

The size and layout of activation records are determined by the code gener ator via the information about names stored in the symbol table. We shall rst illustrate how to store the return address in an activation record on a procedure

8 3 ADDRESSES IN THE TARGET CODE

call and how to return control to it after the procedure call For convenience we assume the rst location in the activation record holds the return address

Let us rst consider the code needed to implement the simplest case static allocation. Here a call callee statement in the intermediate code can be implemented by a sequence of two target machine instructions

```
ST callee staticArea here 20
BR callee codeArea
```

The ST instruction saves the return address at the beginning of the activation record for callee and the BR transfers control to the target code for the called procedure callee. The attribute callee staticArea is a constant that gives the address of the beginning of the activation record for callee and the attribute callee codeArea is a constant referring to the address of the rest instruction of the called procedure callee in the Code area of the run time memory

The operand here 20 in the ST instruction is the literal return address it is the address of the instruction following the BR instruction. We assume that here is the address of the current instruction and that the three constants plus the two instructions in the calling sequence have a length of 5 words or 20 bytes.

The code for a procedure ends with a return to the calling procedure except that the rst procedure has no caller so its nal instruction is HALT which re turns control to the operating system A return statement can be implemented by a simple jump instruction

```
BR callee staticArea
```

which transfers control to the address saved at the beginning of the activation record for *callee*

Example 8 3 Suppose we have the following three address code

```
\begin{array}{c} \operatorname{code} \ \operatorname{for} \ c \\ \\ \operatorname{action_1} \\ \\ \operatorname{call} \ p \\ \\ \operatorname{action_2} \\ \\ \operatorname{halt} \\ \\ \operatorname{code} \ \operatorname{for} \ p \\ \\ \operatorname{action_3} \\ \\ \operatorname{return} \end{array}
```

Figure 8 4 shows the target program for this three address code. We use the pseudoinstruction ACTION to represent the sequence of machine instructions to execute the statement action which represents three address code that is not relevant for this discussion. We arbitrarily start the code for procedure c at address 100 and for procedure p at address 200. We assume that each ACTION instruction takes 20 bytes. We further assume that the activation records for these procedures are statically allocated starting at locations 300 and 364 respectively.

The instructions starting at address 100 implement the statements

 $action_1$ call p $action_2$ halt

of the $\,$ rst procedure c $\,$ Execution therefore starts with the instruction $ACTION_1$ at address 100 $\,$ The ST instruction at address 120 saves the return address 140 in the machine status $\,$ eld which is the $\,$ rst word in the activation record of p $\,$ The BR instruction at address 132 transfers control the $\,$ rst instruction in the target code of the called procedure p

100 120 132 140	ACTION ₁ ST 364 BR 200 ACTION ₂	140	$\begin{array}{l} \operatorname{code} \operatorname{for} \ c \\ \operatorname{code} \operatorname{for} \ \operatorname{action}_1 \\ \operatorname{save} \ \operatorname{return} \ \operatorname{address} \ 140 \ \operatorname{in} \ \operatorname{location} \ 364 \\ \operatorname{call} \ p \end{array}$
160	HALT		return to operating system
			code for p
$\begin{array}{c} 200 \\ 220 \end{array}$	\mathtt{ACTION}_3 BR 364		return to address saved in location 364
300 304			300 363 hold activation record for c return address local data for c
364 368			364 451 hold activation record for p return address local data for p

Figure 8 4 Target code for static allocation

After executing ACTION₃ the jump instruction at location 220 is executed Since location 140 was saved at address 364 by the call sequence above 364 represents 140 when the BR statement at address 220 is executed Therefore when procedure p terminates control returns to address 140 and execution of procedure c resumes \Box

8 3 2 Stack Allocation

Static allocation can become stack allocation by using relative addresses for storage in activation records. In stack allocation, however, the position of an activation record for a procedure is not known until run time. This position is usually stored in a register, so words in the activation record can be accessed as o sets from the value in this register. The indexed address mode of our target machine is convenient for this purpose.

Relative addresses in an activation record can be taken as o sets from any known position in the activation record as we saw in Chapter 7 For conve

8 3 ADDRESSES IN THE TARGET CODE

nience we shall use positive o sets by maintaining in a register SP a pointer to the beginning of the activation record on top of the stack. When a procedure call occurs the calling procedure increments SP and transfers control to the called procedure. After control returns to the caller, we decrement SP thereby deallocating the activation record of the called procedure.

The code for the start of the stack area in memory

 $\begin{array}{lll} {\tt LD} & {\tt SP} & stackStart & {\tt initialize~the~stack} \\ {\tt code~for~the~rst~procedure} & & & \\ {\tt HALT} & & {\tt terminate~execution} \end{array}$

A procedure call sequence increments SP saves the return address and transfers control to the called procedure

ADD	SP SP	$caller\ recordSize$	increment stack pointer
ST	0 SP	here 16	save return address
BR	$callee \ co$	deArea	jump to the callee

The operand caller recordSize represents the size of an activation record so the ADD instruction makes SP point to the next activation record. The operand here—16 in the ST instruction is the address of the instruction following BR it is saved in the address pointed to by SP

The return sequence consists of two parts The called procedure transfers control to the return address using

BR 0 SP return to caller

The reason for using 0 SP in the BR instruction is that we need two levels of indirection 0 SP is the address of the rst word in the activation record and 0 SP is the return address saved there

The second part of the return sequence is in the caller which decrements SP thereby restoring SP to its previous value. That is after the subtraction SP points to the beginning of the activation record of the caller

SUB SP SP caller recordSize decrement stack pointer

Chapter 7 contains a broader discussion of calling sequences and the trade o s in the division of labor between the calling and called procedures

Example 8 4 The program in Fig. 8.5 is an abstraction of the quicksort program in the previous chapter Procedure q is recursive so more than one activation of q can be alive at the same time

Suppose that the sizes of the activation records for procedures m p and q have been determined to be *msize psize* and *qsize* respectively. The rst word in each activation record will hold a return address. We arbitrarily assume that the code for these procedures starts at addresses 100, 200, and 300, respectively.

CHAPTER 8 CODE GENERATION

code for m $action_1$ call q $action_2$ halt code for p $action_3$ return code for q $action_4$ call p action₅ call q action₆ call q return

Figure 8 5 Code for Example 8 4

and that the stack starts at address 600 The target program is shown in Figure 8.6

We assume that $\mathtt{ACTION_4}$ contains a conditional jump to the address 456 of the return sequence from q otherwise the recursive procedure q is condemned to call itself forever

Let $msize\ psize\$ and $qsize\$ be 20 40 and 60 respectively. The rst instruction at address 100 initializes the SP to 600 the starting address of the stack SP holds 620 just before control transfers from m to q because msize is 20 Subsequently when q calls p the instruction at address 320 increments SP to 680 where the activation record for p begins. SP reverts to 620 after control returns to q. If the next two recursive calls of q return immediately, the maximum value of SP during this execution is 680. Note, however, that the last stack location used is 739 since the activation record of q starting at location 680 extends for 60 bytes. \Box

8 3 3 Run Time Addresses for Names

The storage allocation strategy and the layout of local data in an activation record for a procedure determine how the storage for names is accessed. In Chapter 6 we assumed that a name in a three address statement is really a pointer to a symbol table entry for that name. This approach has a significant advantage it makes the compiler more portable since the front end need not be changed even when the compiler is moved to a different machine where a different run time organization is needed. On the other hand, generating the specific sequence of access steps while generating intermediate code can be of

signi cant advantage in an optimizing compiler since it lets the optimizer take advantage of details it would not see in the simple three address statement

In either case names must eventually be replaced by code to access storage locations. We thus consider some elaborations of the simple three address copy statement $\mathbf{x}=0$. After the declarations in a procedure are processed suppose the symbol table entry for \mathbf{x} contains a relative address 12 for \mathbf{x} . For example consider the case in which \mathbf{x} is in a statically allocated area beginning at address static. Then the actual run time address of \mathbf{x} is static. 12. Although the compiler can eventually determine the value of static. 12 at compile time the position of the static area may not be known when intermediate code to access the name is generated. In that case, it makes sense to generate three address code to compute static. 12 with the understanding that this computation will be carried out during the code generation phase or possibly by the loader before the program runs. The assignment $\mathbf{x}=0$ then translates into

```
static 12 0
```

If the static area starts at address 100 the target code for this statement is

```
LD 112 0
```

8 4 Basic Blocks and Flow Graphs

This section introduces a graph representation of intermediate code that is help ful for discussing code generation even if the graph is not constructed explicitly by a code generation algorithm. Code generation bene to from context. We can do a better job of register allocation if we know how values are defined and used as we shall see in Section 8.8. We can do a better job of instruction selection by looking at sequences of three address statements as we shall see in Section 8.9.

The representation is constructed as follows

- 1 Partition the intermediate code into basic blocks which are maximal se quences of consecutive three address instructions with the properties that
 - a The ow of control can only enter the basic block through the rst instruction in the block. That is there are no jumps into the middle of the block
 - b Control will leave the block without halting or branching except possibly at the last instruction in the block
- 2 The basic blocks become the nodes of a ow graph whose edges indicate which blocks can follow which other blocks

The E ect of Interrupts

The notion that control once it reaches the beginning of a basic block is certain to continue through to the end requires a bit of thought. There are many reasons why an interrupt not rejected explicitly in the code could cause control to leave the block perhaps never to return. For example, an instruction like $\mathbf{x} = \mathbf{y} = \mathbf{z}$ appears not to a ject control ow but if z is 0 it could actually cause the program to abort

We shall not worry about such possibilities The reason is as follows. The purpose of constructing basic blocks is to optimize the code. Generally when an interrupt occurs either it will be handled and control will come back to the instruction that caused the interrupt as if control had never deviated or the program will halt with an error. In the latter case it doesn't matter how we optimized the code even if we depended on control reaching the end of the basic block because the program didn't produce its intended result anyway.

Starting in Chapter 9 we discuss transformations on ow graphs that turn the original intermediate code into optimized intermediate code from which better target code can be generated. The optimized intermediate code is turned into machine code using the code generation techniques in this chapter

8 4 1 Basic Blocks

Our rst job is to partition a sequence of three address instructions into basic blocks. We begin a new basic block with the rst instruction and keep adding instructions until we meet either a jump a conditional jump or a label on the following instruction. In the absence of jumps and labels control proceeds sequentially from one instruction to the next. This idea is formalized in the following algorithm.

Algorithm 8 5 Partitioning three address instructions into basic blocks

INPUT A sequence of three address instructions

OUTPUT A list of the basic blocks for that sequence in which each instruction is assigned to exactly one basic block

METHOD First we determine those instructions in the intermediate code that are *leaders* that is the rst instructions in some basic block. The instruction just past the end of the intermediate program is not included as a leader. The rules for inding leaders are

1 The rst three address instruction in the intermediate code is a leader

8 4 BASIC BLOCKS AND FLOW GRAPHS

- 2 Any instruction that is the target of a conditional or unconditional jump is a leader
- 3 Any instruction that immediately follows a conditional or unconditional jump is a leader

Then for each leader its basic block consists of itself and all instructions up to but not including the next leader or the end of the intermediate program \Box

Figure 8 7 Intermediate code to set a 10 10 matrix to an identity matrix

Example 8 6 The intermediate code in Fig 8 7 turns a 10 10 matrix a into an identity matrix Although it is not important where this code comes from it might be the translation of the pseudocode in Fig 8 8 In generating the intermediate code we have assumed that the real valued array elements take 8 bytes each and that the matrix a is stored in row major form

Figure 8 8 Source code for Fig 8 7

First instruction 1 is a leader by rule 1 of Algorithm 8.5 To nd the other leaders we rst need to nd the jumps In this example there are three jumps all conditional at instructions 9.11 and 17. By rule 2, the targets of these jumps are leaders they are instructions 3.2 and 13 respectively. Then by rule 3, each instruction following a jump is a leader those are instructions 10 and 12. Note that no instruction follows 17 in this code but if there were code following the 18th instruction would also be a leader

We conclude that the leaders are instructions 1 2 3 10 12 and 13 The basic block of each leader contains all the instructions from itself until just before the next leader. Thus, the basic block of 1 is just 1 for leader 2 the block is just 2. Leader 3 however has a basic block consisting of instructions 3 through 9 inclusive. Instruction 10 s block is 10 and 11 instruction 12 s block is just 12 and instruction 13 s block is 13 through 17. \Box

8 4 2 Next Use Information

Knowing when the value of a variable will be used next is essential for generating good code. If the value of a variable that is currently in a register will never be referenced subsequently, then that register can be assigned to another variable.

The use of a name in a three address statement is defined as follows. Suppose three address statement i assigns a value to x. If statement j has x as an operand and control can ow from statement i to j along a path that has no intervening assignments to x then we say statement j uses the value of x computed at statement i. We further say that x is live at statement i.

We wish to determine for each three address statement x-y-z what the next uses of x-y-z and z are For the present we do not concern ourselves with uses outside the basic block containing this three address statement

Our algorithm to determine liveness and next use information makes a back ward pass over each basic block. We store the information in the symbol table. We can easily scan a stream of three address statements to -nd the ends of basic blocks as in Algorithm 8.5. Since procedures can have arbitrary side elects we assume for convenience that each procedure call starts a new basic block.

Algorithm 8 7 Determining the liveness and next use information for each statement in a basic block

INPUT A basic block B of three address statements. We assume that the symbol table initially shows all nontemporary variables in B as being live on exit

OUTPUT At each statement i x y z in B we attach to i the liveness and next use information of x y and z

METHOD We start at the last statement in B and scan backwards to the beginning of B At each statement i x y z in B we do the following

1 Attach to statement i the information currently found in the symbol table regarding the next use and liveness of x y and z

8 4 BASIC BLOCKS AND FLOW GRAPHS

- 2 In the symbol table set x to not live and no next use
- 3 In the symbol table set y and z to live and the next uses of y and z to i

Here we have used as a symbol representing any operator. If the three address statement i is of the form x y or x y the steps are the same as above ignoring z. Note that the order of steps 2 and 3 may not be interchanged because x may be y or z

8 4 3 Flow Graphs

Once an intermediate code program is partitioned into basic blocks we represent the ow of control between them by a ow graph. The nodes of the ow graph are the basic blocks. There is an edge from block B to block C if and only if it is possible for the rst instruction in block C to immediately follow the last instruction in block B. There are two ways that such an edge could be justified.

There is a conditional or unconditional jump from the end of B to the beginning of C

C immediately follows B in the original order of the three address instructions and B does not end in an unconditional jump

We say that B is a predecessor of C and C is a successor of B

Often we add two nodes called the *entry* and *exit* that do not correspond to executable intermediate instructions. There is an edge from the entry to the rst executable node of the low graph that is to the basic block that comes from the rst instruction of the intermediate code. There is an edge to the exit from any basic block that contains an instruction that could be the last executed instruction of the program. If the lock containing the lock rate in an unconditional jump, then the block containing the lock that has a jump to code that is not part of the program.

Example 8 8 The set of basic blocks constructed in Example 8 6 yields the ow graph of Fig 8 9 The entry points to basic block B_1 since B_1 contains the rst instruction of the program The only successor of B_1 is B_2 because B_1 does not end in an unconditional jump and the leader of B_2 immediately follows the end of B_1

Block B_3 has two successors. One is itself–because the leader of B_3 —instruction 3 is the target of the conditional jump at the end of B_3 —instruction 9. The other successor is B_4 —because control can fall through the conditional jump at the end of B_3 and next enter the leader of B_4

Only B_6 points to the exit of the ow graph since the only way to get to code that follows the program from which we constructed the ow graph is to fall through the conditional jump that ends B_6

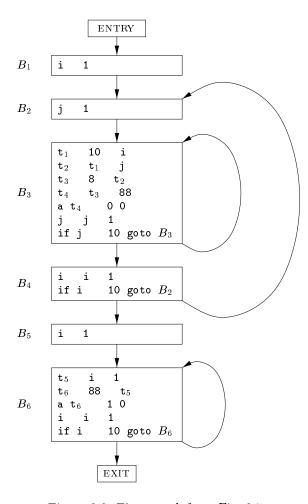

Figure 8 9 Flow graph from Fig 8 7

8 4 4 Representation of Flow Graphs

First note from Fig. 8.9 that in the ow graph it is normal to replace the jumps to instruction numbers or labels by jumps to basic blocks. Recall that every conditional or unconditional jump is to the leader of some basic block and it is to this block that the jump will now refer. The reason for this change is that after constructing the ow graph it is common to make substantial changes to the instructions in the various basic blocks. If jumps were to instructions we would have to -x the targets of the jumps every time one of the target instructions was changed.

Flow graphs being quite ordinary graphs can be represented by any of the data structures appropriate for graphs. The content of nodes basic blocks need their own representation. We might represent the content of a node by a

8 4 BASIC BLOCKS AND FLOW GRAPHS

pointer to the leader in the array of three address instructions together with a count of the number of instructions or a second pointer to the last instruction. However since we may be changing the number of instructions in a basic block frequently it is likely to be more e cient to create a linked list of instructions for each basic block

8 4 5 Loops

Programming language constructs like while statements do while statements and for statements naturally give rise to loops in programs. Since virtually every program spends most of its time in executing its loops it is especially important for a compiler to generate good code for loops. Many code transformations depend upon the identication of loops in a loop way when the loop entry such that

- 1 e is not ENTRY the entry of the entire ow graph
- 2 No node in L besides e has a predecessor outside L That is every path from ENTRY to any node in L goes through e
- 3 Every node in L has a nonempty path completely within L to e

Example 8 9 The ow graph of Fig 8 9 has three loops

- 1 B_3 by itself
- $2 B_6$ by itself
- $\{B_2 \ B_3 \ B_4\}$

The rst two are single nodes with an edge to the node itself. For instance B_3 forms a loop with B_3 as its entry. Note that the last requirement for a loop is that there be a nonempty path from B_3 to itself. Thus, a single node like B_2 which does not have an edge B_2 — B_2 is not a loop—since there is no nonempty path from B_2 to itself within $\{B_2\}$

The third loop L $\{B_2 \ B_3 \ B_4\}$ has B_2 as its loop entry. Note that among these three nodes only B_2 has a predecessor B_1 that is not in L. Further each of the three nodes has a nonempty path to B_2 staying within L. For instance B_2 has the path B_2 B_3 B_4 B_2 \square

8 5 Optimization of Basic Blocks

We can often obtain a substantial improvement in the running time of code merely by performing local optimization within each basic block by itself. More thorough global optimization which looks at how information ows among the basic blocks of a program is covered in later chapters starting with Chapter 9. It is a complex subject with many different techniques to consider

8 5 1 The DAG Representation of Basic Blocks

Many important techniques for local optimization begin by transforming a basic block into a DAG directed acyclic graph. In Section 6.1.1 we introduced the DAG as a representation for single expressions. The idea extends naturally to the collection of expressions that are created within one basic block. We construct a DAG for a basic block as follows.

- 1 There is a node in the DAG for each of the initial values of the variables appearing in the basic block
- 2 There is a node N associated with each statement s within the block The children of N are those nodes corresponding to statements that are the last de nitions prior to s of the operands used by s
- 3 Node N is labeled by the operator applied at s and also attached to N is the list of variables for which it is the last de nition within the block
- 4 Certain nodes are designated output nodes These are the nodes whose variables are live on exit from the block that is their values may be used later in another block of the ow graph Calculation of these live variables is a matter for global ow analysis discussed in Section 9 2 5

The DAG representation of a basic block lets us perform several code improving transformations on the code represented by the block

- a We can eliminate *local common subexpressions* that is instructions that compute a value that has already been computed
- b We can eliminate *dead code* that is instructions that compute a value that is never used
- c We can reorder statements that do not depend on one another such reordering may reduce the time a temporary value needs to be preserved in a register
- d We can apply algebraic laws to reorder operands of three address instructions and sometimes thereby simplify the computation

8 5 2 Finding Local Common Subexpressions

Common subexpressions can be detected by noticing as a new node M is about to be added whether there is an existing node N with the same children in the same order and with the same operator. If so N computes the same value as M and may be used in its place. This technique was introduced as the value number method of detecting common subexpressions in Section 6.1.1

Example 8 10 A DAG for the block

abc bad cbc dad

is shown in Fig 812. When we construct the node for the third statement c b c we know that the use of b in b c refers to the node of Fig 812 labeled because that is the most recent de nition of b. Thus we do not confuse the values computed at statements one and three

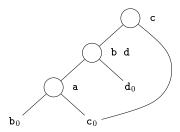

Figure 8 12 DAG for basic block in Example 8 10

However the node corresponding to the fourth statement d a d has the operator and the nodes with attached variables a and d_0 as children. Since the operator and the children are the same as those for the node corresponding to statement two we do not create this node but add d to the list of de nitions for the node labeled.

It might appear that since there are only three nonleaf nodes in the DAG of Fig 8 12 the basic block in Example 8 10 can be replaced by a block with only three statements. In fact, if b is not live on exit from the block, then we do not need to compute that variable, and can use d to receive the value represented by the node labeled — in Fig 8 12. The block then becomes

a b c d a d c

8 5 OPTIMIZATION OF BASIC BLOCKS

However if both ${\tt b}$ and ${\tt d}$ are live on exit then a fourth statement must be used to copy the value from one to the other 1

Example 8 11 When we look for common subexpressions we really are look ing for expressions that are guaranteed to compute the same value no matter how that value is computed. Thus, the DAG method will miss the fact that the expression computed by the rest and fourth statements in the sequence

a b c b d c c d e b c

is the same namely b_0 c_0 That is even though b and c both change between the rst and last statements their sum remains the same because b c b d c d The DAG for this sequence is shown in Fig. 8.13 but does not exhibit any common subexpressions. However algebraic identities applied to the DAG as discussed in Section 8.5.4 may expose the equivalence.

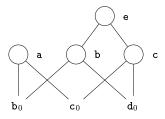

Figure 8 13 DAG for basic block in Example 8 11

8 5 3 Dead Code Elimination

The operation on DAG s that corresponds to dead code elimination can be im plemented as follows. We delete from a DAG any root node with no ancestors that has no live variables attached. Repeated application of this transformation will remove all nodes from the DAG that correspond to dead code.

Example 8 12 If in Fig 8 13 a and b are live but c and e are not we can immediately remove the root labeled e Then the node labeled c becomes a root and can be removed. The roots labeled a and b remain since they each have live variables attached. \Box

 $^{^1}$ In general we must be careful when reconstructing code from DAGs how we choose the names of variables. If a variable x is defined twice or if it is assigned once and the initial value x_0 is also used then we must make sure that we do not change the value of x until we have made all uses of the node whose value x previously held

8 5 4 The Use of Algebraic Identities

Algebraic identities represent another important class of optimizations on basic blocks. For example, we may apply arithmetic identities, such as

to eliminate computations from a basic block

Another class of algebraic optimizations includes local reduction in strength that is replacing a more expensive operator by a cheaper one as in

EXPENSIVE	Cheaper	
x^2	x - x	
2 x	x - x	
x 2	x = 0.5	

A third class of related optimizations is constant folding. Here we evaluate constant expressions at compile time and replace the constant expressions by their values ². Thus the expression 2 - 3.14 would be replaced by 6.28. Many constant expressions arise in practice because of the frequent use of symbolic constants in programs.

The DAG construction process can help us apply these and other more general algebraic transformations such as commutativity and associativity. For example, suppose the language reference manual specifies that is commutative that is x y y x Before we create a new node labeled with left child M and right child N we always check whether such a node already exists. However because is commutative, we should then check for a node having operator left child N and right child M

The relational operators such as and sometimes generate unexpected common subexpressions. For example, the condition x-y can also be tested by subtracting the arguments and performing a test on the condition code set by the subtraction 3 . Thus, only one node of the DAG may need to be generated for x-y and x-y.

Associative laws might also be applicable to expose common subexpressions For example if the source code has the assignments

the following intermediate code might be generated

² Arithmetic expressions should be evaluated the same way at compile time as they are at run time K Thompson has suggested an elegant solution to constant folding compile the constant expression execute the target code on the spot and replace the expression with the result Thus the compiler does not need to contain an interpreter

 $^{^3}$ The subtraction can however introduce over ows and under ows while a compare in struction would not

8 5 OPTIMIZATION OF BASIC BLOCKS

If t is not needed outside this block we can change this sequence to

using both the associativity and commutativity of

The compiler writer should examine the language reference manual care fully to determine what rearrangements of computations are permitted since because of possible over ows or under ows computer arithmetic does not al ways obey the algebraic identities of mathematics. For example, the Fortran standard states that a compiler may evaluate any mathematically equivalent expression provided that the integrity of parentheses is not violated. Thus a compiler may evaluate x y x z as x y z but it may not evaluate a b c as a b c A Fortran compiler must therefore keep track of where parentheses were present in the source language expressions if it is to optimize programs in accordance with the language de nition

8 5 5 Representation of Array References

At rst glance it might appear that the array indexing instructions can be treated like any other operator Consider for instance the sequence of three address statements

If we think of a i as an operation involving a and i similar to a i then it might appear as if the two uses of a i were a common subexpression. In that case we might be tempted to optimize by replacing the third instruction \mathbf{z} a i by the simpler \mathbf{z} x. However since j could equal i the middle statement may in fact change the value of a i thus it is not legal to make this change.

The proper way to represent array accesses in a DAG is as follows

- 1 An assignment from an array like \mathbf{x} a \mathbf{i} is represented by creating a node with operator—and two children representing the initial value of the array \mathbf{a}_0 in this case and the index \mathbf{i} Variable \mathbf{x} becomes a label of this new node
- 2 An assignment to an array like a j y is represented by a new node with operator and three children representing $a_0 j$ and y There is no variable labeling this node. What is different is that the creation of

CHAPTER 8 CODE GENERATION

this node kills all currently constructed nodes whose value depends on \mathbf{a}_0 A node that has been killed cannot receive any more labels that is it cannot become a common subexpression

Example 8 13 The DAG for the basic block

is shown in Fig 8.14. The node N for x is created rst but when the node labeled is created N is killed. Thus when the node for z is created it cannot be identified with N and a new node with the same operands \mathbf{a}_0 and \mathbf{i}_0 must be created instead. \square

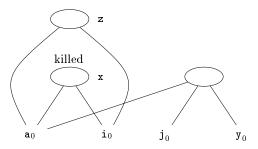

Figure 8 14 The DAG for a sequence of array assignments

Example 8 14 Sometimes a node must be killed even though none of its children have an array like a_0 in Example 8 13 as attached variable. Likewise a node can kill if it has a descendant that is an array even though none of its children are array nodes. For instance, consider the three address code.

What is happening here is that for exciency reasons behas been desired to be a position in an array axFor example if the elements of a are four bytes long then by represents the fourth element of axIf j and is represent the same value then by it and by j represent the same location. Therefore it is important to have the third instruction by j will the node with x as its attached variable. However, as we see in Fig. 8.15 both the killed node and the node that does the killing have a_0 as a grandchild not as a child.

8 5 OPTIMIZATION OF BASIC BLOCKS

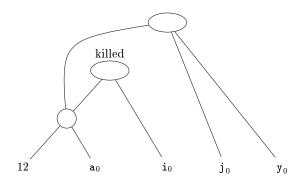

Figure 8 15 A node that kills a use of an array need not have that array as a child

8 5 6 Pointer Assignments and Procedure Calls

When we assign indirectly through a pointer as in the assignments

we do not know what p or q point to In e ect x p is a use of every variable whatsoever and q y is a possible assignment to every variable As a consequence the operator must take all nodes that are currently associated with identifiers as arguments which is relevant for dead code elimination. More importantly the operator kills all other nodes so far constructed in the DAG

There are global pointer analyses one could perform that might limit the set of variables a pointer could reference at a given place in the code Even local analysis could restrict the scope of a pointer For instance in the sequence

we know that x and no other variable is given the value of y so we don't need to kill any node but the node to which x was attached

Procedure calls behave much like assignments through pointers. In the absence of global data ow information we must assume that a procedure uses and changes any data to which it has access. Thus, if procedure P is in the scope of variable x a call to P both uses the node with attached variable x and kills that node

8 5 7 Reassembling Basic Blocks From DAG s

After we perform whatever optimizations are possible while constructing the DAG or by manipulating the DAG once constructed we may reconstitute the three address code for the basic block from which we built the DAG For each

node that has one or more attached variables we construct a three address statement that computes the value of one of those variables. We prefer to compute the result into a variable that is live on exit from the block. However, if we do not have global live variable information to work from we need to assume that every variable of the program but not temporaries that are generated by the compiler to process expressions is live on exit from the block.

If the node has more than one live variable attached then we have to in troduce copy statements to give the correct value to each of those variables Sometimes global optimization can eliminate those copies if we can arrange to use one of two variables in place of the other

Example 8 15 Recall the DAG of Fig 8 12 In the discussion following Example 8 10 we decided that if b is not live on exit from the block then the three statements

abc dad cdc

su ce to reconstruct the basic block. The third instruction c d c must use d as an operand rather than b because the optimized block never computes b

If both b and d are live on exit or if we are not sure whether or not they are live on exit then we need to compute b as well as d. We can do so with the sequence

a b c d a d b d c d c

This basic block is still more e cient than the original Although the number of instructions is the same we have replaced a subtraction by a copy which tends to be less expensive on most machines. Further it may be that by doing a global analysis we can eliminate the use of this computation of b outside the block by replacing it by uses of d. In that case we can come back to this basic block and eliminate b d later. Intuitively we can eliminate this copy if wherever this value of b is used d is still holding the same value. That situation may or may not be true depending on how the program recomputes d.

When reconstructing the basic block from a DAG we not only need to worry about what variables are used to hold the values of the DAG s nodes but we also need to worry about the order in which we list the instructions computing the values of the various nodes. The rules to remember are

1 The order of instructions must respect the order of nodes in the DAG
That is we cannot compute a node s value until we have computed a
value for each of its children

8 5 OPTIMIZATION OF BASIC BLOCKS

- 2 Assignments to an array must follow all previous assignments to or eval uations from the same array according to the order of these instructions in the original basic block
- 3 Evaluations of array elements must follow any previous according to the original block assignments to the same array. The only permutation allowed is that two evaluations from the same array may be done in either order as long as neither crosses over an assignment to that array
- 4 Any use of a variable must follow all previous according to the original block procedure calls or indirect assignments through a pointer
- 5 Any procedure call or indirect assignment through a pointer must follow all previous according to the original block evaluations of any variable

That is when reordering code no statement may cross a procedure call or assignment through a pointer and uses of the same array may cross each other only if both are array accesses but not assignments to elements of the array

CHAPTER 8 CODE GENERATION

on the assumption that

a p can point anywhere

b p can point only to b or d

Exercise 8 5 7 If a pointer or array expression such as a i or p is assigned and then used without the possibility of being changed in the interim we can take advantage of the situation to simplify the DAG For example in the code of Exercise 8 5 6 if p cannot point to d then the fourth statement e p can be replaced by e c Revise the DAG construction algorithm to take advantage of such situations and apply your algorithm to the code of Exercise 8 5 6

Exercise 8 5 8 Suppose a basic block is formed from the C assignment state ments

- a Give the three address statements only one addition per statement for this block
- b Use the associative and commutative laws to modify the block to use the fewest possible number of instructions assuming both ${\bf x}$ and ${\bf y}$ are live on exit from the block

8 6 A Simple Code Generator

In this section we shall consider an algorithm that generates code for a single basic block. It considers each three address instruction in turn, and keeps track of what values are in what registers so it can avoid generating unnecessary loads and stores.

One of the primary issues during code generation is deciding how to use registers to best advantage. There are four principal uses of registers

In most machine architectures some or all of the operands of an operation must be in registers in order to perform the operation

Registers make good temporaries — places to hold the result of a subex pression while a larger expression is being evaluated or more generally a place to hold a variable that is used only within a single basic block

86 A SIMPLE CODE GENERATOR

Registers are used to hold *global* values that are computed in one basic block and used in other blocks for example a loop index that is incremented going around the loop and is used several times within the loop

Registers are often used to help with run time storage management for example to manage the run time stack including the maintenance of stack pointers and possibly the top elements of the stack itself

These are competing needs since the number of registers available is limited

The algorithm in this section assumes that some set of registers is available to hold the values that are used within the block. Typically this set of registers does not include all the registers of the machine since some registers are reserved for global variables and managing the stack. We assume that the basic block has already been transformed into a preferred sequence of three address instructions by transformations such as combining common subexpressions. We further assume that for each operator, there is exactly one machine instruction that takes the necessary operands in registers and performs that operation leaving the result in a register. The machine instructions are of the form

LD reg mem
ST mem reg
OP reg reg reg

8 6 1 Register and Address Descriptors

Our code generation algorithm considers each three address instruction in turn and decides what loads are necessary to get the needed operands into registers After generating the loads it generates the operation itself. Then if there is a need to store the result into a memory location it also generates that store

In order to make the needed decisions we require a data structure that tells us what program variables currently have their value in a register and which register or registers if so We also need to know whether the memory location for a given variable currently has the proper value for that variable since a new value for the variable may have been computed in a register and not yet stored. The desired data structure has the following descriptors

- 1 For each available register a register descriptor keeps track of the variable names whose current value is in that register. Since we shall use only those registers that are available for local use within a basic block we assume that initially all register descriptors are empty. As the code generation progresses each register will hold the value of zero or more names
- 2 For each program variable an address descriptor keeps track of the location or locations where the current value of that variable can be found. The location might be a register a memory address a stack location or some set of more than one of these. The information can be stored in the symbol table entry for that variable name.

8 6 2 The Code Generation Algorithm

An essential part of the algorithm is a function $getReg\ I$ which selects regis ters for each memory location associated with the three address instruction I. Function getReg has access to the register and address descriptors for all the variables of the basic block and may also have access to certain useful data ow information such as the variables that are live on exit from the block. We shall discuss getReg after presenting the basic algorithm. While we do not know the total number of registers available for local data belonging to a basic block we assume that there are enough registers so that after freeing all available registers by storing their values in memory, there are enough registers to accomplish any three address operation

In a three address instruction such as $x \ y \ z$ we shall treat—as a generic operator and ADD as the equivalent machine instruction. We do not therefore take advantage of commutativity of—Thus—when we implement the operation the value of y must be in the second register mentioned in the ADD instruction never the third—A possible improvement to the algorithm is to generate code for both $x \ y \ z$ and $x \ z \ y$ whenever—is a commutative operator—and pick the better code sequence

Machine Instructions for Operations

For a three address instruction such as x - y - z do the following

- 1 Use $getReg\ x$ y z to select registers for x y and z Call these R_x R_y and R_z
- 2 If y is not in R_y according to the register descriptor for R_y then issue an instruction LD R_y y' where y' is one of the memory locations for y according to the address descriptor for y
- 3 Similarly if z is not in R_z issue an instruction LD R_z z' where z' is a location for z
- 4 Issue the instruction ADD R_x R_y R_z

Machine Instructions for Copy Statements

There is an important special case a three address copy statement of the form x-y. We assume that getReg will always choose the same register for both x and y. If y is not already in that register R_y , then generate the machine instruction LD R_y , y. If y was already in R_y , we do nothing. It is only necessary that we adjust the register descriptor for R_y so that it includes x as one of the values found there

86 A SIMPLE CODE GENERATOR

Ending the Basic Block

As we have described the algorithm variables used by the block may wind up with their only location being a register. If the variable is a temporary used only within the block that is ne when the block ends we can forget about the value of the temporary and assume its register is empty. However, if the variable is live on exit from the block or if we don't know which variables are live on exit, then we need to assume that the value of the variable is needed later. In that case, for each variable x whose address descriptor does not say that its value is located in the memory location for x we must generate the instruction ST x R where R is a register in which x s value exists at the end of the block

Managing Register and Address Descriptors

As the code generation algorithm issues load store and other machine instructions it needs to update the register and address descriptors. The rules are as follows

- 1 For the instruction LD R x
 - a Change the register descriptor for register R so it holds only x
 - b Change the address descriptor for x by adding register R as an additional location
- 2 For the instruction ST x R change the address descriptor for x to include its own memory location
- 3 For an operation such as ADD $R_x \ R_y \ R_z$ implementing a three address instruction x y z
 - a Change the register descriptor for R_x so that it holds only x
 - b Change the address descriptor for x so that its only location is R_x Note that the memory location for x is *not* now in the address descriptor for x
 - c Remove R_x from the address descriptor of any variable other than x
- 4 When we process a copy statement x-y after generating the load for y into register R_y if needed and after managing descriptors as for all load statements per rule 1
 - a Add x to the register descriptor for R_y
 - b Change the address descriptor for x so that its only location is R_y

Example 8 16 Let us translate the basic block consisting of the three address statements

```
t a b u a c v t u a d d v u
```

Here we assume that t u and v are temporaries local to the block while a b c and d are variables that are live on exit from the block. Since we have not yet discussed how the function getReg might work we shall simply assume that there are as many registers as we need but that when a register s value is no longer needed for example it holds only a temporary all of whose uses have been passed—then we reuse its register

A summary of all the machine code instructions generated is in Fig. $8\,16$ The gure also shows the register and address descriptors before and after the translation of each three address instruction

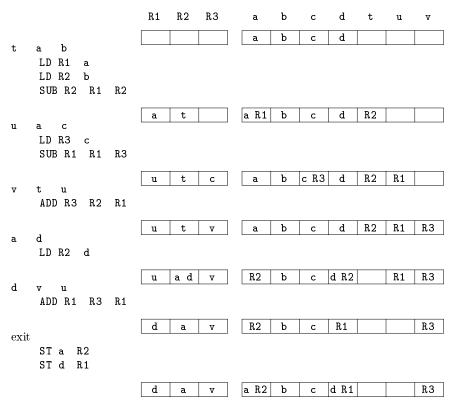

Figure 8 16 Instructions generated and the changes in the register and address descriptors

For the struction t a b we need to issue three in structions since nothing is in a register initially. Thus we see a and b loaded

86 A SIMPLE CODE GENERATOR

into registers R1 and R2 and the value t produced in register R2 Notice that we can use R2 for t because the value b previously in R2 is not needed within the block Since b is presumably live on exit from the block had it not been in its own memory location as indicated by its address descriptor we would have had to store R2 into b rst The decision to do so had we needed R2 would be taken by getReg

The second instruction u a c does not require a load of a since it is already in register R1 Further we can reuse R1 for the result u since the value of a previously in that register is no longer needed within the block and its value is in its own memory location if a is needed outside the block. Note that we change the address descriptor for a to indicate that it is no longer in R1 but is in the memory location called a

The third instruction v t u requires only the addition Further we can use R3 for the result v since the value of c in that register is no longer needed within the block and c has its value in its own memory location

The copy instruction a d requires a load of d since it is not in a register We show register R2 s descriptor holding both a and d The addition of a to the register descriptor is the result of our processing the copy statement and is not the result of any machine instruction

The fth instruction d v u uses two values that are in registers. Since u is a temporary whose value is no longer needed, we have chosen to reuse its register R1 for the new value of d. Notice that d is now in only R1 and is not in its own memory location. The same holds for a which is in R2 and not in the memory location called a As a result, we need a coda to the machine code for the basic block that stores the live on exit variables a and d into their memory locations. We show these as the last two instructions.

8 6 3 Design of the Function getReg

Lastly let us consider how to implement $getReg\ I$ for a three address in struction I. There are many options although there are also some absolute prohibitions against choices that lead to incorrect code due to the loss of the value of one or more live variables. We begin our examination with the case of an operation step for which we again use x-y-z as the generic example. First, we must pick a register for y and a register for z. The issues are the same so we shall concentrate on picking register R_y for y. The rules are as follows

- 1 If y is currently in a register pick a register already containing y as R_y Do not issue a machine instruction to load this register as none is needed
- 2 If y is not in a register but there is a register that is currently empty pick one such register as R_y
- 3 The discutt case occurs when y is not in a register and there is no register that is currently empty. We need to pick one of the allowable registers anyway and we need to make it safe to reuse. Let R be a candidate

CHAPTER 8 CODE GENERATION

register and suppose v is one of the variables that the register descriptor for R says is in R. We need to make sure that v s value either is not really needed or that there is somewhere else we can go to get the value of v. The possibilities are

- a If the address descriptor for v says that v is somewhere besides R then we are OK
- b If v is x the variable being computed by instruction I and x is not also one of the other operands of instruction I z in this example then we are OK. The reason is that in this case we know this value of x is never again going to be used so we are free to ignore it
- c Otherwise if v is not used later that is after the instruction I there are no further uses of v and if v is live on exit from the block then v is recomputed within the block—then we are OK
- d If we are not OK by one of the rst three cases then we need to generate the store instruction ST v R to place a copy of v in its own memory location. This operation is called a spill

Since R may hold several variables at the moment we repeat the above steps for each such variable v. At the end R s score is the number of store instructions we needed to generate. Pick one of the registers with the lowest score

Now consider the selection of the register R_x The issues and options are almost as for y so we shall only mention the di erences

- 1 Since a new value of x is being computed a register that holds only x is always an acceptable choice for R_x . This statement holds even if x is one of y and z since our machine instructions allows two registers to be the same in one instruction
- 2 If y is not used after instruction I in the sense described for variable v in item 3c and R_y holds only y after being loaded if necessary then R_y can also be used as R_x A similar option holds regarding z and R_z

The last matter to consider specially is the case when I is a copy instruction x-y. We pick the register R_y as above. Then we always choose R_x-R_y

8 6 4 Exercises for Section 8 6

```

generate three address code assuming that all array elements are integers taking four bytes each. In parts, d, and e, assume that a, b, and c are constants giving the location of the rst. Oth elements of the arrays with those names as in all previous examples of array accesses in this chapter.

Exercise 8 6 2 Repeat Exercise 8 6 1 parts d and e assuming that the arrays a b and c are located via pointers pa pb and pc respectively pointing to the locations of their respective rst elements

Exercise 8 6 3 Convert your three address code from Exercise 8 6 1 into ma chine code for the machine model of this section You may use as many registers as you need

Exercise 8 6 4 Convert your three address code from Exercise 8 6 1 into ma chine code using the simple code generation algorithm of this section assuming three registers are available. Show the register and address descriptors after each step

Exercise 8 6 5 Repeat Exercise 8 6 4 but assuming only two registers are available

8 7 Peephole Optimization

While most production compilers produce good code through careful instruction selection and register allocation a few use an alternative strategy they generate naive code and then improve the quality of the target code by applying optimizing transformations to the target program. The term optimizing is somewhat misleading because there is no guarantee that the resulting code is optimal under any mathematical measure. Nevertheless many simple transformations can significantly improve the running time or space requirement of the target program.

A simple but e ective technique for locally improving the target code is peephole optimization which is done by examining a sliding window of target instructions called the peephole and replacing instruction sequences within the peephole by a shorter or faster sequence whenever possible Peephole optimization can also be applied directly after intermediate code generation to improve the intermediate representation

The peephole is a small sliding window on a program The code in the peephole need not be contiguous although some implementations do require this It is characteristic of peephole optimization that each improvement may

spawn opportunities for additional improvements In general repeated passes over the target code are necessary to get the maximum bene t In this sec tion we shall give the following examples of program transformations that are characteristic of peephole optimizations

Redundant instruction elimination

Flow of control optimizations

Algebraic simpli cations

Use of machine idioms

8 7 1 Eliminating Redundant Loads and Stores

If we see the instruction sequence

```
LD RO a
ST a RO
```

in a target program we can delete the store instruction because whenever it is executed the rst instruction will ensure that the value of a has already been loaded into register RO Note that if the store instruction had a label we could not be sure that the rst instruction is always executed before the second so we could not remove the store instruction Put another way the two instructions have to be in the same basic block for this transformation to be safe

Redundant loads and stores of this nature would not be generated by the simple code generation algorithm of the previous section. However, a naive code generation algorithm like the one in Section $8\,1\,3$ would generate redundant sequences such as these

8 7 2 Eliminating Unreachable Code

Another opportunity for peephole optimization is the removal of unreachable instructions. An unlabeled instruction immediately following an unconditional jump may be removed. This operation can be repeated to eliminate a sequence of instructions. For example, for debugging purposes, a large program may have within it certain code fragments that are executed only if a variable debug is equal to 1. In the intermediate representation, this code may look like

```
if debug 1 goto L1
goto L2
L1 print debugging information
L2
```

One obvious peephole optimization is to eliminate jumps over jumps Thus no matter what the value of debug the code sequence above can be replaced by

87 PEEPHOLE OPTIMIZATION

L2

```
if debug 1 goto L2
print debugging information
```

If debug is set to 0 at the beginning of the program constant propagation would transform this sequence into

```
if 0 1 goto L2
print debugging information
L2
```

Now the argument of the rst statement always evaluates to *true* so the statement can be replaced by **goto** L2 Then all statements that print debug ging information are unreachable and can be eliminated one at a time

8 7 3 Flow of Control Optimizations

Simple intermediate code generation algorithms frequently produce jumps to jumps jumps to conditional jumps or conditional jumps to jumps. These unnecessary jumps can be eliminated in either the intermediate code or the target code by the following types of peephole optimizations. We can replace the sequence

```
goto L1
```

L1 goto L2

by the sequence

goto L2

L1 goto L2

If there are now no jumps to L1 then it may be possible to eliminate the statement L1 goto L2 provided it is preceded by an unconditional jump Similarly the sequence

L1 goto L2

can be replaced by the sequence

L1 goto L2

Finally suppose there is only one jump to L1 and L1 is preceded by an unconditional goto Then the sequence

```
goto L1

L1 if a b goto L2
L3

may be replaced by the sequence
if a b goto L2
goto L3

L3
```

While the number of instructions in the two sequences is the same we sometimes skip the unconditional jump in the second sequence but never in the rst Thus the second sequence is superior to the rst in execution time

8 7 4 Algebraic Simpli cation and Reduction in Strength

In Section 8 5 we discussed algebraic identities that could be used to simplify DAG s. These algebraic identities can also be used by a peephole optimizer to eliminate three address statements such as

```
x x 0
or
x x 1
```

in the peephole

Similarly reduction in strength transformations can be applied in the peep hole to replace expensive operations by equivalent cheaper ones on the target machine. Certain machine instructions are considerably cheaper than others and can often be used as special cases of more expensive operators. For example x^2 is invariably cheaper to implement as x-x than as a call to an exponentiation routine. Fixed point multiplication or division by a power of two is cheaper to implement as a shift. Floating point division by a constant can be approximated as multiplication by a constant which may be cheaper

8 7 5 Use of Machine Idioms

The target machine may have hardware instructions to implement certain spe ci c operations e ciently Detecting situations that permit the use of these instructions can reduce execution time signi cantly. For example, some matchines have auto increment and auto decrement addressing modes. These addressing modes are subtract one from an operand before or after using its value. The use of the modes greatly improves the quality of code when pushing or popping a stack as in parameter passing. These modes can also be used in code for statements like \mathbf{x} and \mathbf{x} and \mathbf{x} and \mathbf{x} are the following properties of the statements like \mathbf{x} and \mathbf{x} are the following properties of the statements like \mathbf{x} and \mathbf{x} are the following properties of the statements like \mathbf{x} and \mathbf{x} are the following properties of the statements like \mathbf{x} and \mathbf{x} are the following properties of the statements like \mathbf{x} and \mathbf{x} are the statement \mathbf{x} are the statement \mathbf{x} and \mathbf{x} are the statement \mathbf{x} are the statement \mathbf{x} and \mathbf{x} are the statement \mathbf{x} are the statement \mathbf{x} and \mathbf{x} are the statemen

8 7 6 Exercises for Section 8 7

Exercise 8 7 1 Construct an algorithm that will perform redundant instruction elimination in a sliding peephole on target machine code

Exercise 8 7 2 Construct an algorithm that will do ow of control optimizations in a sliding peephole on target machine code

Exercise 8 7 3 Construct an algorithm that will do simple algebraic simplications and reductions in strength in a sliding peephole on target machine code

8 8 Register Allocation and Assignment

Instructions involving only register operands are faster than those involving memory operands. On modern machines processor speeds are often an order of magnitude or more faster than memory speeds. Therefore, e. cient utilization of registers is vitally important in generating good code. This section presents various strategies for deciding at each point in a program what values should reside in registers register allocation, and in which register each value should reside register assignment.

One approach to register allocation and assignment is to assign speci c values in the target program to certain registers. For example, we could decide to assign base addresses to one group of registers arithmetic computations to another the top of the stack to a xed register and so on

This approach has the advantage that it simplifies the design of a code generator. Its disadvantage is that applied too strictly it uses registers inecciently certain registers may go unused over substantial portions of code while unnecessary loads and stores are generated into the other registers. Nevertheless it is reasonable in most computing environments to reserve a few registers for base registers stack pointers and the like and to allow the remaining registers to be used by the code generator as it sees.

8 8 1 Global Register Allocation

The code generation algorithm in Section 8 6 used registers to hold values for the duration of a single basic block. However all live variables were stored at the end of each block. To save some of these stores and corresponding loads we might arrange to assign registers to frequently used variables and keep these registers consistent across block boundaries globally. Since programs spend most of their time in inner loops a natural approach to global register assignment is to try to keep a frequently used value in a xed register throughout a loop. For the time being assume that we know the loop structure of a ow graph and that we know what values computed in a basic block are used outside that block. The next chapter covers techniques for computing this information

One strategy for global register allocation is to assign some xed number of registers to hold the most active values in each inner loop. The selected values may be different in different loops. Registers not already allocated may be used to hold values local to one block as in Section 8.6. This approach has the drawback that the xed number of registers is not always the right number to make available for global register allocation. Yet the method is simple to implement and was used in Fortran H. the optimizing Fortran compiler developed by IBM for the 360 series machines in the late 1960s.

With early C compilers a programmer could do some register allocation explicitly by using register declarations to keep certain values in registers for the duration of a procedure Judicious use of register declarations did speed up many programs but programmers were encouraged to rst pro le their programs to determine the program s hotspots before doing their own register allocation

8 8 2 Usage Counts

In this section we shall assume that the savings to be realized by keeping a variable x in a register for the duration of a loop L is one unit of cost for each reference to x if x is already in a register. However, if we use the approach in Section 8.6 to generate code for a block, there is a good chance that after x has been computed in a block it will remain in a register if there are subsequent uses of x in that block. Thus we count a savings of one for each use of x in loop L that is not preceded by an assignment to x in the same block. We also save two units if we can avoid a store of x at the end of a block. Thus if x is allocated a register, we count a savings of two for each block in loop L for which x is live on exit and in which x is assigned a value

On the debit side if x is live on entry to the loop header we must load x into its register just before entering loop L. This load costs two units. Similarly for each exit block B of loop L at which x is live on entry to some successor of B outside of L we must store x at a cost of two. However, on the assumption that the loop is iterated many times we may neglect these debits since they occur only once each time we enter the loop. Thus, an approximate formula for the bene to be realized from allocating a register for x within loop L is

$$\sum_{\text{blocks } B \text{ in } L} use \ x \ B \qquad 2 \quad live \ x \ B \qquad \qquad 8 \ 1$$

where $use\ x\ B$ is the number of times x is used in B prior to any denition of x live x B is 1 if x is live on exit from B and is assigned a value in B and live x B is 0 otherwise. Note that 8.1 is approximate because not all blocks in a loop are executed with equal frequency and also because 8.1 is based on the assumption that a loop is iterated many times. On special contains a formula analogous to 8.1 but possibly quite different from it would have to be developed.

8 8 REGISTER ALLOCATION AND ASSIGNMENT

Example 8 17 Consider the basic blocks in the inner loop depicted in Fig 8 17 where jump and conditional jump statements have been omitted. Assume registers R0 R1 and R2 are allocated to hold values throughout the loop. Variables live on entry into and on exit from each block are shown in Fig 8 17 for convenience immediately above and below each block respectively. There are some subtle points about live variables that we address in the next chapter. For example, notice that both $\mathbf e$ and $\mathbf f$ are live at the end of B_1 but of these only $\mathbf e$ is live on entry to B_2 and only $\mathbf f$ on entry to B_3 . In general, the variables live at the end of a block are the union of those live at the beginning of each of its successor blocks.

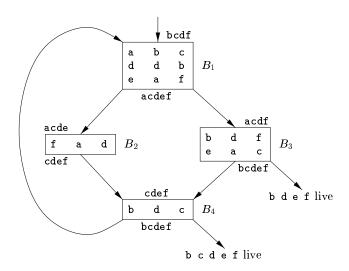

Figure 8 17 Flow graph of an inner loop

To evaluate 81 for x a we observe that a is live on exit from B_1 and is assigned a value there but is not live on exit from B_2 B_3 or B_4 . Thus $\sum_{B\ in\ L} use$ a B 2. Hence the value of 81 for x a is 4. That is four units of cost can be saved by selecting a for one of the global registers. The values of 81 for b c d e and f are 5 3 6 4 and 4 respectively. Thus we may select a b and d for registers R0 R1 and R2 respectively. Using R0 for e or f instead of a would be another choice with the same apparent benent. Figure 8.18 shows the assembly code generated from Fig. 8.17 assuming that the strategy of Section 8.6 is used to generate code for each block. We do not show the generated code for the omitted conditional or unconditional jumps that end each block in Fig. 8.17 and we therefore do not show the generated code as a single stream as it would appear in practice.

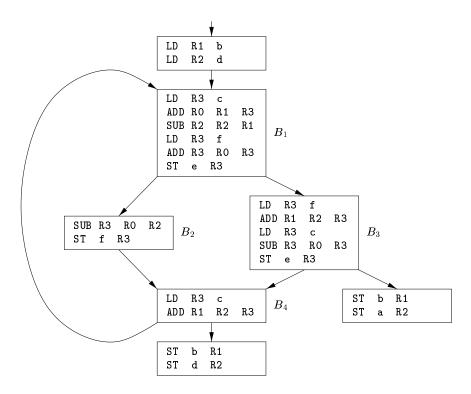

Figure 8 18 Code sequence using global register assignment

8 8 3 Register Assignment for Outer Loops

Having assigned registers and generated code for inner loops we may apply the same idea to progressively larger enclosing loops. If an outer loop L_1 contains an inner loop L_2 the names allocated registers in L_2 need not be allocated registers in L_1 . However if we choose to allocate x a register in L_2 but not L_1 we must load x on entrance to L_2 and store x on exit from x0 We leave as an exercise the derivation of a criterion for selecting names to be allocated registers in an outer loop x1 given that choices have already been made for all loops nested within x2.

8 8 4 Register Allocation by Graph Coloring

When a register is needed for a computation but all available registers are in use the contents of one of the used registers must be stored *spilled* into a memory location in order to free up a register. Graph coloring is a simple systematic technique for allocating registers and managing register spills

In the method two passes are used In the rst target machine instructions are selected as though there are an in nite number of symbolic registers in e ect names used in the intermediate code become names of registers and

8 8 REGISTER ALLOCATION AND ASSIGNMENT

the three address instructions become machine language instructions. If access to variables requires instructions that use stack pointers display pointers base registers or other quantities that assist access then we assume that these quantities are held in registers reserved for each purpose. Normally, their use is directly translatable into an access mode for an address mentioned in a machine instruction. If access is more complex, the access must be broken into several machine instructions, and a temporary symbolic register or several may need to be created.

Once the instructions have been selected a second pass assigns physical registers to symbolic ones. The goal is to and an assignment that minimizes the cost of spills

In the second pass for each procedure a register interference graph is constructed in which the nodes are symbolic registers and an edge connects two nodes if one is live at a point where the other is dened. For example, a register interference graph for Fig. 8.17 would have nodes for names ${\tt a}$ and ${\tt d}$. In block B_1 a is live at the second statement which denes ${\tt d}$ therefore in the graph there would be an edge between the nodes for ${\tt a}$ and ${\tt d}$.

An attempt is made to color the register interference graph using k colors where k is the number of assignable registers. A graph is said to be *colored* if each node has been assigned a color in such a way that no two adjacent nodes have the same color. A color represents a register, and the color makes sure that no two symbolic registers that can interfere with each other are assigned the same physical register.

Although the problem of determining whether a graph is k colorable is NP complete in general the following heuristic technique can usually be used to do the coloring quickly in practice Suppose a node n in a graph G has fewer than k neighbors nodes connected to n by an edge Remove n and its edges from G to obtain a graph G' A k coloring of G' can be extended to a k coloring of G by assigning n a color not assigned to any of its neighbors

By repeatedly eliminating nodes having fewer than k edges from the register interference graph—either we obtain the empty graph—in which case we can produce a k coloring for the original graph by coloring the nodes in the reverse order in which they were removed—or we obtain a graph in which each node has k or more adjacent nodes. In the latter case a k coloring is no longer possible. At this point a node is spilled by introducing code to store and reload the register—Chaitin has devised several heuristics for choosing the node to spill A general rule is to avoid introducing spill code into inner loops

8 8 5 Exercises for Section 8 8

Exercise 8 8 1 Construct the register interference graph for the program in Fig. 8 17

Exercise 8 8 2 Devise a register allocation strategy on the assumption that we automatically store all registers on the stack before each procedure call and restore them after the return

8 9 Instruction Selection by Tree Rewriting

Instruction selection can be a large combinatorial task especially for machines that are rich in addressing modes such as CISC machines or on machines with special purpose instructions say for signal processing. Even if we assume that the order of evaluation is given and that registers are allocated by a separate mechanism instruction selection—the problem of selecting target language instructions to implement the operators in the intermediate representation remains a large combinatorial task

In this section we treat instruction selection as a tree rewriting problem Tree representations of target instructions have been used e ectively in code generator generators which automatically construct the instruction selection phase of a code generator from a high level speci cation of the target machine Better code might be obtained for some machines by using DAG s rather than trees but DAG matching is more complex than tree matching

8 9 1 Tree Translation Schemes

Throughout this section the input to the code generation process will be a sequence of trees at the semantic level of the target machine. The trees are what we might get after inserting run time addresses into the intermediate representation as described in Section 8.3. In addition the leaves of the trees contain information about the storage types of their labels

Example 8 18 Figure 8 19 contains a tree for the assignment statement a i b 1 where the array a is stored on the run time stack and the variable b is a global in memory location M_b . The run time addresses of locals a and b are given as constant b sets b and b are given as constant b sets b and b are given as constant b sets b and b are given as constant b sets b and b are given as constant b sets b and b are given as containing the pointer to the beginning of the current activation record

The assignment to a i is an indirect assignment in which the r value of the location for a i is set to the r value of the expression b 1 The addresses of array a and variable i are given by adding the values of the constant C_a and C_i respectively to the contents of register SP We simplify array address calculations by assuming that all values are one byte characters. Some instruction sets make special provisions for multiplications by constants such as 2–4 and 8 during address calculations

In the tree the ind operator treats its argument as a memory address. As the left child of an assignment operator, the ind node gives the location into which the r value on the right side of the assignment operator is to be stored. If an argument of a — or ind operator is a memory location or a register, then the contents of that memory location or register are taken as the value. The leaves in the tree are labeled with attributes — a subscript indicates the value of the attribute.

The target code is generated by applying a sequence of tree rewriting rules to reduce the input tree to a single node Each tree rewriting rule has the form

8 9 INSTRUCTION SELECTION BY TREE REWRITING

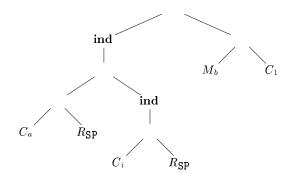

Figure 8 19 Intermediate code tree for a i b 1

replacement template { action }

where replacement is a single node template is a tree and action is a code fragment as in a syntax directed translation scheme

A set of tree rewriting rules is called a tree translation scheme

Each tree rewriting rule represents the translation of a portion of the tree given by the template. The translation consists of a possibly empty sequence of machine instructions that is emitted by the action associated with the template. The leaves of the template are attributes with subscripts as in the input tree. Sometimes certain restrictions apply to the values of the subscripts in the templates these restrictions are specified as semantic predicates that must be satisfied before the template is said to match. For example, a predicate might specify that the value of a constant fall in a certain range.

A tree translation scheme is a convenient way to represent the instruction selection phase of a code generator. As an example of a tree rewriting rule consider the rule for the register to register add instruction

$$R_i$$
 { ADD R i R i R j } R_j

This rule is used as follows. If the input tree contains a subtree that matches this tree template that is a subtree whose root is labeled by the operator and whose left and right children are quantities in registers i and j then we can replace that subtree by a single node labeled R_i and emit the instruction ADD Ri Ri Rj as output. We call this replacement a tiling of the subtree More than one template may match a subtree at a given time, we shall describe shortly some mechanisms for deciding which rule to apply in cases of conject.

Example 8 19 Figure 8 20 contains tree rewriting rules for a few instructions of our target machine. These rules will be used in a running example throughout this section. The rst two rules correspond to load instructions, the next two

to store instructions and the remainder to indexed loads and additions. Note that rule 8 requires the value of the constant to be 1. This condition would be specified by a semantic predicate \Box

8 9 2 Code Generation by Tiling an Input Tree

A tree translation scheme works as follows. Given an input tree, the templates in the tree rewriting rules are applied to tile its subtrees. If a template matches the matching subtree in the input tree is replaced with the replacement node of the rule and the action associated with the rule is done. If the action contains a sequence of machine instructions, the instructions are emitted. This process is repeated until the tree is reduced to a single node or until no more templates match. The sequence of machine instructions generated as the input tree is reduced to a single node constitutes the output of the tree translation scheme on the given input tree.

The process of specifying a code generator becomes similar to that of us ing a syntax directed translation scheme to specify a translator. We write a tree translation scheme to describe the instruction set of a target machine. In practice, we would like to find a scheme that causes a minimal cost instruction sequence to be generated for each input tree. Several tools are available to help build a code generator automatically from a tree translation scheme.

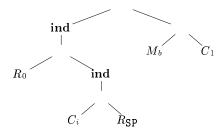

Example 8 20 Let us use the tree translation scheme in Fig. 8 20 to generate code for the input tree in Fig. 8 19. Suppose that the -rst rule is applied to load the constant C_a into register R0

$$1 R_0 C_a \{ exttt{LD RO a } \}$$

The label of the leftmost leaf then changes from C_a to R_0 and the instruction LD RO a is generated. The seventh rule now matches the leftmost subtree with root labeled

7
$$R_0$$
 { ADD RO RO SP } R_0 R_{SP}

Using this rule we rewrite this subtree as a single node labeled R_0 and generate the instruction ADD RO RO SP Now the tree looks like

$8\,9$ INSTRUCTION SELECTION BY TREE REWRITING

1	R_i	C_a	{ LD Ri a }
2	R_i	${M}_x$	$\{ LD Ri x \}$
3	M	M_x R_i	$\{ \text{ ST } x \text{ R}i \}$
4	M	$ind \qquad R_j \\ \mid \\ R_i$	$\{$ ST R i R j $\}$
5	R_i	$\begin{matrix} \textbf{ind} \\ \\ C_a \end{matrix} \qquad R_j$	{ LD Ri a Rj }
6	R_i	R_i ind $ $ C_a R_j	{ ADD Ri Ri a Rj }
7	R_i	R_i R_j	$\{$ ADD R i R i R j $\}$
8	R_i	R_i C_1	{ INC Ri }

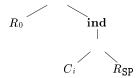

Figure 8 20 $\,$ Tree rewriting rules for some target machine instructions

CHAPTER 8 CODE GENERATION

At this point we could apply rule 5 to reduce the subtree

to a single node labeled $\,$ say $\,R_1\,\,$ We could also use rule $\,$ 6 $\,$ to reduce the larger subtree

to a single node labeled R_0 and generate the instruction ADD RO i SP Assuming that it is more e cient to use a single instruction to compute the larger subtree rather than the smaller one we choose rule 6 to get

In the right subtree rule 2 applies to the leaf M_b It generates an instruction to load b into register R1 say Now using rule 8 we can match the subtree

and generate the increment instruction INC R1 At this point the input tree has been reduced to

This remaining tree is matched by rule $\,4\,$ which reduces the tree to a single node and generates the instruction ST $\,$ RO $\,$ R1 $\,$ We generate the following code sequence

LD RO a
ADD RO RO SP
ADD RO RO i SP
LD R1 b
INC R1
ST RO R1

8 9 INSTRUCTION SELECTION BY TREE REWRITING

in the process of reducing the tree to a single node

In order to implement the tree reduction process in Example 8 18 we must address some issues related to tree pattern matching

How is tree pattern matching to be done. The e-ciency of the code generation process at compile time-depends on the e-ciency of the tree matching algorithm

What do we do if more than one template matches at a given time. The e-ciency of the generated code at run time may depend on the order in which templates are matched since di erent match sequences will in general lead to di erent target machine code sequences some more e-cient than others

If no template matches then the code generation process blocks. At the other extreme we need to guard against the possibility of a single node being rewritten indenitely generating an in nite sequence of register move instructions or an in nite sequence of loads and stores

To prevent blocking we assume that each operator in the intermediate code can be implemented by one or more target machine instructions. We further assume that there are enough registers to compute each tree node by itself. Then no matter how the tree matching proceeds the remaining tree can always be translated into target machine instructions.

8 9 3 Pattern Matching by Parsing

Before considering general tree matching we consider a specialized approach that uses an LR parser to do the pattern matching. The input tree can be treated as a string by using its pre x representation. For example, the pre x representation for the tree in Fig. 8 19 is

ind
$$C_a R_{SP}$$
 ind $C_i R_{SP} M_b C_1$

The tree translation scheme can be converted into a syntax directed trans lation scheme by replacing the tree rewriting rules with the productions of a context free grammar in which the right sides are pre x representations of the instruction templates

Example 8 21 The syntax directed translation scheme in Fig. 8 21 is based on the tree translation scheme in Fig. 8 20

The nonterminals of the underlying grammar are R and M The terminal \mathbf{m} represents a special content of the global variable \mathbf{b} in Example 8.18. The production M \mathbf{m} in Rule 10 can be thought of as matching M with \mathbf{m} prior to using one of the templates involving M Similarly we introduce a terminal \mathbf{sp} for register SP and add the production R \mathbf{sp} Finally terminal \mathbf{c} represents constants

Using these terminals the string for the input tree in Fig 819 is

```
1
         R_i
                                                          LD
                                                                  Ri
                                                                           a }
                     \mathbf{c}_a
 2
         R_i
                     M_x
                                                           LD
 3
         M
                         M_x R_i
                                                           ST
                                                                        Ri
                                                          ST
 4
         M
                         ind R_i R_j
                                                                         Rj
 5
         R_i
                                                          LD
                                                                         a Rj }
                                 \mathbf{c}_a R_i
                                                                  \mathbf{R}i
 6
                                                           ADD Ri
         R_i
                         R_i ind
                                                                         Ri \quad a \quad Rj \quad \}
 7
         R_i
                         R_i R_i
                                                           ADD Ri Ri
 8
         R_i
                         R_i \mathbf{c}_1
                                                        \{ \text{ INC } \mathbf{R}i \}
 9
          R
                     \mathbf{sp}

```

From the productions of the translation scheme we build an LR parser using one of the LR parser construction techniques of Chapter 4 The target code is generated by emitting the machine instruction corresponding to each reduction

A code generation grammar is usually highly ambiguous and some care needs to be given to how the parsing action con icts are resolved when the parser is constructed. In the absence of cost information a general rule is to favor larger reductions over smaller ones. This means that in a reduce reduce con ict the longer reduction is favored in a shift reduce con ict the shift move is chosen. This maximal munch approach causes a larger number of operations to be performed with a single machine instruction.

There are some bene ts to using LR parsing in code generation First the parsing method is e-cient and well understood so reliable and e-cient code generators can be produced using the algorithms described in Chapter 4 Second it is relatively easy to retarget the resulting code generator a code selector for a new machine can be constructed by writing a grammar to describe the instructions of the new machine. Third the the code generated can be made more e-cient by adding special case productions to take advantage of machine idioms.

However there are some challenges as well. A left to right order of evaluation is xed by the parsing method. Also for some machines with large numbers of addressing modes the machine description grammar and resulting parser can become inordinately large. As a consequence specialized techniques are necessary to encode and process the machine description grammars. We must also be careful that the resulting parser does not block has no next move while parsing an expression tree either because the grammar does not handle some operator patterns or because the parser has made the wrong resolution of some parsing action conflict. We must also make sure the parser does not get into an

8 9 INSTRUCTION SELECTION BY TREE REWRITING

in nite loop of reductions of productions with single symbols on the right side. The looping problem can be solved using a state splitting technique at the time the parser tables are generated

8 9 4 Routines for Semantic Checking

In a code generation translation scheme the same attributes appear as in an input tree but often with restrictions on what values the subscripts can have For example a machine instruction may require that an attribute value fall in a certain range or that the values of two attributes be related

These restrictions on attribute values can be specified as predicates that are invoked before a reduction is made. In fact, the general use of semantic actions and predicates can provide greater exibility and ease of description than a purely grammatical specification of a code generator. Generic templates can be used to represent classes of instructions and the semantic actions can then be used to pick instructions for specific classes. For example, two forms of the addition instruction can be represented with one template.

$$R_i$$
 { if a 1 INC R i else ADD R i R i a }

Parsing action con icts can be resolved by disambiguating predicates that can allow di erent selection strategies to be used in di erent contexts. A smaller description of a target machine is possible because certain aspects of the machine architecture such as addressing modes can be factored into the attributes. The complication in this approach is that it may become discult to verify the accuracy of the translation scheme as a faithful description of the target machine although this problem is shared to some degree by all code generators

8 9 5 General Tree Matching

The LR parsing approach to pattern matching based on pre x representations favors the left operand of a binary operator. In a pre x representation $\mathbf{op} E_1 E_2$ the limited lookahead LR parsing decisions must be made on the basis of some pre x of E_1 since E_1 can be arbitrarily long. Thus pattern matching can miss nuances of the target instruction set that are due to right operands

Instead pre x representation we could use a post x representation But then an LR parsing approach to pattern matching would favor the right oper and

For a hand written code generator we can use tree templates as in Fig. 8 20 as a guide and write an ad hoc matcher. For example, if the root of the input tree is labeled ${\bf ind}$ then the only pattern that could match is for rule 5 otherwise if the root is labeled — then the patterns that could match are for rules 6 8

For a code generator generator we need a general tree matching algorithm An e cient top down algorithm can be developed by extending the string pattern matching techniques of Chapter 3 The idea is to represent each tem plate as a set of strings where a string corresponds to a path from the root to a leaf in the template We treat all operands equally by including the position number of a child from left to right in the strings

Example 8 22 In building the set of strings for an instruction set we shall drop the subscripts since pattern matching is based on the attributes alone not on their values

The templates in Fig. 8 22 have the following set of strings from the root to a leaf

The string C represents the template with C at the root. The string 1 R represents the α and its left operand R in the two templates that have α at the root. \square

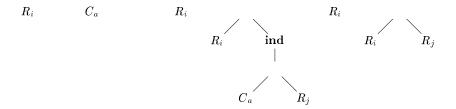

Figure 8 22 An instruction set for tree matching

Using sets of strings as in Example 8 22 a tree pattern matcher can be con structed by using techniques for e-ciently matching multiple strings in parallel

In practice the tree rewriting process can be implemented by running the tree pattern matcher during a depth—rst traversal of the input tree and per forming the reductions as the nodes are visited for the last time

Instruction costs can be taken into account by associating with each tree rewriting rule the cost of the sequence of machine instructions generated if that rule is applied In Section 8 11 we discuss a dynamic programming algorithm that can be used in conjunction with tree pattern matching

By running the dynamic programming algorithm concurrently we can select an optimal sequence of matches using the cost information associated with each rule. We may need to defer deciding upon a match until the cost of all alternatives is known. Using this approach a small excient code generator can

8 10 OPTIMAL CODE GENERATION FOR EXPRESSIONS

be constructed quickly from a tree rewriting scheme. Moreover, the dynamic programming algorithm frees the code generator designer from having to resolve conjecting matches or decide upon an order for the evaluation.

8 9 6 Exercises for Section 8 9

Exercise 8 9 1 Construct syntax trees for each of the following statements assuming all nonconstant operands are in memory locations

Use the tree rewriting scheme in Fig. 8 20 to generate code for each statement

Exercise 8 9 2 Repeat Exercise 8 9 1 above using the syntax directed trans lation scheme in Fig. 8 21 in place of the tree rewriting scheme

Exercise 8 9 3 Extend the tree rewriting scheme in Fig 8 20 to apply to while statements

Exercise 8 9 4 How would you extend tree rewriting to apply to DAG s

8 10 Optimal Code Generation for Expressions

We can choose registers optimally when a basic block consists of a single expres sion evaluation or if we accept that it is su-cient to generate code for a block one expression at a time. In the following algorithm we introduce a numbering scheme for the nodes of an expression tree—a syntax tree for an expression—that allows us to generate optimal code for an expression tree when there is a—xed number of registers with which to evaluate the expression

8 10 1 Ershov Numbers

We begin by assigning to each node of an expression tree a number that tells how many registers are needed to evaluate that node without storing any tem poraries. These numbers are sometimes called *Ershov numbers* after A. Ershov who used a similar scheme for machines with a single arithmetic register. For our machine model, the rules are

- 1 Label all leaves 1
- 2 The label of an interior node with one child is the label of its child
- 3 The label of an interior node with two children is

- a The larger of the labels of its children if those labels are di erent
- b One plus the label of its children if the labels are the same

Example 8 23 In Fig 8 23 we see an expression tree with operators omitted that might be the tree for expression a b e c d or the three address code

t1 a b t2 c d t3 e t2 t4 t1 t3

Each of the ve leaves is labeled 1 by rule 1 Then we can label the interior node for t1 a b since both of its children are labeled Rule 3b applies so it gets label one more than the labels of its children that is 2 The same holds for the interior node for t2 c d

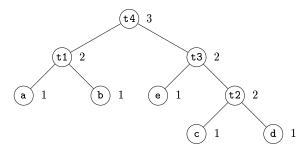

Figure 8 23 A tree labeled with Ershov numbers

Now we can work on the node for t3 e t2 Its children have labels 1 and 2 so the label of the node for t3 is the maximum 2 by rule 3a Finally the root the node for t4 t1 t3 has two children with label 2 and therefore it gets label 3 \Box

8 10 2 Generating Code From Labeled Expression Trees

It can be proved that in our machine model where all operands must be in registers and registers can be used by both an operand and the result of an operation the label of a node is the fewest registers with which the expression can be evaluated using no stores of temporary results. Since in this model we are forced to load each operand and we are forced to compute the result cor responding to each interior node the only thing that can make the generated code inferior to the optimal code is if there are unnecessary stores of temporaries. The argument for this claim is embedded in the following algorithm for generating code with no stores of temporaries using a number of registers equal to the label of the root

Algorithm 8 24 Generating code from a labeled expression tree

8 10 OPTIMAL CODE GENERATION FOR EXPRESSIONS

INPUT A labeled tree with each operand appearing once that is no common subexpressions

OUTPUT An optimal sequence of machine instructions to evaluate the root into a register

METHOD The following is a recursive algorithm to generate the machine code. The steps below are applied starting at the root of the tree. If the algorithm is applied to a node with label k, then only k registers will be used. However, there is a base b-1 for the registers used so that the actual registers used are R_b , R_b ,

- 1 To generate machine code for an interior node with label k and two children with equal labels which must be k-1 do the following
 - a Recursively generate code for the right child using base b-1 The result of the right child appears in register R_{b-k-1}
 - b Recursively generate code for the left child using base b the result appears in R_{b-k-2}
 - c Generate the instruction OP R_{b-k-1} R_{b-k-2} R_{b-k-1} where OP is the appropriate operation for the interior node in question
- 2 Suppose we have an interior node with label k and children with unequal labels. Then one of the children which well call the big child has label k and the other child the little child has some label m k. Do the following to generate code for this interior node using base b
 - a Recursively generate code for the big child using base b the result appears in register R_{b-k-1}
 - b Recursively generate code for the little child using base b the result appears in register R_{b-m-1} Note that since m-k neither R_{b-k-1} nor any higher numbered register is used
 - c Generate the instruction OP R_{b-k-1} R_{b-m-1} R_{b-k-1} or the instruction OP R_{b-k-1} R_{b-k-1} R_{b-m-1} depending on whether the big child is the right or left child respectively
- 3 For a leaf representing operand x if the base is b generate the instruction LD R_b x

Example 8 25 Let us apply Algorithm 8 24 to the tree of Fig 8 23 Since the label of the root is 3 the result will appear in R_3 and only R_1 R_2 and R_3 will be used. The base for the root is b-1. Since the root has children of equal labels, we generate code for the right child rst with base 2

When we generate code for the right child of the root labeled t3 we nd the big child is the right child and the little child is the left child. We thus generate code for the right child rst with b-2 Applying the rules for equal labeled children and leaves we generate the following code for the node labeled t2

CHAPTER 8 CODE GENERATION

```
LD R3 d
LD R2 c
ADD R3 R2 R3
```

Next we generate code for the left child of the right child of the root this node is the leaf labeled e Since b 2 the proper instruction is

```
LD R2 e
```

Now we can complete the code for the right child of the root by adding the instruction

```
MUL R3 R2 R3
```

The algorithm proceeds to generate code for the left child of the root leaving the result in R_2 and with base 1. The complete sequence of instructions is shown in Fig. 8.24. \Box

```
LD R3
       d

      R1
           R2
ADD R3 R2
          R3
```

Figure 8 24 Optimal three register code for the tree of Fig. 8 23 $\,$

8 10 3 Evaluating Expressions with an Insu cient Supply of Registers

When there are fewer registers available than the label of the root of the tree we cannot apply Algorithm 8 24 directly. We need to introduce some store instructions that spill values of subtrees into memory and we then need to load those values back into registers as needed. Here is the modi ed algorithm that takes into account a limitation on the number of registers

Algorithm 8 26 Generating code from a labeled expression tree

INPUT A labeled tree with each operand appearing once i.e. no common subexpressions and a number of registers r=2

OUTPUT An optimal sequence of machine instructions to evaluate the root into a register using no more than r registers which we assume are R_1 R_2 R_r

8 10 OPTIMAL CODE GENERATION FOR EXPRESSIONS

METHOD Apply the following recursive algorithm starting at the root of the tree with base b-1. For a node N with label r or less the algorithm is exactly the same as Algorithm 8 24 and we shall not repeat those steps here. However for interior nodes with a label k-r we need to work on each side of the tree separately and store the result of the larger subtree. That result is brought back from memory just before node N is evaluated, and the nal step will take place in registers R_{r-1} and R_r . The modifications to the basic algorithm are as follows

- 1 Node N has at least one child with label r or greater Pick the larger child or either if their labels are the same to be the big child and let the other child be the little child
- 2 Recursively generate code for the big child using base b-1 The result of this evaluation will appear in register R_r
- 3 Generate the machine instruction ST t_k R_r where t_k is a temporary variable used for temporary results used to help evaluate nodes with label k
- 4 Generate code for the little child as follows If the little child has label r or greater pick base b-1 If the label of the little child is j-r then pick b-r-j Then recursively apply this algorithm to the little child the result appears in R_r
- 5 Generate the instruction LD R_{r-1} t_k
- 6 If the big child is the right child of N then generate the instruction OP R_r R_r R_{r-1} If the big child is the left child generate OP R_r R_{r-1} R_r

Example 8 27 Let us revisit the expression represented by Fig 8 23 but now assume that r-2 that is only registers R1 and R2 are available to hold tem poraries used in the evaluation of expressions. When we apply Algorithm 8 26 to Fig 8 23 we see that the root with label 3 has a label that is larger than r-2. Thus we need to identify one of the children as the big child. Since they have equal labels either would do. Suppose we pick the right child as the big child.

Since the label of the big child of the root is 2 there are enough registers. We thus apply Algorithm 8 24 to this subtree with b-1 and two registers. The result looks very much like the code we generated in Fig. 8 24 but with registers R1 and R2 in place of R2 and R3. This code is

LD R2 d
LD R1 c
ADD R2 R1 R2
LD R1 e
MUL R2 R1 R2

CHAPTER 8 CODE GENERATION

Now since we need both registers for the left child of the root we need to generate the instruction

Next the left child of the root is handled Again the number of registers is su cient for this child and the code is

```
LD R2 b
LD R1 a
SUB R2 R1 R2
```

Finally we reload the temporary that holds the right child of the root with the instruction

and execute the operation at the root of the tree with the instruction

The complete sequence of instructions is shown in Fig. 8 25 \Box

```
LD R2
       d
LD R1
       С
ADD R2
       R1
          R2
LD R1
MUL R2
      R1
           R2
ST t3
       R2
LD
   R2
LD R1
       a
SUB R2
       R1
          R2
LD R1

Exercise 8 10 1 Compute Ershov numbers for the following expressions

8 11 DYNAMIC PROGRAMMING CODE GENERATION

c a p b q c r

Exercise 8 10 2 Generate optimal code using two registers for each of the expressions of Exercise 8 10 1

Exercise 8 10 3 Generate optimal code using three registers for each of the expressions of Exercise 8 10 1

Exercise 8 10 4 Generalize the computation of Ershov numbers to expression trees with interior nodes with three or more children

Exercise 8 10 5 An assignment to an array element such as a i x appears to be an operator with three operands a i and x How would you modify the tree labeling scheme to generate optimal code for this machine model

Exercise 8 10 6 The original Ershov numbers were used for a machine that allowed the right operand of an expression to be in memory rather than a register. How would you modify the tree labeling scheme to generate optimal code for this machine model

Exercise 8 10 7 Some machines require two registers for certain single pre cision values Suppose that the result of a multiplication of single register quan tities requires two consecutive registers and when we divide a b the value of a must be held in two consecutive registers. How would you modify the tree labeling scheme to generate optimal code for this machine model

8 11 Dynamic Programming Code Generation

Algorithm 8 26 in Section 8 10 produces optimal code from an expression tree using an amount of time that is a linear function of the size of the tree. This procedure works for machines in which all computation is done in registers and in which instructions consist of an operator applied to two registers or to a register and a memory location

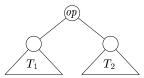

An algorithm based on the principle of dynamic programming can be used to extend the class of machines for which optimal code can be generated from expression trees in linear time. The dynamic programming algorithm applies to a broad class of register machines with complex instruction sets

The dynamic programming algorithm can be used to generate code for any machine with r interchangeable registers R0 R1 $\,$ Rr 1 and load store and operation instructions. For simplicity we assume every instruction costs one unit although the dynamic programming algorithm can easily be modiled to work even if each instruction has its own cost

8 11 1 Contiguous Evaluation

The dynamic programming algorithm partitions the problem of generating optimal code for an expression into the subproblems of generating optimal code for the subexpressions of the given expression. As a simple example consider an expression E of the form E_1 and E_2 an optimal program for E is formed by combining optimal programs for E_1 and E_2 in one or the other order followed by code to evaluate the operator. The subproblems of generating optimal code for E_1 and E_2 are solved similarly

An optimal program produced by the dynamic programming algorithm has an important property. It evaluates an expression E E_1 op E_2 contiguously. We can appreciate what this means by looking at the syntax tree T for E

Here T_1 and T_2 are trees for E_1 and E_2 respectively

We say a program P evaluates a tree T contiguously if it—rst evaluates those subtrees of T that need to be computed into memory. Then it evaluates the remainder of T either in the order T_1 — T_2 —and then the root or in the order T_2 — T_1 —and then the root in either case using the previously computed values from memory whenever necessary. As an example of noncontiguous evaluation P might—rst evaluate part of T_1 —leaving the value in a register—instead of memory—next evaluate T_2 —and then return to evaluate the rest of T_1

For the register machine in this section we can prove that given any mach ine language program P to evaluate an expression tree T we can P and an equivalent program P' such that

- 1 P' is of no higher cost than P
- P' uses no more registers than P and
- 3 P' evaluates the tree contiguously

This result implies that every expression tree can be evaluated optimally by a contiguous program

By way of contrast machines with even odd register pairs do not always have optimal contiguous evaluations the x86 architecture uses register pairs for mul tiplication and division. For such machines we can give examples of expression trees in which an optimal machine language program must—rst evaluate into a register a portion of the left subtree of the root then a portion of the right subtree then another part of the left subtree then another part of the right and so on. This type of oscillation is unnecessary for an optimal evaluation of any expression tree using the machine in this section.

8 11 DYNAMIC PROGRAMMING CODE GENERATION

The contiguous evaluation property de ned above ensures that for any expression tree T there always exists an optimal program that consists of optimal programs for subtrees of the root followed by an instruction to evaluate the root. This property allows us to use a dynamic programming algorithm to generate an optimal program for T

8 11 2 The Dynamic Programming Algorithm

The dynamic programming algorithm proceeds in three phases suppose the target machine has r registers

- 1 Compute bottom up for each node n of the expression tree T an array C of costs in which the ith component C i is the optimal cost of computing the subtree S rooted at n into a register assuming i registers are available for the computation for 1 i r
- 2 Traverse T using the cost vectors to determine which subtrees of T must be computed into memory
- 3 Traverse each tree using the cost vectors and associated instructions to generate the nal target code The code for the subtrees computed into memory locations is generated rst

Each of these phases can be implemented to run in time linearly proportional to the size of the expression tree

The cost of computing a node n includes whatever loads and stores are necessary to evaluate S in the given number of registers. It also includes the cost of computing the operator at the root of S. The zeroth component of the cost vector is the optimal cost of computing the subtree S into memory. The contiguous evaluation property ensures that an optimal program for S can be generated by considering combinations of optimal programs only for the subtrees of the root of S. This restriction reduces the number of cases that need to be considered

In order to compute the costs C i at node n we view the instructions as tree rewriting rules as in Section 8.9. Consider each template E that matches the input tree at node n. By examining the cost vectors at the corresponding descendants of n determine the costs of evaluating the operands at the leaves of E. For those operands of E that are registers consider all possible orders in which the corresponding subtrees of E can be evaluated into registers. In each ordering the rst subtree corresponding to a register operand can be evaluated using E available registers the second using E 1 registers and so on To account for node E add in the cost of the instruction associated with the template E. The value E is then the minimum cost over all possible orders

The cost vectors for the entire tree T can be computed bottom up in time linearly proportional to the number of nodes in T It is convenient to store at each node the instruction used to achieve the best cost for C i for each value

of i The smallest cost in the vector for the root of T gives the minimum cost of evaluating T

Example 8 28 Consider a machine having two registers RO and R1 and the following instructions each of unit cost

LD	$\mathbf{R}i$	$\mathtt{M}j$		${\mathtt R}i$	$\mathtt{M}j$		
op	$\mathbf{R}i$	$\mathbf{R}i$	$\mathtt{R} j$	$\mathtt{R}i$	$\mathbf{R}i$	оp	${\tt R} j$
op	$\mathbf{R}i$	$\mathbf{R}i$	$\mathtt{M} j$	${\mathtt R}i$	$\mathbf{R}i$	оp	$\mathtt{M}j$
LD	$\mathbf{R}i$	$\mathtt{R} j$		$\mathtt{R}i$	$\mathtt{R} j$		
ST	$\mathtt{M}i$	$\mathtt{R} j$		$\mathtt{M}i$	$\mathtt{R} j$		

In these instructions Ri is either RO or R1 and Mj is a memory location. The operator op represents any arithmetic operator

Let us apply the dynamic programming algorithm to generate optimal code for the syntax tree in Fig. 8.26. In the first phase, we compute the cost vectors shown at each node. To illustrate this cost computation consider the cost vector at the leaf a C 0, the cost of computing a into memory is 0 since it is already there C 1, the cost of computing a into a register is 1 since we can load it into a register with the instruction LD RO a C 2, the cost of loading a into a register with two registers available is the same as that with one register available. The cost vector at leaf a is therefore 0.1.1

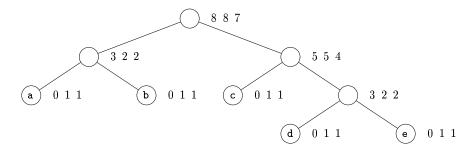

Figure 8 26 Syntax tree for a b c d e with cost vector at each node

Consider the cost vector at the root. We rst determine the minimum cost of computing the root with one and two registers available. The machine instruction ADD RO RO M matches the root because the root is labeled with the operator. Using this instruction, the minimum cost of evaluating the root with one register available is the minimum cost of computing its right subtree into memory plus the minimum cost of computing its left subtree into the register plus 1 for the instruction. No other way exists. The cost vectors at the right and left children of the root show that the minimum cost of computing the root with one register available is 5 2 1 8

Now consider the minimum cost of evaluating the root with two registers available Three cases arise depending on which instruction is used to compute the root and in what order the left and right subtrees of the root are evaluated

8 11 DYNAMIC PROGRAMMING CODE GENERATION

- 1 Compute the left subtree with two registers available into register RO compute the right subtree with one register available into register R1 and use the instruction ADD RO RO R1 to compute the root. This sequence has cost 2 5 1 8
- 2 Compute the right subtree with two registers available into R1 compute the left subtree with one register available into R0 and use the instruction ADD R0 R0 R1 This sequence has cost 4 2 1 7
- 3 Compute the right subtree into memory location M compute the left subtree with two registers available into register RO and use the instruction ADD RO RO M This sequence has cost 5 2 1 8

The second choice gives the minimum cost 7

The minimum cost of computing the root into memory is determined by adding one to the minimum cost of computing the root with all registers avail able that is we compute the root into a register and then store the result. The cost vector at the root is therefore $8\ 8\ 7$

From the cost vectors we can easily construct the code sequence by making a traversal of the tree
From the tree in Fig 8 26 assuming two registers are available an optimal code sequence is

LD	RO	С		RO	С	
LD	R1	d		R1	d	
DIV	R1	R1	е	R1	R1	е
\mathtt{MUL}	RO	RO	R1	RO	RO	R1
LD	R1	a		R1	a	
SUB	R1	R1	b	R1	R1	b
ADD	R1	R1	RO	R1	R1	RO

Dynamic programming techniques have been used in a number of compilers including the second version of the portable C compiler PCC2. The technique facilitates retargeting because of the applicability of the dynamic programming technique to a broad class of machines.

8 12 Summary of Chapter 8

- ◆ Code generation is the nal phase of a compiler The code generator maps the intermediate representation produced by the front end or if there is a code optimization phase by the code optimizer into the target program
- ◆ Instruction selection is the process of choosing target language instructions for each IR statement
- ◆ Register allocation is the process of deciding which IR values to keep in registers Graph coloring is an e ective technique for doing register allocation in compilers
- ♦ Register assignment is the process of deciding which register should hold a given IR value
- lacktriangle A $retargetable\ compiler$ is one that can generate code for multiple instruction sets
- ♦ A *virtual machine* is an interpreter for a bytecode intermediate language produced for languages such as Java and C
- ♦ A CISC machine is typically a two address machine with relatively few registers several register classes and variable length instructions with complex addressing modes
- ♦ A RISC machine is typically a three address machine with many registers in which operations are done in registers
- ◆ A basic block is a maximal sequence of consecutive three address state ments in which ow of control can only enter at the rst statement of the block and leave at the last statement without halting or branching except possibly at the last statement in the basic block
- ◆ A ow graph is a graphical representation of a program in which the nodes of the graph are basic blocks and the edges of the graph show how control can ow among the blocks
- ◆ A *loop* in a ow graph is a strongly connected region with a single entry point called the loop entry
- ◆ A *DAG* representation of a basic block is a directed acyclic graph in which the nodes of the DAG represent the statements within the block and each child of a node corresponds to the statement that is the last de nition of an operand used in the statement
- ◆ Peephole optimizations are local code improving transformations that can be applied to a program—usually through a sliding window

8 13 REFERENCES FOR CHAPTER 8

- ◆ Instruction selection can be done by a tree rewriting process in which tree patterns corresponding to machine instructions are used to tile a syntax tree We can associate costs with the tree rewriting rules and apply dynamic programming to obtain an optimal tiling for useful classes of machines and expressions
- ♦ An Ershov number tells how many registers are needed to evaluate an expression without storing any temporaries
- ◆ Spill code is an instruction sequence that stores a value in a register into memory in order to make room to hold another value in that register

8 13 References for Chapter 8

Many of the techniques covered in this chapter have their origins in the earliest compilers. Ershov s labeling algorithm appeared in 1958. 7. Sethi and Ullman 16 used this labeling in an algorithm that they prove generated optimal code for arithmetic expressions. Aho and Johnson 1 used dynamic programming to generate optimal code for expression trees on CISC machines. Hennessy and Patterson 12 has a good discussion on the evolution of CISC and RISC machine architectures and the tradeo is involved in designing a good instruction set.

RISC architectures became popular after 1990 although their origins go back to computers like the CDC 6600 – rst delivered in 1964 – Many of the computers designed before 1990 were CISC machines but most of the general purpose computers installed after 1990 are still CISC machines because they are based on the Intel 80x86 architecture and its descendants such as the Pentium The Burroughs B5000 delivered in 1963 was an early stack based machine

Many of the heuristics for code generation proposed in this chapter have been used in various compilers. Our strategy of allocating a xed number of registers to hold variables for the duration of a loop was used in the implementation of Fortran H by Lowry and Medlock 13

E cient register allocation techniques have also been studied from the time of the earliest compilers. Graph coloring as a register allocation technique was proposed by Cocke Ershov 8 and Schwartz 15. Many variants of graph coloring algorithms have been proposed for register allocation. Our treatment of graph coloring follows Chaitin 3. 4. Chow and Hennessy describe their priority based coloring algorithm for register allocation in 5. See 6 for a discussion of more recent graph splitting and rewriting techniques for register allocation.

Lexical analyzer and parser generators spurred the development of pattern directed instruction selection. Glanville and Graham 11 used LR parser generation techniques for automated instruction selection. Table driven code generators evolved into a variety of tree pattern matching code generation tools. 14 Aho Ganapathi and Tjiang 2 combined e cient tree pattern matching

Chapter 9

Machine Independent Optimizations

High level language constructs can introduce substantial run time overhead if we naively translate each construct independently into machine code. This chapter discusses how to eliminate many of these inecciences. Elimination of unnecessary instructions in object code or the replacement of one sequence of instructions by a faster sequence of instructions that does the same thing is usually called code improvement or code optimization.

Local code optimization—code improvement within a basic block—was introduced in Section 8.5—This chapter deals with global code optimization—where improvements take into account what happens across basic blocks—We begin in Section 9.1 with a discussion of the principal opportunities for code improvement

Most global optimizations are based on data ow analyses which are algo rithms to gather information about a program. The results of data ow analyses all have the same form for each instruction in the program, they specify some property that must hold every time that instruction is executed. The analyses differ in the properties they compute. For example, a constant propagation analysis computes for each point in the program, and for each variable used by the program, whether that variable has a unique constant value at that point. This information may be used to replace variable references by constant values for instance. As another example, a liveness analysis determines for each point in the program, whether the value held by a particular variable at that point is sure to be overwritten before it is read. If so, we do not need to preserve that value either in a register or in a memory location.

We introduce data ow analysis in Section 9 2 including several important examples of the kind of information we gather globally and then use to improve the code Section 9 3 introduces the general idea of a data ow framework of which the data ow analyses in Section 9 2 are special cases. We can use essentially the same algorithms for all these instances of data ow analysis and

we can measure the performance of these algorithms and show their correctness on all instances as well. Section 9.4 is an example of the general framework that does more powerful analysis than the earlier examples. Then in Section 9.5 we consider a powerful technique called partial redundancy elimination for optimizing the placement of each expression evaluation in the program. The solution to this problem requires the solution of a variety of different data ow problems

In Section 9 6 we take up the discovery and analysis of loops in programs. The identication of loops leads to another family of algorithms for solving data ow problems that is based on the hierarchical structure of the loops of a well formed reducible program. This approach to data ow analysis is covered in Section 9 7. Finally Section 9 8 uses hierarchical analysis to eliminate induction variables essentially variables that count the number of iterations around a loop. This code improvement is one of the most important we can make for programs written in commonly used programming languages.

9 1 The Principal Sources of Optimization

A compiler optimization must preserve the semantics of the original program Except in very special circumstances once a programmer chooses and imple ments a particular algorithm the compiler cannot understand enough about the program to replace it with a substantially di erent and more e-cient al gorithm. A compiler knows only how to apply relatively low level semantic transformations using general facts such as algebraic identities like i-0-i or program semantics such as the fact that performing the same operation on the same values yields the same result

9 1 1 Causes of Redundancy

There are many redundant operations in a typical program Sometimes the redundancy is available at the source level. For instance, a programmer may nd it more direct and convenient to recalculate some result leaving it to the compiler to recognize that only one such calculation is necessary. But more often the redundancy is a side elect of having written the program in a high level language. In most languages other than C or C where pointer arithmetic is allowed programmers have no choice but to refer to elements of an array or elds in a structure through accesses like Aij or X

As a program is compiled each of these high level data structure accesses expands into a number of low level arithmetic operations such as the computation of the location of the i j th element of a matrix A Accesses to the same data structure often share many common low level operations. Programmers are not aware of these low level operations and cannot eliminate the redundancies themselves. It is in fact preferable from a software engineering perspective that programmers only access data elements by their high level names the

91 THE PRINCIPAL SOURCES OF OPTIMIZATION

programs are easier to write and more importantly easier to understand and evolve By having a compiler eliminate the redundancies we get the best of both worlds the programs are both e cient and easy to maintain

9 1 2 A Running Example Quicksort

In the following we shall use a fragment of a sorting program called quicksort to illustrate several important code improving transformations. The C program in Fig. 9.1 is derived from Sedgewick 1 who discussed the hand optimization of such a program. We shall not discuss all the subtle algorithmic aspects of this program here for example, the fact that a 0 must contain the smallest of the sorted elements, and a max the largest

```
void quicksort int m int n
       recursively sorts a m through a n
    int i
           j
    int v
    if n
             m return
       fragment begins here
   i
        m 1
            j
                 n
    while
        do i
               i 1
                    while a i
                    while
        do j
               j 1
                    break
                                             swap a i

```

Figure 9.1 C code for quicksort

Before we can optimize away the redundancies in address calculations the address operations in a program—rst must be broken down into low level arith metic operations to expose the redundancies. In the rest of this chapter we as sume that the intermediate representation consists of three address statements where temporary variables are used to hold all the results of intermediate expressions. Intermediate code for the marked fragment of the program in Fig. 9.1 is shown in Fig. 9.2

In this example we assume that integers occupy four bytes The assignment x a i is translated as in Section 6 4 4 into the two three address statements

                                              a t15
```

Figure 9.2 Three address code for fragment in Fig. 9.1

```
t6 4 i x a t6
```

as shown in steps 14 and 15 of Fig 9.2 Similarly a j x becomes

```
t10 4 j a t10 x
```

in steps 20 and 21 Notice that every array access in the original program translates into a pair of steps consisting of a multiplication and an array subscripting operation As a result this short program fragment translates into a rather long sequence of three address operations

Figure 9 3 is the ow graph for the program in Fig 9 2 Block B_1 is the entry node All conditional and unconditional jumps to statements in Fig 9 2 have been replaced in Fig 9 3 by jumps to the block of which the statements are leaders as in Section 8 4 In Fig 9 3 there are three loops Blocks B_2 and B_3 are loops by themselves Blocks B_2 B_3 B_4 and B_5 together form a loop with B_2 the only entry point

9 1 3 Semantics Preserving Transformations

There are a number of ways in which a compiler can improve a program without changing the function it computes Common subexpression elimination copy propagation dead code elimination and constant folding are common examples of such function preserving or *semantics preserving* transformations we shall consider each in turn

91 THE PRINCIPAL SOURCES OF OPTIMIZATION

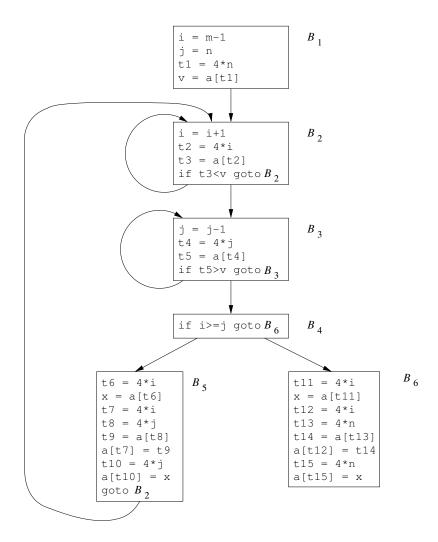

Figure 9.3 Flow graph for the quicksort fragment

Frequently a program will include several calculations of the same value such as an o set in an array. As mentioned in Section 9.1.2 some of these duplicate calculations cannot be avoided by the programmer because they lie below the level of detail accessible within the source language. For example block B_5 shown in Fig. 9.4 a recalculates 4 i and 4 j although none of these calculations were requested explicitly by the programmer

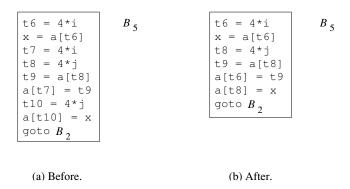

Figure 9 4 Local common subexpression elimination

9 1 4 Global Common Subexpressions

An occurrence of an expression E is called a *common subexpression* if E was previously computed and the values of the variables in E have not changed since the previous computation. We avoid recomputing E if we can use its previously computed value that is the variable x to which the previous computation of E was assigned has not changed in the interim 2

Example 9 1 The assignments to t7 and t10 in Fig 9 4 a compute the common subexpressions 4 i and 4 j respectively. These steps have been eliminated in Fig 9 4 b which uses t6 instead of t7 and t8 instead of t10

Example 9 2 Figure 9 5 shows the result of eliminating both global and local common subexpressions from blocks B_5 and B_6 in the ow graph of Fig 9 3 We rst discuss the transformation of B_5 and then mention some subtleties involving arrays

After local common subexpressions are eliminated $\,B_5$ still evaluates 4 $\,i$ and 4 $\,j$ as shown in Fig. 9.4 b. Both are common subexpressions in particular the three statements

 $^{^2}$ If x has changed it may still be possible to reuse the computation of E if we assign its value to a new variable y as well as to x and use the value of y in place of a recomputation of E

91 THE PRINCIPAL SOURCES OF OPTIMIZATION

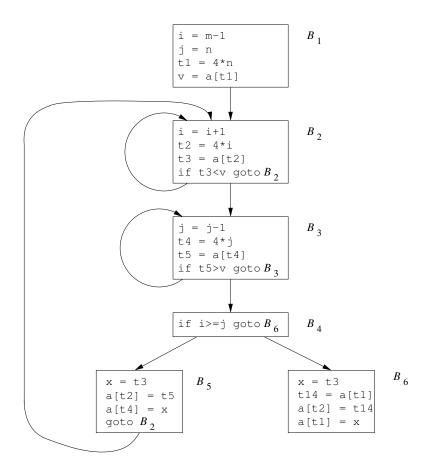

Figure 9.5 B_5 and B_6 after common subexpression elimination

in B_5 can be replaced by

using t4 computed in block B_3 In Fig. 9.5 observe that as control passes from the evaluation of 4 j in B_3 to B_5 there is no change to j and no change to t4 so t4 can be used if 4 j is needed

Another common subexpression comes to light in B_5 after t4 replaces t8. The new expression a t4 corresponds to the value of a j at the source level. Not only does j retain its value as control leaves B_3 and then enters B_5 but

a j a value computed into a temporary t5 does too because there are no assignments to elements of the array a in the interim. The statements

in B_5 therefore can be replaced by

Analogously the value assigned to x in block B_5 of Fig. 9.4 b is seen to be the same as the value assigned to t3 in block B_2 Block B_5 in Fig. 9.5 is the result of eliminating common subexpressions corresponding to the values of the source level expressions a i and a j from B_5 in Fig. 9.4 b A similar series of transformations has been done to B_6 in Fig. 9.5

The expression $a\ t1$ in blocks B_1 and B_6 of Fig 9.5 is not considered a common subexpression although t1 can be used in both places. After control leaves B_1 and before it reaches B_6 it can go through B_5 where there are assignments to a. Hence $a\ t1$ may not have the same value on reaching B_6 as it did on leaving B_1 and it is not safe to treat $a\ t1$ as a common subexpression \Box

9 1 5 Copy Propagation

Block B_5 in Fig 9.5 can be further improved by eliminating x using two new transformations. One concerns assignments of the form u v called copy state ments or copies for short. Had we gone into more detail in Example 9.2 copies would have arisen much sooner because the normal algorithm for eliminating common subexpressions introduces them, as do several other algorithms

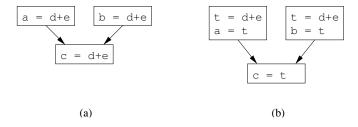

Figure 9 6 Copies introduced during common subexpression elimination

Example 9 3 In order to eliminate the common subexpression from the state ment c d e in Fig 96 a we must use a new variable t to hold the value of d e The value of variable t instead of that of the expression d e is assigned to c in Fig 96 b Since control may reach c d e either after the assignment to a or after the assignment to b it would be incorrect to replace c d e by either c a or by c b \Box

9 1 THE PRINCIPAL SOURCES OF OPTIMIZATION

The idea behind the copy propagation transformation is to use v for u wherever possible after the copy statement u v For example the assignment x t3 in block B_5 of Fig 9.5 is a copy Copy propagation applied to B_5 yields the code in Fig 9.7 This change may not appear to be an improvement but as we shall see in Section 9.1.6 it gives us the opportunity to eliminate the assignment to x

Figure 9 7 Basic block B_5 after copy propagation

9 1 6 Dead Code Elimination

A variable is *live* at a point in a program if its value can be used subsequently otherwise it is *dead* at that point. A related idea is *dead* or *useless code* statements that compute values that never get used. While the programmer is unlikely to introduce any dead code intentionally it may appear as the result of previous transformations.

Example 9 4 Suppose debug is set to TRUE or FALSE at various points in the program and used in statements like

if debug print

It may be possible for the compiler to deduce that each time the program reaches this statement the value of debug is FALSE Usually it is because there is one particular statement

debug FALSE

that must be the last assignment to debug prior to any tests of the value of debug no matter what sequence of branches the program actually takes. If copy propagation replaces debug by FALSE then the print statement is dead because it cannot be reached. We can eliminate both the test and the print operation from the object code. More generally deducing at compile time that the value of an expression is a constant and using the constant instead is known as $constant\ folding$

One advantage of copy propagation is that it often turns the copy state ment into dead code. For example, copy propagation followed by dead code elimination removes the assignment to x and transforms the code in Fig 9.7 into

a t2 t5 a t4 t3 goto
$$B_2$$

This code is a further improvement of block B_5 in Fig. 9.5

9 1 7 Code Motion

Loops are a very important place for optimizations especially the inner loops where programs tend to spend the bulk of their time. The running time of a program may be improved if we decrease the number of instructions in an inner loop even if we increase the amount of code outside that loop

An important modi cation that decreases the amount of code in a loop is code motion. This transformation takes an expression that yields the same result independent of the number of times a loop is executed a loop invariant computation and evaluates the expression before the loop. Note that the notion before the loop assumes the existence of an entry for the loop that is one basic block to which all jumps from outside the loop go see Section 8.4.5

Example 9 5 Evaluation of *limit* 2 is a loop invariant computation in the following while statement

```
while i limit 2 statement does not change limit
```

Code motion will result in the equivalent code

```
t limit 2
while i t statement does not change limit or t
```

Now the computation of limit 2 is performed once before we enter the loop Previously there would be n-1 calculations of limit-2 if we iterated the body of the loop n times \square

9 1 8 Induction Variables and Reduction in Strength

Another important optimization is to $\,$ nd induction variables in loops and optimize their computation $\,$ A variable $\,$ x is said to be an induction variable if there is a positive or negative constant $\,$ c such that each time $\,$ x is assigned its value increases by $\,$ c $\,$ For instance $\,$ i and $\,$ t2 are induction variables in the loop containing $\,$ B₂ of Fig 9.5 Induction variables can be computed with a single increment addition or subtraction per loop iteration. The transformation of replacing an expensive operation such as multiplication by a cheaper one such as addition is known as $\,$ strength $\,$ reduction. But induction variables not only allow us sometimes to perform a strength reduction often it is possible to eliminate all but one of a group of induction variables whose values remain in lock step as we go around the loop

91 THE PRINCIPAL SOURCES OF OPTIMIZATION

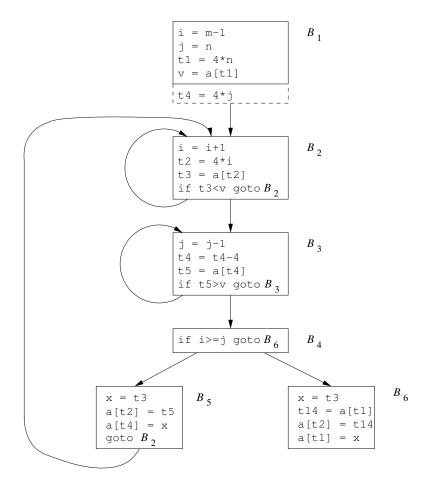

Figure 9.8 Strength reduction applied to 4 j in block B_3

When processing loops it is useful to work inside out that is we shall start with the inner loops and proceed to progressively larger surrounding loops. Thus we shall see how this optimization applies to our quicksort example by beginning with one of the innermost loops B_3 by itself. Note that the values of j and t4 remain in lock step, every time the value of j decreases by 1, the value of t4 decreases by 4, because 4, t4 is assigned to t4. These variables t4 and t4 thus form a good example of a pair of induction variables.

When there are two or more induction variables in a loop it may be possible to get rid of all but one. For the inner loop of B_3 in Fig. 9.5 we cannot get rid of either j or t4 completely. t4 is used in B_3 and j is used in B_4 . However, we can illustrate reduction in strength and a part of the process of induction variable elimination. Eventually j will be eliminated when the outer loop consisting of blocks B_2 B_3 B_4 and B_5 is considered

Example 9 6 As the relationship t4-4-j surely holds after assignment to t4 in Fig 9 5 and t4 is not changed elsewhere in the inner loop around B_3 it follows that just after the statement j-j-1 the relationship t4-4-j-4 must hold. We may therefore replace the assignment t4-4-j by t4-t4-4. The only problem is that t4 does not have a value when we enter block B_3 for the rst time

Since we must maintain the relationship t4-4-j on entry to the block B_3 we place an initialization of t4 at the end of the block where j itself is initialized shown by the dashed addition to block B_1 in Fig. 9.8 Although we have added one more instruction which is executed once in block B_1 the replacement of a multiplication by a subtraction will speed up the object code if multiplication takes more time than addition or subtraction as is the case on many machines

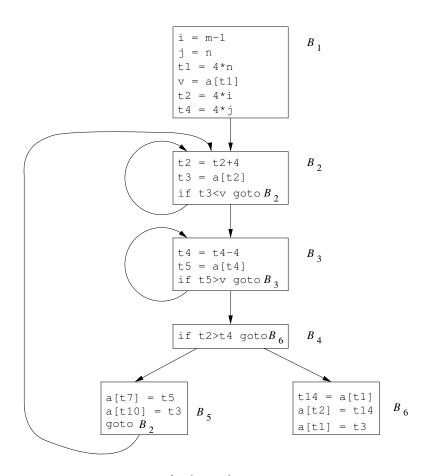

Figure 9 9 Flow graph after induction variable elimination

We conclude this section with one more instance of induction variable elim

91 THE PRINCIPAL SOURCES OF OPTIMIZATION

ination This example treats i and j in the context of the outer loop containing B_2 B_3 B_4 and B_5

Example 9 7 After reduction in strength is applied to the inner loops around B_2 and B_3 the only use of i and j is to determine the outcome of the test in block B_4 We know that the values of i and t2 satisfy the relationship t2-4 i while those of j and t4 satisfy the relationship t4-4 j. Thus the test t2-t4 can substitute for i-j. Once this replacement is made i in block B_2 and j in block B_3 become dead variables and the assignments to them in these blocks become dead code that can be eliminated. The resulting ow graph is shown in Fig. 9.9. \square

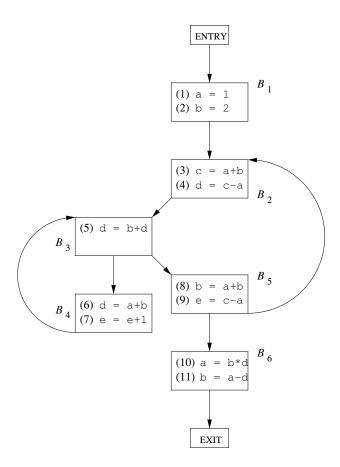

Figure 9 10 Flow graph for Exercise 9 1 1

The code improving transformations we have discussed have been e ective In Fig 9 9 the numbers of instructions in blocks B_2 and B_3 have been reduced from 4 to 3 compared with the original ow graph in Fig 9 3 In B_5 the number

has been reduced from 9 to 3 and in B_6 from 8 to 3. True B_1 has grown from four instructions to six but B_1 is executed only once in the fragment so the total running time is barely a ected by the size of B_1

9 1 9 Exercises for Section 9 1

Exercise 9 1 1 For the ow graph in Fig 9 10

- a Identify the loops of the ow graph
- b Statements 1 and 2 in B_1 are both copy statements in which a and b are given constant values. For which uses of a and b can we perform copy propagation and replace these uses of variables by uses of a constant. Do so wherever possible
- c Identify any global common subexpressions for each loop
- d Identify any induction variables for each loop Be sure to take into account any constants introduced in b
- e Identify any loop invariant computations for each loop

9 2 Introduction to Data Flow Analysis

All the optimizations introduced in Section 9.1 depend on data ow analysis. Data ow analysis refers to a body of techniques that derive information about the ow of data along program execution paths. For example, one way to implement global common subexpression elimination requires us to determine whether two textually identical expressions evaluate to the same value along any possible execution path of the program. As another example, if the result of an assignment is not used along any subsequent execution path, then we can eliminate the assignment as dead code. These and many other important questions can be answered by data—ow analysis.

9 2 1 The Data Flow Abstraction

Following Section 1 6 2 the execution of a program can be viewed as a series of transformations of the program state which consists of the values of all the variables in the program including those associated with stack frames below the top of the run time stack. Each execution of an intermediate code statement transforms an input state to a new output state. The input state is associated with the *program point before* the statement and the output state is associated with the *program point after* the statement.

When we analyze the behavior of a program we must consider all the possible sequences of program points—paths—through a ow graph that the program execution can take—We then extract from the possible program states at each point—the information we need for the particular data—ow analysis problem we want to solve—In more complex analyses—we must consider paths that jump among the—ow graphs for various procedures—as calls and returns are executed—However—to begin our study—we shall concentrate on the paths through a single—ow graph for a single procedure

Let us see what the ow graph tells us about the possible execution paths

Within one basic block the program point after a statement is the same as the program point before the next statement

If there is an edge from block B_1 to block B_2 —then the program point after the last statement of B_1 may be followed immediately by the program point before the —rst statement of B_2

Thus we may de ne an execution path or just path from point p_1 to point p_n to be a sequence of points p_1 p_2 p_n such that for each i 1 2 n 1 either

- 1 p_i is the point immediately preceding a statement and p_{i-1} is the point immediately following that same statement or
- 2 p_i is the end of some block and p_{i-1} is the beginning of a successor block

In general there is an in nite number of possible execution paths through a program and there is no nite upper bound on the length of an execution path Program analyses summarize all the possible program states that can occur at a point in the program with a nite set of facts Di erent analyses may choose to abstract out di erent information and in general no analysis is necessarily a perfect representation of the state

Example 9 8 Even the simple program in Fig 9 12 describes an unbounded number of execution paths. Not entering the loop at all the shortest complete execution path consists of the program points 1 2 3 4 9. The next shortest path executes one iteration of the loop and consists of the points 1 2 3 4 5 6 7 8 3 4 9. We know that for example the rst time program point 5 is executed the value of a is 1 due to de nition d_1 . We say that d_1 reaches point 5 in the rst iteration. In subsequent iterations d_3 reaches point 5 and the value of a is 243

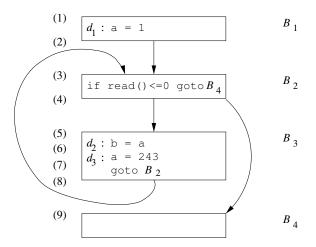

Figure 9 12 Example program illustrating the data ow abstraction

In general it is not possible to keep track of all the program states for all possible paths. In data, ow analysis, we do not distinguish among the paths taken to reach a program point. Moreover, we do not keep track of entire states rather, we abstract out certain details, keeping only the data we need for the purpose of the analysis. Two examples will illustrate how the same program states may lead to different information abstracted at a point

1 To help users debug their programs we may wish to $\,$ nd out what are all the values a variable may have at a program point and where these values may be de $\,$ ned $\,$ For instance we may summarize all the program states at point $\,$ 5 by saying that the value of a is one of $\{1\ 243\}$ and that it may be de $\,$ ned $\,$ by one of $\{d_1\ d_3\}$ The de $\,$ nitions that $\,$ may reach a program point along some path are known as $\,$ reaching $\,$ de $\,$ nitions

92 INTRODUCTION TO DATA FLOW ANALYSIS

2 Suppose instead we are interested in implementing constant folding. If a use of the variable x is reached by only one definition and that definition assigns a constant to x then we can simply replace x by the constant. If on the other hand, several definitions of x may reach a single program point, then we cannot perform constant folding on x. Thus, for constant folding we wish to find those definitions that are the unique definition of their variable to reach a given program point from matter which execution path is taken. For point 5 of Fig. 9.12, there is no definition that x be the definition of x at that point so this set is empty for x at point 5. Even if a variable has a unique definition at a point that definition must assign a constant to the variable. Thus, we may simply describe certain variables as not a constant instead of collecting all their possible values or all their possible definitions.

Thus we see that the same information may be summarized di erently de pending on the purpose of the analysis \Box

9 2 2 The Data Flow Analysis Schema

In each application of data ow analysis we associate with every program point a data ow value that represents an abstraction of the set of all possible program states that can be observed for that point. The set of possible data ow values is the domain for this application. For example, the domain of data ow values for reaching de nitions is the set of all subsets of de nitions in the program. A particular data ow value is a set of de nitions and we want to associate with each point in the program the exact set of de nitions that can reach that point. As discussed above, the choice of abstraction depends on the goal of the analysis to be elicient, we only keep track of information that is relevant.

We denote the data ow values before and after each statement s by IN s and OUT s respectively. The data ow problem is to indicate a set of constraints on the IN s is and OUT s is for all statements s. There are two sets of constraints those based on the semantics of the statements it transfer functions and those based on the low of control

Transfer Functions

The data ow values before and after a statement are constrained by the se mantics of the statement. For example, suppose our data ow analysis involves determining the constant value of variables at points. If variable a has value v before executing statement b a then both a and b will have the value v after the statement. This relationship between the data ow values before and after the assignment statement is known as a $transfer\ function$

Transfer functions come in two avors information may propagate forward along execution paths or it may ow backwards up the execution paths. In a forward ow problem, the transfer function of a statement s which we shall

usually denote f_s takes the data ow value before the statement and produces a new data ow value after the statement. That is

OUT
$$s$$
 f_s IN s

Conversely in a backward ow problem the transfer function f_s for statement s converts a data ow value after the statement to a new data ow value before the statement. That is

IN
$$s$$
 f_s OUT s

Control Flow Constraints

The second set of constraints on data ow values is derived from the ow of control Within a basic block control ow is simple If a block B consists of statements s_1 s_2 s_n in that order then the control ow value out of s_i is the same as the control ow value into s_{i-1} That is

IN
$$s_{i-1}$$
 OUT s_i for all $i-1$ 2 $n-1$

However control ow edges between basic blocks create more complex constraints between the last statement of one basic block and the rst statement of the following block. For example, if we are interested in collecting all the denitions that may reach a program point, then the set of denitions reaching the leader statement of a basic block is the union of the denitions after the last statements of each of the predecessor blocks. The next section gives the details of how data ows among the blocks.

9 2 3 Data Flow Schemas on Basic Blocks

While a data ow schema technically involves data ow values at each point in the program we can save time and space by recognizing that what goes on inside a block is usually quite simple Control ows from the beginning to the end of the block without interruption or branching. Thus we can restate the schema in terms of data ow values entering and leaving the blocks. We denote the data ow values immediately before and immediately after each basic block B by IN B and OUT B respectively. The constraints involving IN B and OUT B can be derived from those involving IN B and OUT B for the various statements B in B as follows

Suppose block B consists of statements s_1 s_n in that order If s_1 is the rst statement of basic block B then IN B IN s_1 Similarly if s_n is the last statement of basic block B then OUT B OUT s_n The transfer function of a basic block B which we denote f_B can be derived by composing the transfer functions of the statements in the block. That is let f_{s_i} be the transfer function of statement s_i . Then f_B f_{s_n} f_{s_2} f_{s_1} . The relationship between the beginning and end of the block is

OUT
$$B$$
 f_B IN B

92 INTRODUCTION TO DATA FLOW ANALYSIS

The constraints due to control ow between basic blocks can easily be rewrit ten by substituting IN B and OUT B for IN s_1 and OUT s_n respectively For instance if data ow values are information about the sets of constants that may be assigned to a variable then we have a forward ow problem in which

IN
$$B$$
 P a predecessor of B OUT P

When the data ow is backwards as we shall soon see in live variable analy sis the equations are similar but with the roles of the IN s and OUT s reversed. That is

IN
$$B$$
 f_B OUT B
OUT B
 S a successor of B IN S

Unlike linear arithmetic equations the data ow equations usually do not have a unique solution. Our goal is to indicate the most precise solution that satisfies the two sets of constraints control ow and transfer constraints. That is we need a solution that encourages valid code improvements but does not justify unsafe transformations—those that change what the program computes. This issue is discussed brieny in the box on Conservatism—and more extensively in Section 9.3.4. In the following subsections we discuss some of the most important examples of problems that can be solved by data—ow analysis.

9 2 4 Reaching De nitions

Reaching de nitions is one of the most common and useful data ow schemas By knowing where in a program each variable x may have been de ned when control reaches each point p we can determine many things about x. For just two examples a compiler then knows whether x is a constant at point p and a debugger can tell whether it is possible for x to be an unde ned variable should x be used at p

We say a de nition d reaches a point p if there is a path from the point immediately following d to p such that d is not killed along that path. We kill a de nition of a variable x if there is any other de nition of x anywhere along the path 3 Intuitively if a de nition d of some variable x reaches point p then d might be the place at which the value of x used at p was last de ned

A de nition of a variable x is a statement that assigns or may assign a value to x. Procedure parameters array accesses and indirect references all may have aliases and it is not easy to tell if a statement is referring to a particular variable x. Program analysis must be conservative if we do not

 $^{^3}$ Note that the path may have loops so we could come to another occurrence of d along the path which does not kill d

Detecting Possible Uses Before De nition

Here is how we use a solution to the reaching denitions problem to detect uses before denition. The trick is to introduce a dummy denition for each variable x in the entry to the low graph. If the dummy denition of x reaches a point p where x might be used then there might be an opportunity to use x before denition. Note that we can never be absolutely certain that the program has a bug since there may be some reason possibly involving a complex logical argument why the path along which p is reached without a real denition of x can never be taken

know whether a statement s is assigning a value to x we must assume that it may assign to it that is variable x after statement s may have either its original value before s or the new value created by s. For the sake of simplicity the rest of the chapter assumes that we are dealing only with variables that have no aliases. This class of variables includes all local scalar variables in most languages in the case of C and C. local variables whose addresses have been computed at some point are excluded

Example 9 9 Shown in Fig. 9.13 is a ow graph with seven definitions. Let us focus on the definitions reaching block B_2 . All the definitions in block B_1 reach the beginning of block B_2 . The definition d_5 j j 1 in block B_2 also reaches the beginning of block B_2 because no other definitions of j can be found in the loop leading back to B_2 . This definition however kills the definition d_2 j in preventing it from reaching B_3 or B_4 . The statement d_4 i in 1 in B_2 does not reach the beginning of B_2 though because the variable i is always redefined by d_7 i in unit in the definition d_6 a in unit in unit in unit in the beginning of block B_2 .

By de ning reaching de nitions as we have we sometimes allow inaccuracies However they are all in the safe or conservative direction For example notice our assumption that all edges of a ow graph can be traversed. This assumption may not be true in practice. For example, for no values of a and b can the ow of control actually reach $statement\ 2$ in the following program fragment

if a b statement 1 else if a b statement 2

To decide in general whether each path in a ow graph can be taken is an undecidable problem. Thus we simply assume that every path in the ow graph can be followed in some execution of the program. In most applications of reaching de nitions it is conservative to assume that a de nition can reach a point even if it might not. Thus we may allow paths that are never be traversed in any execution of the program, and we may allow de nitions to pass through ambiguous de nitions of the same variable safely.

Conservatism in Data Flow Analysis

Since all data ow schemas compute approximations to the ground truth as de ned by all possible execution paths of the program we are obliged to assure that any errors are in the safe direction A policy decision is safe or conservative if it never allows us to change what the program computes Safe policies may unfortunately cause us to miss some code improvements that would retain the meaning of the program but in essentially all code optimizations there is no safe policy that misses nothing It would generally be unacceptable to use an unsafe policy one that speeds up the code at the expense of changing what the program computes

Thus when designing a data ow schema we must be conscious of how the information will be used and make sure that any approximations we make are in the conservative or safe direction Each schema and application must be considered independently. For instance if we use reaching de nitions for constant folding it is safe to think a de nition reaches when it doesn't we might think x is not a constant when in fact it is and could have been folded but not safe to think a de nition doesn't reach when it does we might replace x by a constant when the program would at times have a value for x other than that constant

Transfer Equations for Reaching De nitions

We shall now set up the constraints for the reaching de nitions problem We start by examining the details of a single statement Consider a de nition

$$d$$
 u v w

Here and frequently in what follows — is used as a generic binary operator — This statement—generates—a de nition d of variable u and kills—all the other de nitions in the program that de ne variable u—while leaving the remaining incoming de nitions una ected—The transfer function of de nition d—thus can be expressed as

$$f_d x gen_d x kill_d$$
 9 1

where $gen_d = \{d\}$ the set of de nitions generated by the statement and $kill_d$ is the set of all other de nitions of u in the program

As discussed in Section 9 2 2 the transfer function of a basic block can be found by composing the transfer functions of the statements contained therein The composition of functions of the form 9 1 which we shall refer to as gen kill form is also of that form as we can see as follows Suppose there are two functions f_1 x gen_1 x $kill_1$ and f_2 x gen_2 x $kill_2$ Then

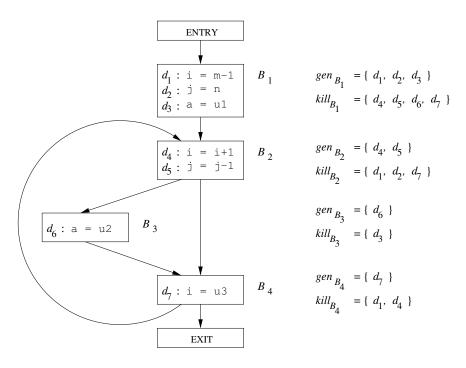

Figure 9 13 Flow graph for illustrating reaching de nitions

$$egin{array}{lll} f_2 & f_1 & x & gen_2 & gen_1 & x & kill_1 & kill_2 \ & gen_2 & gen_1 & kill_2 & x & kill_1 & kill_2 \end{array}$$

This rule extends to a block consisting of any number of statements Suppose block B has n statements with transfer functions f_i x gen_i x $kill_i$ for i 1 2 n Then the transfer function for block B may be written as

$$f_B x gen_B x kill_B$$

where

$$kill_B \quad kill_1 \quad kill_2 \qquad \qquad kill_n$$

and

92 INTRODUCTION TO DATA FLOW ANALYSIS

Thus like a statement a basic block also generates a set of de nitions and kills a set of de nitions. The gen set contains all the de nitions inside the block that are visible immediately after the block—we refer to them as downwards exposed—A de nition is downwards exposed in a basic block only if it is not killed—by a subsequent de nition to the same variable inside the same basic block. A basic block s kill set is simply the union of all the de nitions killed by the individual statements. Notice that a de nition may appear in both the gen and kill set of a basic block. If so the fact that it is in gen takes precedence because in gen kill form—the kill set is applied before the gen set

Example 9 10 The *gen* set for the basic block

$$egin{array}{cccc} d_1 & ext{a} & ext{3} \ d_2 & ext{a} & ext{4} \end{array}$$

is $\{d_2\}$ since d_1 is not downwards exposed. The kill set contains both d_1 and d_2 since d_1 kills d_2 and vice versa. Nonetheless since the subtraction of the kill set precedes the union operation with the gen set, the result of the transfer function for this block always includes definition d_2 . \square

Control Flow Equations

Next we consider the set of constraints derived from the control ow between basic blocks. Since a definition reaches a program point as long as there exists at least one path along which the definition reaches OUT P — IN B whenever there is a control ow edge from P to B — However since a definition cannot reach a point unless there is a path along which it reaches. In B — needs to be no larger than the union of the reaching definitions of all the predecessor blocks. That is it is safe to assume

IN
$$B$$
 P a predecessor of B OUT P

We refer to union as the *meet operator* for reaching de nitions. In any data ow schema, the meet operator is the one we use to create a summary of the contributions from different paths at the confuence of those paths.

Iterative Algorithm for Reaching De nitions

We assume that every control ow graph has two empty basic blocks an ENTRY node which represents the starting point of the graph and an EXIT node to which all exits out of the graph go Since no de nitions reach the beginning of the graph the transfer function for the ENTRY block is a simple constant function that returns as an answer That is OUT ENTRY

The reaching de nitions problem is de ned by the following equations

OUT ENTRY

and for all basic blocks B other than entry

OUT
$$B$$
 gen_B IN B $kill_B$

IN
$$B$$
 P a predecessor of B OUT P

These equations can be solved using the following algorithm. The result of the algorithm is the *least xedpoint* of the equations i.e. the solution whose assigned values to the IN s and OUT s is contained in the corresponding values for any other solution to the equations. The result of the algorithm below is acceptable since any de nition in one of the sets IN or OUT surely must reach the point described. It is a desirable solution since it does not include any de nitions that we can be sure do not reach

Algorithm 9 11 Reaching de nitions

INPUT A ow graph for which $kill_B$ and gen_B have been computed for each block B

OUTPUT IN B and OUT B the set of definitions reaching the entry and exit of each block B of the ow graph

METHOD We use an iterative approach in which we start with the estimate OUT B for all B and converge to the desired values of IN and OUT. As we must iterate until the IN's and hence the OUT's converge we could use a boolean variable change to record on each pass through the blocks whether any OUT has changed. However in this and in similar algorithms described later, we assume that the exact mechanism for keeping track of changes is understood, and we elide those details

The algorithm is sketched in Fig 9 14. The first two lines initialize certain data of walues 4 Line 3 starts the loop in which we iterate until convergence and the inner loop of lines 4 through 6 applies the data of equations to every block other than the entry \Box

Intuitively Algorithm 9 11 propagates de nitions as far as they will go with out being killed thus simulating all possible executions of the program. Algorithm 9 11 will eventually halt because for every B OUT B never shrinks once a de nition is added it stays there forever. See Exercise 9 2 6. Since the set of all de nitions is nite eventually there must be a pass of the while loop during which nothing is added to any OUT and the algorithm then terminates. We are safe terminating then because if the OUT s have not changed the IN s will

 $^{^4}$ The observant reader will notice that we could easily combine lines 1 and 2. However in similar data—ow algorithms—it may be necessary to initialize the entry or exit node differently from the way we initialize the other nodes—Thus—we follow a pattern in all iterative algorithms of applying a—boundary condition—like line—1—separately from the initialization of line—2

9 2 INTRODUCTION TO DATA FLOW ANALYSIS

```
1 OUT ENTRY
2 for each basic block B other than ENTRY OUT B
3 while changes to any OUT occur
4 for each basic block B other than ENTRY {
5 IN B \bigcup_{P \text{ a predecessor of } B} OUT P
6 OUT B gen_B IN B kill_B
}
```

Figure 9 14 Iterative algorithm to compute reaching de nitions

not change on the next pass And if the IN s do not change the OUT s cannot so on all subsequent passes there can be no changes

The number of nodes in the ow graph is an upper bound on the number of times around the while loop. The reason is that if a de nition reaches a point it can do so along a cycle free path, and the number of nodes in a ow graph is an upper bound on the number of nodes in a cycle free path. Each time around the while loop each de nition progresses by at least one node along the path in question, and it often progresses by more than one node depending on the order in which the nodes are visited.

In fact if we properly order the blocks in the for loop of line 4 there is empirical evidence that the average number of iterations of the while loop is under 5 see Section 9 6 7 Since sets of de nitions can be represented by bit vectors and the operations on these sets can be implemented by logical operations on the bit vectors Algorithm 9 11 is surprisingly e cient in practice

Example 9 12 We shall represent the seven denitions d_1 d_2 d_7 in the ow graph of Fig. 9 13 by bit vectors where bit i from the left represents denition d_i . The union of sets is computed by taking the logical OR of the corresponding bit vectors. The dierence of two sets S T is computed by complementing the bit vector of T and then taking the logical AND of that complement with the bit vector for S

Shown in the table of Fig. 9.15 are the values taken on by the IN and OUT sets in Algorithm 9.11. The initial values indicated by a superscript 0 as in OUT $B^{\,\,0}$ are assigned by the loop of line 2 of Fig. 9.14. They are each the empty set represented by bit vector 000 0000. The values of subsequent passes of the algorithm are also indicated by superscripts and labeled IN $B^{\,\,1}$ and OUT $B^{\,\,1}$ for the rst pass and IN $B^{\,\,2}$ and OUT $B^{\,\,2}$ for the second

Suppose the for loop of lines $\,4\,$ through $\,6\,$ is executed with B taking on the values

$$B_1$$
 B_2 B_3 B_4 EXIT

in that order With B B_1 since OUT ENTRY IN B_1 is the empty set and OUT B_1 is gen_{B_1} This value differs from the previous value OUT B_1 oso

CHAPTER 9 MACHINE INDEPENDENT OPTIMIZATIONS

Block B	OUT $B^{\ 0}$	IN B^{-1}	OUT $B^{\ 1}$	IN $B^{\ 2}$	OUT B^{2}
$\overline{B_1}$	000 0000	000 0000	111 0000	000 0000	111 0000
B_2	000 0000	111 0000	001 1100	111 0111	001 1110
B_3	000 0000	001 1100	000 1110	001 1110	000 1110
B_4	000 0000	001 1110	001 0111	001 1110	001 0111
EXIT	000 0000	001 0111	001 0111	001 0111	001 0111

Figure 9 15 Computation of IN and OUT

we now know there is a change on the $\,$ rst round $\,$ and will proceed to a second round

Then we consider $B = B_2$ and compute

This computation is summarized in Fig. 9.15. For instance at the end of the rst pass OUT B_2 1 001 1100 re-ecting the fact that d_4 and d_5 are generated in B_2 while d_3 reaches the beginning of B_2 and is not killed in B_2

Notice that after the second round OUT B_2 has changed to re ect the fact that d_6 also reaches the beginning of B_2 and is not killed by B_2 . We did not learn that fact on the rst pass because the path from d_6 to the end of B_2 which is B_3 and B_4 are is not traversed in that order by a single pass. That is by the time we learn that d_6 reaches the end of B_4 we have already computed IN B_2 and OUT B_2 on the rst pass.

There are no changes in any of the OUT sets after the second pass. Thus after a third pass, the algorithm terminates, with the IN's and OUT's as in the nal two columns of Fig. 9.15 \Box

9 2 5 Live Variable Analysis

Some code improving transformations depend on information computed in the direction opposite to the ow of control in a program we shall examine one such example now In $live\ variable\ analysis$ we wish to know for variable x and point p whether the value of x at p could be used along some path in the ow graph starting at p If so we say x is live at p otherwise x is dead at p

An important use for live variable information is register allocation for basic blocks. Aspects of this issue were introduced in Sections 8.6 and 8.8. After a value is computed in a register, and presumably used within a block, it is not

92 INTRODUCTION TO DATA FLOW ANALYSIS

necessary to store that value if it is dead at the end of the block. Also if all registers are full and we need another register we should favor using a register with a dead value since that value does not have to be stored

Here we de ne the data ow equations directly in terms of IN B and OUT B which represent the set of variables live at the points immediately before and after block B respectively. These equations can also be derived by rst de ning the transfer functions of individual statements and composing them to create the transfer function of a basic block. De ne

- 1 def_B as the set of variables de ned i.e. de nitely assigned values in B prior to any use of that variable in B and
- 2 use_B as the set of variables whose values may be used in B prior to any de nition of the variable

Example 9 13 For instance block B_2 in Fig 9 13 de nitely uses i It also uses j before any rede nition of j unless it is possible that i and j are aliases of one another. Assuming there are no aliases among the variables in Fig 9 13 then use_{B_2} $\{i\ j\}$ Also B_2 clearly de nes i and j Assuming there are no aliases def_{B_2} $\{i\ j\}$ as well. \square

As a consequence of the de nitions any variable in use_B must be considered live on entrance to block B while de nitions of variables in def_B de nitely are dead at the beginning of B In e ect membership in def_B kills any opportunity for a variable to be live because of paths that begin at B

Thus the equations relating def and use to the unknowns IN and OUT are defined as follows

IN EXIT

and for all basic blocks B other than EXIT

IN
$$B$$
 use B OUT B def B OUT B IN B S a successor of B

The rst equation speci es the boundary condition which is that no variables are live on exit from the program. The second equation says that a variable is live coming into a block if either it is used before rede nition in the block or it is live coming out of the block and is not rede ned in the block. The third equation says that a variable is live coming out of a block if and only if it is live coming into one of its successors.

The relationship between the equations for liveness and the reaching defin itions equations should be noticed

Both sets of equations have union as the meet operator. The reason is that in each data ow schema we propagate information along paths and we care only about whether *any* path with desired properties exist rather than whether something is true along *all* paths

However information ow for liveness travels backward opposite to the direction of control ow because in this problem we want to make sure that the use of a variable x at a point p is transmitted to all points prior to p in an execution path so that we may know at the prior point that x will have its value used

To solve a backward problem instead of initializing OUT ENTRY we initialize IN EXIT—Sets IN and OUT have their roles interchanged and use and def substitute for gen and kill respectively. As for reaching de nitions, the solution to the liveness equations is not necessarily unique, and we want the solution with the smallest sets of live variables. The algorithm used is essentially a backwards version of Algorithm 9 11

Algorithm 9 14 Live variable analysis

```

Figure 9 16 Iterative algorithm to compute live variables

9 2 6 Available Expressions

An expression x y is available at a point p if every path from the entry node to p evaluates x y and after the last such evaluation prior to reaching p there are no subsequent assignments to x or y 5 For the available expressions data ow schema we say that a block kills expression x y if it assigns or may

 $^{^5\}mathrm{Note}$ that as usual in this chapter we use the operator — as a generic operator not necessarily standing for addition

92 INTRODUCTION TO DATA FLOW ANALYSIS

assign x or y and does not subsequently recompute x-y. A block generates expression x-y if it definitely evaluates x-y and does not subsequently define x or y

Note that the notion of killing or generating an available expression is not exactly the same as that for reaching de nitions Nevertheless these notions of kill and generate behave essentially as they do for reaching de nitions

The primary use of available expression information is for detecting global common subexpressions. For example, in Fig. 9.17 a, the expression 4i in block B_3 will be a common subexpression if 4i is available at the entry point of block B_3 . It will be available if i is not assigned a new value in block B_2 or if as in Fig. 9.17 b, 4i is recomputed after i is assigned in B_2 .

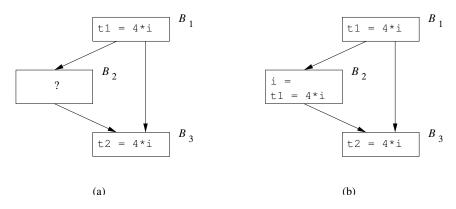

Figure 9 17 Potential common subexpressions across blocks

We can compute the set of generated expressions for each point in a block working from beginning to end of the block. At the point prior to the block no expressions are generated. If at point p set S of expressions is available and q is the point after p with statement $\mathbf{x} = \mathbf{y} \mathbf{z}$ between them, then we form the set of expressions available at q by the following two steps

- 1 Add to S the expression y = z
- 2 Delete from S any expression involving variable x

Note the steps must be done in the correct order as x could be the same as y or z. After we reach the end of the block S is the set of generated expressions for the block. The set of killed expressions is all expressions say y-z such that either y or z is defined in the block and y-z is not generated by the block

Example 9 15 Consider the four statements of Fig. 9 18 After the rst b c is available. After the second statement a d becomes available but b c is no longer available because b has been rede ned. The third statement does not make b c available again because the value of c is immediately changed

After the last statement a-d is no longer available because d has changed Thus no expressions are generated and all expressions involving a-b-c or d are killed \square

Sta	Statement		Available Expressions		
a	b	С	$\{b-c\}$		
b	a	d	$\{a d\}$		
С	b	С	$\{a d\}$		
d	a	d	<u> </u>		

Figure 9 18 Computation of available expressions

We can not available expressions in a manner reminiscent of the way reach ing de nitions are computed Suppose U is the universal set of all expressions appearing on the right of one or more statements of the program. For each block B let IN B be the set of expressions in U that are available at the point just before the beginning of B. Let OUT B be the same for the point following the end of B. De ne e_gen_B to be the expressions generated by B and e_kill_B to be the set of expressions in U killed in B. Note that IN OUT e_gen and e_kill can all be represented by bit vectors. The following equations relate the unknowns IN and OUT to each other and the known quantities e_gen and e_kill

OUT ENTRY

and for all basic blocks B other than entry

OUT
$$B$$
 e_gen_B IN B e_kill_B IN B OUT P

The above equations look almost identical to the equations for reaching de nitions Like reaching de nitions the boundary condition is OUT ENTRY

because at the exit of the ENTRY node there are no available expressions. The most important difference is that the meet operator is intersection rather than union. This operator is the proper one because an expression is available at the beginning of a block only if it is available at the end of all its predecessors. In contrast, a definition reaches the beginning of a block whenever it reaches the end of any one or more of its predecessors.

9 2 INTRODUCTION TO DATA FLOW ANALYSIS

The use of rather than makes the available expression equations behave differently from those of reaching definitions. While neither set has a unique solution for reaching definitions it is the solution with the smallest sets that corresponds to the definition of reaching and we obtained that solution by starting with the assumption that nothing reached anywhere and building up to the solution. In that way we never assumed that a definition d could reach a point p unless an actual path propagating d to p could be found. In contrast for available expression equations we want the solution with the largest sets of available expressions so we start with an approximation that is too large and work down

It may not be obvious that by starting with the assumption—everything i e—the set U—is available everywhere except at the end of the entry block and eliminating only those expressions for which we can discover a path along which it is not available we do reach a set of truly available expressions. In the case of available expressions it is conservative to produce a subset of the exact set of available expressions. The argument for subsets being conservative is that our intended use of the information is to replace the computation of an available expression by a previously computed value. Not knowing an expression is available only inhibits us from improving the code—while believing an expression is available when it is not could cause us to change what the program computes

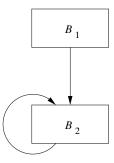

Figure 9 19 Initializing the OUT sets to is too restrictive

Example 9 16 We shall concentrate on a single block B_2 in Fig 9 19 to illustrate the e ect of the initial approximation of OUT B_2 on IN B_2 Let G and K abbreviate $e_gen_{B_2}$ and $e_kill_{B_2}$ respectively. The data ow equations for block B_2 are

IN
$$B_2$$
 OUT B_1 OUT B_2
OUT B_2 G IN B_2 K

These equations may be rewritten as recurrences with I^{j} and O^{j} being the jth

approximations of IN B_2 and OUT B_2 respectively

$$I^{j-1}$$
 OUT B_1 O^j O^{j-1} G I^{j-1} K

Starting with O^0 we get I^1 OUT B_1 O^0 However if we start with O^0 U then we get I^1 OUT B_1 O^0 OUT B_1 as we should Intuitively the solution obtained starting with O^0 U is more desirable because it correctly refects the fact that expressions in OUT B_1 that are not killed by B_2 are available at the end of B_2 \square

Algorithm 9 17 Available expressions

INPUT A ow graph with e_kill_B and e_gen_B computed for each block B The initial block is B_1

OUTPUT IN B and OUT B the set of expressions available at the entry and exit of each block B of the ow graph

METHOD Execute the algorithm of Fig. 9 20. The explanation of the steps is similar to that for Fig. 9 14. \Box

```

OUT B e\_gen_B IN B e\_kill_B
}
```

Figure 9 20 Iterative algorithm to compute available expressions

9 2 7 Summary

In this section we have discussed three instances of data ow problems reach ing de nitions live variables and available expressions. As summarized in Fig. 9.21, the de nition of each problem is given by the domain of the data ow values the direction of the data ow the family of transfer functions the boundary condition and the meet operator. We denote the meet operator generically as

The last row shows the initial values used in the iterative algorithm. These values are chosen so that the iterative algorithm will and the most precise solution to the equations. This choice is not strictly a part of the definition of

92 INTRODUCTION TO DATA FLOW ANALYSIS

the data ow problem since it is an artifact needed for the iterative algorithm There are other ways of solving the problem. For example, we saw how the transfer function of a basic block can be derived by composing the transfer functions of the individual statements in the block, a similar compositional approach may be used to compute a transfer function for the entire procedure or transfer functions from the entry of the procedure to any program point. We shall discuss such an approach in Section 9.7

	Reaching De nitions	Live Variables	Available Expressions	
Domain	Sets of de nitions	Sets of variables	Sets of expressions

Figure 9 21 Summary of three data ow problems

9 2 8 Exercises for Section 9 2

Exercise 9 2 1 For the $\$ ow graph of Fig 9 10 see the exercises for Section 9 1 $\$ compute

- a The gen and kill sets for each block
- b The $\scriptstyle ext{IN}$ and $\scriptstyle ext{OUT}$ sets for each block

Exercise 9 2 2 For the ow graph of Fig 9 10 compute the e_gen e_kill in and out sets for available expressions

Exercise 9 2 3 For the ow graph of Fig 9 10 compute the *def use* IN and OUT sets for live variable analysis

Exercise 9 2 4 Suppose V is the set of complex numbers. Which of the following operations can serve as the meet operation for a semilattice on V

- a Addition a ib c id a c i b d
- b Multiplication a ib c id ac bd i ad bc

Why the Available Expressions Algorithm Works

We need to explain why starting all OUTs except that for the entry block with U the set of all expressions leads to a conservative solution to the data ow equations that is all expressions found to be available really are available. First because intersection is the meet operation in this data ow schema any reason that an expression x-y is found not to be available at a point will propagate forward in the ow graph along all possible paths until x-y is recomputed and becomes available again. Second there are only two reasons x-y could be unavailable

- 1 x y is killed in block B because x or y is defined without a subsequent computation of x y In this case the first time we apply the transfer function f_B x y will be removed from OUT B
- 2 x y is never computed along some path. Since x y is never in OUT ENTRY and it is never generated along the path in question we can show by induction on the length of the path that x y is eventually removed from IN s and OUT s along that path

Thus after changes subside the solution provided by the iterative algorithm of Fig 9 20 will include only truly available expressions

- c Componentwise minimum a ib c id $\min a$ c $i\min b$ d
- d Componentwise maximum a ib c id $\max a c$ $i \max b d$

Exercise 9 2 5 We claimed that if a block B consists of n statements and the ith statement has gen and kill sets gen_i and $kill_i$ then the transfer function for block B has gen and kill sets gen_B and $kill_B$ given by

$$kill_B \quad kill_1 \quad kill_2 \quad kill_n$$

$$gen_B \quad gen_n \quad gen_{n-1} \quad kill_n \quad gen_{n-2} \quad kill_{n-1} \quad kill_n$$
 $gen_1 \quad kill_2 \quad kill_3 \quad kill_n$

Prove this claim by induction on n

Exercise 9 2 6 Prove by induction on the number of iterations of the for loop of lines 4 through 6 of Algorithm 9 11 that none of the IN s or OUT s ever shrinks That is once a de nition is placed in one of these sets on some round it never disappears on a subsequent round

9.2 INTRODUCTION TO DATA FLOW ANALYSIS

Exercise 9 2 7 Show the correctness of Algorithm 9 11 That is show that

- a If de nition d is put in IN B or OUT B then there is a path from d to the beginning or end of block B respectively along which the variable de ned by d might not be rede ned
- b If de nition d is not put in IN B or OUT B then there is no path from d to the beginning or end of block B respectively along which the variable de ned by d might not be rede ned

Exercise 9 2 8 Prove the following about Algorithm 9 14

- a The IN s and OUT s never shrink
- b If variable x is put in IN B or OUT B then there is a path from the beginning or end of block B respectively along which x might be used
- c If variable x is not put in IN B or OUT B then there is no path from the beginning or end of block B respectively along which x might be used

Exercise 9 2 9 Prove the following about Algorithm 9 17

- a The IN s and OUT s never grow that is successive values of these sets are subsets not necessarily proper of their previous values
- b If expression e is removed from IN B or OUT B then there is a path from the entry of the ow graph to the beginning or end of block B respectively along which e is either never computed or after its last computation one of its arguments might be rede ned
- c If expression e remains in IN B or OUT B then along every path from the entry of the ow graph to the beginning or end of block B respectively e is computed and after the last computation no argument of e could be rede ned

Exercise 9 2 10 The astute reader will notice that in Algorithm 9 11 we could have saved some time by initializing OUT B to gen_B for all blocks B Likewise in Algorithm 9 14 we could have initialized IN B to gen_B We did not do so for uniformity in the treatment of the subject as we shall see in Algorithm 9 25 However is it possible to initialize OUT B to e_gen_B in Algorithm 9 17 Why or why not

Exercise 9 2 11 Our data ow analyses so far do not take advantage of the semantics of conditionals Suppose we nd at the end of a basic block a test such as

if x 10 goto

How could we use our understanding of what the test x=10 means to improve our knowledge of reaching de nitions. Remember improve here means that we eliminate certain reaching de nitions that really cannot ever reach a certain program point.

9 3 Foundations of Data Flow Analysis

Having shown several useful examples of the data ow abstraction we now study the family of data ow schemas as a whole abstractly We shall answer several basic questions about data ow algorithms formally

- 1 Under what circumstances is the iterative algorithm used in data ow analysis correct
- 2 How precise is the solution obtained by the iterative algorithm
- 3 Will the iterative algorithm converge
- 4 What is the meaning of the solution to the equations

In Section 9.2 we addressed each of the questions above informally when describing the reaching de nitions problem. Instead of answering the same questions for each subsequent problem from scratch we relied on analogies with the problems we had already discussed to explain the new problems. Here we present a general approach that answers all these questions once and for all rigorously and for a large family of data ow problems. We rst iden tify the properties desired of data ow schemas and prove the implications of these properties on the correctness precision and convergence of the data ow algorithm as well as the meaning of the solution. Thus, to understand old algorithms or formulate new ones we simply show that the proposed data ow problem de nitions have certain properties and the answers to all the above discust questions are available immediately

The concept of having a common theoretical framework for a class of sche mas also has practical implications. The framework helps us identify the reusable components of the algorithm in our software design. Not only is coding e ort reduced but programming errors are reduced by not having to recode similar details several times.

A data ow analysis framework D V F consists of

- 1 A direction of the data ow D which is either FORWARDS or BACKWARDS
- 2 A semilattice see Section 9 3 1 for the de nition which includes a do main of values V and a meet operator
- 3 A family F of transfer functions from V to V. This family must include functions suitable for the boundary conditions, which are constant transfer functions for the special nodes entry and exit in any ow graph

9 3 1 Semilattices

A semilattice is a set V and a binary meet operator—such that for all $x \ y$ and z in V

93 FOUNDATIONS OF DATA FLOW ANALYSIS

 $1 \quad x \quad x \quad x \quad \text{meet is } idempotent$

 $2 \quad x \quad y \quad y \quad x \quad \text{meet is } commutative$

 $3 \quad x \quad y \quad z \quad x \quad y \quad z \quad \text{meet is } associative$

A semilattice has a *top* element denoted such that

for all x in V x x

Optionally a semilattice may have a *bottom* element denoted such that

for all x in V x

Partial Orders

As we shall see the meet operator of a semilattice de nes a partial order on the values of the domain A relation is a partial order on a set V if for all x y and z in V

 $1 \quad x \quad x$ the partial order is re exive

2 If x = y and y = x then x = y the partial order is antisymmetric

3 If x = y and y = z then x = z the partial order is transitive

The pair V is called a *poset* or *partially ordered set* It is also convenient to have a relation for a poset de ned as

x = y if and only if x = y and $x \neq y$

The Partial Order for a Semilattice

It is useful to de ne a partial order for a semilattice V For all x and y in V we de ne

x = y if and only if x = y = x

Because the meet operator is idempotent commutative and associative the order as de ned is re exive antisymmetric and transitive. To see why observe that

Re exivity for all x x x The proof is that x x x since meet is idempotent

Antisymmetry if x y and y x then x y In proof x y means x y x and y x means y x y By commutativity of x x y y x y

Transitivity if x y and y z then x z In proof x y and y z means that x y x and y z y Then x z x y z x y z has been shown we have x z proving transitivity

Example 9 18 The meet operators used in the examples in Section 9 2 are set union and set intersection. They are both idempotent commutative and associative. For set union, the top element is and the bottom element is U, the universal set since for any subset x of U, and U, and U and U are U. For set intersection, is U and is U, the domain of values of the semilattice is the set of all subsets of U, which is sometimes called the *power set* of U and denoted 2^U .

For all x and y in V x y x implies x y therefore the partial order imposed by set union is set inclusion. Correspondingly the partial order imposed by set intersection is set containment. That is for set intersection sets with fewer elements are considered to be smaller in the partial order. However for set union sets with more elements are considered to be smaller in the partial order. To say that sets larger in size are smaller in the partial order is counterintuitive however this situation is an unavoidable consequence of the definitions 6

As discussed in Section 9 2 there are usually many solutions to a set of data ow equations with the greatest solution in the sense of the partial order being the most precise For example in reaching de nitions the most precise among all the solutions to the data ow equations is the one with the smallest number of de nitions which corresponds to the greatest element in the partial order de ned by the meet operation union In available expressions the most precise solution is the one with the largest number of expressions Again it is the greatest solution in the partial order de ned by intersection as the meet operation \Box

Greatest Lower Bounds

There is another useful relationship between the meet operation and the partial ordering it imposes Suppose V is a semilattice A greatest lower bound or glb of domain elements x and y is an element g such that

It turns out that the meet of x and y is their only greatest lower bound. To see why let g = x = y Observe that

 $^{^6}$ And if we de ned the partial order to be $\,$ instead of $\,$ then the problem would surface when the meet was intersection $\,$ although not for union

Joins Lubs and Lattices

In symmetry to the glb operation on elements of a poset we may de ne the *least upper bound* or lub of elements x and y to be that element b such that x b y b and if z is any element such that x z and y z then b z One can show that there is at most one such element b if it exists

In a true *lattice* there are two operations on domain elements the meet—which we have seen and the operator *join* denoted—which gives the lub of two elements which therefore must always exist in the lattice—We have been discussing only—semi lattices where only one of the meet and join operators exist—That is our semilattices are *meet semilattices*—One could also speak of *join semilattices*—where only the join operator exists—and in fact some literature on program analysis does use the notation of join semilattices—Since the traditional data—ow literature speaks of meet semilattices—we shall also do so in this book

g x because x y x x y The proof involves simple uses of associativity commutativity and idempotence That is

g y by a similar argument

Lattice Diagrams

It often helps to draw the domain V as a lattice diagram which is a graph whose nodes are the elements of V and whose edges are directed downward from x to y if y x For example Fig 9 22 shows the set V for a reaching denitions data ow schema where there are three denitions d_1 d_2 and d_3 Since is an edge is directed downward from any subset of these three denitions to each of its supersets. Since is transitive we conventionally omit the edge from x

to y as long as there is another path from x to y left in the diagram. Thus although $\{d_1 \ d_2 \ d_3\}$ $\{d_1\}$ we do not draw this edge since it is represented by the path through $\{d_1 \ d_2\}$ for example

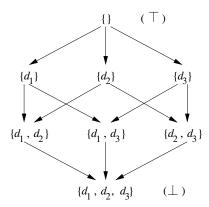

Figure 9 22 Lattice of subsets of de nitions

It is also useful to note that we can read the meet os uch diagrams. Since x y is the glb it is always the highest z for which there are paths downward to z from both x and y. For example, if x is $\{d_1\}$ and y is $\{d_2\}$, then z in Fig. 9.22 is $\{d_1, d_2\}$ which makes sense because the meet operator is union. The top element will appear at the top of the lattice diagram, that is there is a path downward from to each element. Likewise, the bottom element will appear at the bottom with a path downward from every element to

Product Lattices

While Fig 922 involves only three denitions the lattice diagram of a typical program can be quite large. The set of data ow values is the power set of the denitions which therefore contains 2^n elements if there are n denitions in the program. However, whether a denition reaches a program is independent of the reachability of the other denitions. We may thus express the lattice of denitions in terms of a product lattice built from one simple lattice for each denition. That is if there were only one denition d in the program then the lattice would have two elements. $\{\}$ the empty set which is the top element and $\{d\}$ which is the bottom element.

Formally we may build product lattices as follows Suppose A and B are semi-lattices. The *product lattice* for these two lattices is defined as follows

1 The domain of the product lattice is A B

⁷In this discussion and subsequently we shall often drop the semi since lattices like the one under discussion do have a join or lub operator even if we do not make use of it

93 FOUNDATIONS OF DATA FLOW ANALYSIS

2 The meet for the product lattice is de ned as follows. If a b and a' b' are domain elements of the product lattice, then

$$a \ b \quad a' \ b' \quad a \quad A \quad a' \quad b \quad B \quad b'$$

It is simple to express the partial order for the product lattice in terms of the partial orders A and B for A and B

$$a \ b \ a' \ b'$$
 if and only if $a \ A \ a'$ and $b \ B \ b'$ 9 20

To see why 9 20 follows from 9 19 observe that

$$a \ b \qquad a' \ b' \qquad a \quad {}_A \ a' \ b \quad {}_B \ b'$$

So we might ask under what circumstances does a $_Aa'$ b $_Bb'$ a b That happens exactly when a $_A$ a' a and b $_B$ b' b But these two conditions are the same as a $_A$ a' and b $_B$ b'

The product of lattices is an associative operation so one can show that the rules 9 19 and 9 20 extend to any number of lattices. That is if we are given lattices A_{i} i for i 1 2 k then the product of all k lattices in this order has domain A_1 A_2 A_k a meet operator defined by

$$a_1 \ a_2 \qquad a_k \qquad b_1 \ b_2 \qquad b_k \qquad a_{1-1} \ b_1 \ a_{2-2} \ b_2 \qquad a_{k-k} \ b_k$$

and a partial order de ned by

$$a_1 \ a_2 \qquad a_k \qquad b_1 \ b_2 \qquad b_k$$
 if and only if $a_i \quad b_i$ for all i

Height of a Semilattice

We may learn something about the rate of convergence of a data ow analysis algorithm by studying the height of the associated semilattice An ascending chain in a poset V is a sequence where x_1 x_2 x_n . The height of a semilattice is the largest number of relations in any ascending chain that is the height is one less than the number of elements in the chain. For example, the height of the reaching definitions semilattice for a program with n definitions is n

Showing convergence of an iterative data ow algorithm is much easier if the semilattice has nite height Clearly a lattice consisting of a nite set of values will have a nite height it is also possible for a lattice with an in nite number of values to have a nite height The lattice used in the constant propagation algorithm is one such example that we shall examine closely in Section 9 4

9 3 2 Transfer Functions

The family of transfer functions $F \ V \ V$ in a data ow framework has the following properties

- 1 F has an identity function I such that I x = x for all x in V
- 2 F is closed under composition that is for any two functions f and g in F the function h de ned by h x g f x is in F

Example 9 21 In reaching de nitions F has the identity the function where gen and kill are both the empty set. Closure under composition was actually shown in Section 9 2 4 we repeat the argument succinctly here. Suppose we have two functions

$$f_1 x = G_1 = x = K_1$$
 and $f_2 x = G_2 = x = K_2$

Then

$$f_2$$
 f_1 x G_2 G_1 x K_1 K_2

The right side of the above is algebraically equivalent to

$$G_2$$
 G_1 K_2 x K_1 K_2

If we let K K_1 K_2 and G G_2 G_1 K_2 then we have shown that the composition of f_1 and f_2 which is f x G x K is of the form that makes it a member of F If we consider available expressions the same arguments used for reaching definitions also show that F has an identity and is closed under composition \square

Monotone Frameworks

To make an iterative algorithm for data ow analysis work we need for the data ow framework to satisfy one more condition. We say that a framework is monotone if when we apply any transfer function f in F to two members of V the rst being no greater than the second, then the rst result is no greater than the second result

Formally a data ow framework D F V is monotone if

For all
$$x$$
 and y in V and f in F x y implies f x f y 9 22

Equivalently monotonicity can be de ned as

For all
$$x$$
 and y in V and f in F f x y f x f y 9 23

Equation 923 says that if we take the meet of two values and then apply f the result is never greater than what is obtained by applying f to the values individually rst and then meeting the results Because the two de nitions of monotonicity seem so dierent they are both useful. We shall not one or the other more useful under dierent circumstances. Later we sketch a proof to show that they are indeed equivalent

93 FOUNDATIONS OF DATA FLOW ANALYSIS

We shall rst assume 9 22 and show that 9 23 holds Since x-y is the greatest lower bound of x and y we know that

$$x \quad y \quad x \text{ and } x \quad y \quad y$$

Thus by 922

$$f x y f x$$
 and $f x y f y$

Since f x f y is the greatest lower bound of f x and f y we have 9 23 Conversely let us assume 9 23 and prove 9 22 We suppose x y and use 9 23 to conclude f x f y thus proving 9 22 Equation 9 23 tells us

But since x = y is assumed x = y = x by definition. Thus 9.23 says

$$f x \qquad f x \qquad f y$$

Since f(x) = f(y) is the glb of f(x) and f(y) we know f(x) = f(y). Thus

$$f x \qquad f x \qquad f y \qquad f y$$

and 923 implies 922

Distributive Frameworks

Often a framework obeys a condition stronger than 9.23 which we call the $distributivity\ condition$

for all x and y in V and f in F Certainly if a b then a b a by idempotence so a b Thus distributivity implies monotonicity although the converse is not true

Example 9 24 Let y and z be sets of de nitions in the reaching de nitions framework. Let f be a function de ned by f x G x K for some sets of de nitions G and K. We can verify that the reaching de nitions framework satisfies es the distributivity condition by checking that

$$G$$
 y z K G y K G z K

While the equation above may appear formidable consider rst those de nitions in G These de nitions are surely in the sets de ned by both the left and right sides. Thus we have only to consider de nitions that are not in G. In that case we can eliminate G everywhere and verify the equality

$$y \quad z \quad K \quad y \quad K \quad z \quad K$$

The latter equality is easily checked using a Venn diagram \Box

9 3 3 The Iterative Algorithm for General Frameworks

We can generalize Algorithm 9 11 to make it work for a large variety of data ow problems

Algorithm 9 25 Iterative solution to general data ow frameworks

INPUT A data ow framework with the following components

- 1 A data ow graph with specially labeled ENTRY and EXIT nodes
- 2 A direction of the data ow D
- 3 A set of values V
- 4 A meet operator
- 5 A set of functions F where f_B in F is the transfer function for block B and
- 6 A constant value v_{entry} or v_{exit} in V representing the boundary condition for forward and backward frameworks respectively

OUTPUT Values in V for IN B and OUT B for each block B in the data ow graph

METHOD The algorithms for solving forward and backward data ow problems are shown in Fig 9 23 a and 9 23 b respectively. As with the familiar iterative data ow algorithms from Section 9 2 we compute IN and OUT for each block by successive approximation □

It is possible to write the forward and backward versions of Algorithm 9 25 so that a function implementing the meet operation is a parameter as is a function that implements the transfer function for each block. The ow graph itself and the boundary value are also parameters. In this way the compiler implementor can avoid recoding the basic iterative algorithm for each data—ow framework used by the optimization phase of the compiler

We can use the abstract framework discussed so far to prove a number of useful properties of the iterative algorithm

- 1 If Algorithm 9 25 converges the result is a solution to the data ow equations
- 2 If the framework is monotone then the solution found is the maximum xedpoint MFP of the data ow equations A maximum xedpoint is a solution with the property that in any other solution the values of IN B and OUT B are the corresponding values of the MFP
- 3 If the semilattice of the framework is monotone and of nite height then the algorithm is guaranteed to converge

6 IN B \ f_B \text{ OUT } B
}
```

b Iterative algorithm for a backward data ow problem

Figure 9 23 Forward and backward versions of the iterative algorithm

We shall argue these points assuming that the framework is forward. The case of backwards frameworks is essentially the same. The rst property is easy to show. If the equations are not satisted by the time the while loop ends then there will be at least one change to an OUT in the forward case or IN in the backward case, and we must go around the loop again.

To prove the second property we set show that the values taken on by IN B and OUT B for any B can only decrease in the sense of the sense of the relationship for lattices as the algorithm iterates. This claim can be proven by induction

BASIS The base case is to show that the value of IN B and OUT B after the rst iteration is not greater than the initialized value. This statement is trivial because IN B and OUT B for all blocks B / ENTRY are initialized with

INDUCTION Assume that after the kth iteration the values are all no greater than those after the k-1 st iteration and show the same for iteration k-1 compared with iteration k-1 Line 5 of Fig 9 23 a has

IN
$$B$$
 OUT P

Let us use the notation in B^i and out B^i to denote the values of in B and out B after iteration i. Assuming out P^k out P^{k-1} we know that in B^{k-1} in B^k because of the properties of the meet operator. Next line 6

says

OUT
$$B$$
 f_B IN B

Since IN B^{k-1} IN B^k we have OUT B^{k-1} OUT B^k by monotonicity

Note that every change observed for values of IN B and OUT B is necessary to satisfy the equation. The meet operators return the greatest lower bound of their inputs and the transfer functions return the only solution that is consistent with the block itself and its given input. Thus, if the iterative algorithm terminates the result must have values that are at least as great as the corresponding values in any other solution, that is the result of Algorithm 9.25 is the MFP of the equations

Finally consider the third point where the data ow framework has nite height Since the values of every IN B and OUT B decrease with each change and the algorithm stops if at some round nothing changes the algorithm is guaranteed to converge after a number of rounds no greater than the product of the height of the framework and the number of nodes of the ow graph

9 3 4 Meaning of a Data Flow Solution

We now know that the solution found using the iterative algorithm is the max imum—xedpoint—but what does the result represent from a program semantics point of view—To understand the solution of a data—ow framework— $D\ F\ V$ —let us—rst describe what an ideal solution to the framework would be—We show that the ideal cannot be obtained in general—but that Algorithm 9 25 approximates the ideal conservatively

The Ideal Solution

Without loss of generality we shall assume for now that the data—ow framework of interest is a forward—owing problem—Consider the entry point of a basic block B—The ideal solution begins by—nding all the possible execution paths leading from the program entry to the beginning of B—A path is—possible only if there is some computation of the program that follows exactly that path. The ideal solution would then compute the data—ow value at the end of each possible path and apply the meet operator to these values to—nd their greatest lower bound—Then no execution of the program can produce a smaller value for that program point—In addition—the bound is tight—there is no greater data—ow value that is a glb for the value computed along every possible path to B in the—ow graph

We now try to de ne the ideal solution more formally For each block B in a ow graph let f_B be the transfer function for B Consider any path

$$P$$
 ENTRY B_1 B_2 B_{k-1} B_k

from the initial node ENTRY to some block B_k The program path may have cycles so one basic block may appear several times on the path P De ne the

93 FOUNDATIONS OF DATA FLOW ANALYSIS

transfer function for P f_P to be the composition of f_{B_1} f_{B_2} $f_{B_{k-1}}$ Note that f_{B_k} is not part of the composition reflecting the fact that this path is taken to reach the beginning of block B_k not its end. The data ow value created by executing this path is thus f_P v_{ENTRY} where v_{ENTRY} is the result of the constant transfer function representing the initial node ENTRY. The ideal result for block B is thus

IDEAL
$$B$$
 $f_P \ v_{ ext{Entry}}$ P a possible path from ENTRY to B

We claim that in terms of the lattice theoretic partial order for the framework in question

Any answer that is greater than IDEAL is incorrect

Any value smaller than or equal to the ideal is conservative i.e. safe

Intuitively the closer the value to the ideal the more precise it is ⁸ To see why solutions must be the ideal solution note that any solution greater than IDEAL for any block could be obtained by ignoring some execution path that the program could take and we cannot be sure that there is not some e ect along that path to invalidate any program improvement we might make based on the greater solution Conversely any solution less than IDEAL can be viewed as including certain paths that either do not exist in the ow graph or that exist but that the program can never follow This lesser solution will allow only transformations that are correct for all possible executions of the program but may forbid some transformations that IDEAL would permit

The Meet Over Paths Solution

However as discussed in Section 9.1 nding all possible execution paths is undecidable. We must therefore approximate. In the data own abstraction we assume that every path in the own graph can be taken. Thus we can de not the meet over paths solution for B to be

MOP
$$B$$

$$P \ \ \mbox{a path from entry to} \ \ B$$

Note that as for IDEAL the solution MOP B gives values for IN B in forward ow frameworks. If we were to consider backward ow frameworks then we would think of MOP B as a value for OUT B

The paths considered in the MOP solution are a superset of all the paths that are possibly executed. Thus, the MOP solution meets together not only the data—ow values of all the executable paths—but also additional values associated

⁸Note that in forward problems the value <code>ideal</code> B is what we would like <code>in</code> B to be In backward problems which we do not discuss here we would de ne <code>ideal</code> B to be the ideal value of <code>out</code> B

with the paths that cannot possibly be executed. Taking the meet of the ideal solution plus additional terms cannot create a solution larger than the ideal. Thus, for all B we have MOP B IDEAL B and we will simply say that MOP IDEAL

The Maximum Fixedpoint Versus the MOP Solution

Notice that in the MOP solution the number of paths considered is still un bounded if the ow graph contains cycles. Thus the MOP de nition does not lend itself to a direct algorithm. The iterative algorithm certainly does not rst nd all the paths leading to a basic block before applying the meet operator Rather.

- 1 The iterative algorithm visits basic blocks not necessarily in the order of execution
- 2 At each con uence point the algorithm applies the meet operator to the data ow values obtained so far Some of these values used were introduced articially in the initialization process not representing the result of any execution from the beginning of the program

So what is the relationship between the MOP solution and the solution MFP produced by Algorithm 9 25

We rst discuss the order in which the nodes are visited. In an iteration we may visit a basic block before having visited its predecessors. If the predecessor is the ENTRY node OUT ENTRY would have already been initialized with the proper constant value. Otherwise it has been initialized to a value no smaller than the nal answer By monotonicity the result obtained by using as input is no smaller than the desired solution. In a sense, we can think of as representing no information.

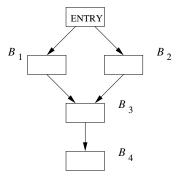

Figure 9 24 Flow graph illustrating the e ect of early meet over paths

What is the e ect of applying the meet operator early Consider the simple example of Fig 9 24 and suppose we are interested in the value of IN B_4 By

93 FOUNDATIONS OF DATA FLOW ANALYSIS

the de nition of MOP

Mop
$$B_4$$
 f_{B_3} f_{B_1} f_{B_3} f_{B_2} $v_{\mathtt{entry}}$

In the iterative algorithm if we visit the nodes in the order B_1 B_2 B_3 B_4 then

IN
$$B_4$$
 f_{B_3} f_{B_1} v_{ENTRY} f_{B_2} v_{ENTRY}

While the meet operator is applied at the end in the de nition of MOP the iterative algorithm applies it early. The answer is the same only if the data ow framework is distributive. If the data ow framework is monotone but not distributive we still have IN B_4 MOP B_4 Recall that in general a solution IN B is safe conservative if IN B IDEAL B for all blocks B Surely MOP B IDEAL B

We now provide a quick sketch of why in general the MFP solution provided by the iterative algorithm is always safe. An easy induction on i shows that the values obtained after i iterations are smaller than or equal to the meet over all paths of length i or less. But the iterative algorithm terminates only if it arrives at the same answer as would be obtained by iterating an unbounded number of times. Thus the result is no greater than the MOP solution. Since MOP—IDEAL and MFP—MOP we know that MFP—IDEAL and therefore the solution MFP provided by the iterative algorithm is safe.

9 3 5 Exercises for Section 9 3

Exercise 9 3 1 Construct a lattice diagram for the product of three lattices each based on a single de nition d_i for i=1,2,3 How is your lattice diagram related to that in Fig. 9.22

Exercise 9 3 2 In Section 9 3 3 we argued that if the framework has nite height then the iterative algorithm converges. Here is an example where the framework does not have nite height and the iterative algorithm does not converge. Let the set of values V be the nonnegative real numbers and let the meet operator be the minimum. There are three transfer functions

- i The identity $f_I x = x$
- ii half that is the function $f_H x = x + 2$
- iii one that is the function $f_O x$

The set of transfer functions F is these three plus the functions formed by composing them in all possible ways

- a Describe the set F
- b What is the relationship for this framework

- c Give an example of a ow graph with assigned transfer functions such that Algorithm 9 25 does not converge
- d Is this framework monotone Is it distributive

Exercise 9 3 3 We argued that Algorithm 9 25 converges if the framework is monotone and of nite height Here is an example of a framework that shows monotonicity is essential nite height is not enough. The domain V is $\{1\ 2\}$ the meet operator is min and the set of functions F is only the identity f_I and the switch function f_S x 3 x that swaps 1 and 2

- a Show that this framework is of nite height but not monotone
- b Give an example of a ow graph and assignment of transfer functions so that Algorithm 9 25 does not converge

Exercise 9 3 4 Let MOP_i B be the meet over all paths of length i or less from the entry to block B Prove that after i iterations of Algorithm 9 25 IN B MOP_i B Also show that as a consequence if Algorithm 9 25 converges then it converges to something that is the MOP solution

Exercise 9 3 5 Suppose the set F of functions for a framework are all of gen kill form. That is the domain V is the power set of some set and f x G x K for some sets G and K. Prove that if the meet operator is either a union or g intersection, then the framework is distributive

94 Constant Propagation

All the data ow schemas discussed in Section 9 2 are actually simple examples of distributive frameworks with nite height. Thus the iterative Algorithm 9 25 applies to them in either its forward or backward version and produces the MOP solution in each case. In this section, we shall examine in detail a useful data ow framework with more interesting properties.

Recall that constant propagation or constant folding replaces expressions that evaluate to the same constant every time they are executed by that constant The constant propagation framework described below is different from all the data ow problems discussed so far in that

- a it has an unbounded set of possible data ow values even for a xed ow graph and
- b it is not distributive

Constant propagation is a forward data ow problem. The semilattice representing the data ow values and the family of transfer functions are presented next.

9 4 1 Data Flow Values for the Constant Propagation Framework

The set of data ow values is a product lattice with one component for each variable in a program The lattice for a single variable consists of the following

- 1 All constants appropriate for the type of the variable
- 2 The value NAC which stands for not a constant A variable is mapped to this value if it is determined not to have a constant value. The variable may have been assigned an input value or derived from a variable that is not a constant or assigned dierent constants along dierent paths that lead to the same program point.
- 3 The value UNDEF which stands for unde ned A variable is assigned this value if nothing may yet be asserted presumably no de nition of the variable has been discovered to reach the point in question

Note that NAC and UNDEF are not the same they are essentially opposites NAC says we have seen so many ways a variable could be de ned that we know it is not constant UNDEF says we have seen so little about the variable that we cannot say anything at all

The semilattice for a typical integer valued variable is shown in Fig. 9.25 Here the top element is UNDEF and the bottom element is NAC. That is, the greatest value in the partial order is UNDEF and the least is NAC. The constant values are unordered but they are all less than UNDEF and greater than NAC. As discussed in Section 9.3.1, the meet of two values is their greatest lower bound. Thus, for all values v

UNDEF
$$v = v$$
 and NAC $v = v$ NAC

For any constant c

$$c$$
 c c

and given two distinct constants c_1 and c_2

$$c_1$$
 c_2 NAC

A data ow value for this framework is a map from each variable in the program to one of the values in the constant semilattice. The value of a variable v in a map m is denoted by m v

9 4 2 The Meet for the Constant Propagation Framework

The semilattice of data ow values is simply the product of the semilattices like Fig 9 25 one for each variable. Thus m-m' if and only if for all variables v we have $m\ v-m'\ v$. Put another way m-m'-m'' if $m''\ v-m\ v-m'\ v$ for all variables v

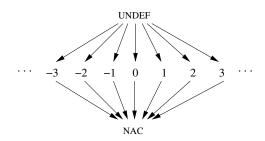

Figure 9 25 Semilattice representing the possible values of a single integer variable

9 4 3 Transfer Functions for the Constant Propagation Framework

We assume in the following that a basic block contains only one statement Transfer functions for basic blocks containing several statements can be constructed by composing the functions corresponding to individual statements. The set F consists of certain transfer functions that accept a map of variables to values in the constant lattice and return another such map

F contains the identity function which takes a map as input and returns the same map as output F also contains the constant transfer function for the ENTRY node. This transfer function given any input map returns a map m_0 where m_0 v UNDEF for all variables v. This boundary condition makes sense because before executing any program statements there are no definitions for any variables.

In general let f_s be the transfer function of statement s and let m and m' represent data—ow values such that $m'-f_s$ —We shall describe f_s in terms of the relationship between m and m'

- 1 If s is not an assignment statement then f_s is simply the identity function
- 2 If s is an assignment to variable x then m'v m v for all variables v / x and m'x is defined as follows
 - a If the right hand side RHS of the statement s is a constant c then m' r .
 - b If the RHS is of the form y = z then⁹

$$m'x$$
 if my and mz are constant values $m'x$ NAC if either my or mz is NAC UNDEF otherwise

c If the RHS is any other expression e.g. a function call or assignment through a pointer then m' x NAC

⁹As usual represents a generic operator not necessarily addition

9 4 4 Monotonicity of the Constant Propagation Framework

Let us show that the constant propagation framework is monotone First we can consider the e ect of a function f_s on a single variable. In all but case 2 b f_s either does not change the value of m x or it changes the map to return a constant or NAC. In these cases f_s must surely be monotone

For case 2 b—the e ect of f_s is tabulated in Fig 9 26. The —rst and second columns represent the possible input values of y and z—the last represents the output value of x—The values are ordered from the greatest to the smallest in each column or subcolumn. To show that the function is monotone we check that for each possible input value of y—the value of x does not get bigger as the value of z gets smaller. For example in the case where y has a constant value c_1 —as the value of z varies from UNDEF to c_2 to NAC—the value of x varies from UNDEF to c_1 — c_2 —and then to NAC—respectively. We can repeat this procedure for all the possible values of y—Because of symmetry—we do not even need to repeat the procedure for the second operand before we conclude that the output value cannot get larger as the input gets smaller

m y	m z	m'x	
	UNDEF	UNDEF	
UNDEF	c_2	UNDEF	
	NAC	NAC	
	UNDEF	UNDEF	
c_1	c_2	c_1 c_2	
	NAC	NAC	
	UNDEF NAC		
NAC	c_2	NAC	
	NAC	NAC	

Figure 9 26 The constant propagation transfer function for x y z

9 4 5 Nondistributivity of the Constant Propagation Framework

The constant propagation framework as de ned is monotone but not distributive. That is the iterative solution MFP is safe but may be smaller than the MOP solution. An example will prove that the framework is not distributive.

Example 9 26 In the program in Fig. 9.27 x and y are set to 2 and 3 in block B_1 and to 3 and 2 respectively in block B_2 . We know that regardless of which path is taken the value of z at the end of block B_3 is 5. The iterative algorithm does not discover this fact however. Rather it applies the meet operator at the entry of B_3 getting NAC s as the values of x and y. Since adding two NAC s

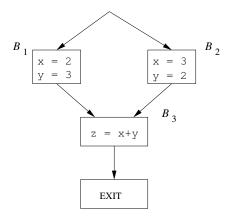

Figure 9 27 An example demonstrating that the constant propagation frame work is not distributive

yields a NAC the output produced by Algorithm 9 25 is that z NAC at the exit of the program. This result is safe but imprecise. Algorithm 9 25 is imprecise because it does not keep track of the correlation that whenever x is 2 y is 3 and vice versa. It is possible but significantly more expensive to use a more complex framework that tracks all the possible equalities that hold among pairs of expressions involving the variables in the program, this approach is discussed in Exercise 9 4 2

Theoretically we can attribute this loss of precision to the nondistributivity of the constant propagation framework. Let f_1 f_2 and f_3 be the transfer functions representing blocks B_1 B_2 and B_3 respectively. As shown in Fig 9 28

$$f_3 \ f_1 \ m_0 \ f_2 \ m_0 \ f_3 \ f_1 \ m_0 \ f_3 \ f_2 \ m_0$$

rendering the framework nondistributive \Box

\overline{m}	m x	m y	m z

f_3 f_2 m_0	3	2	5
$f_3 f_1 m_0 \qquad f_3 f_2 m_0$	NAC	NAC	5

Figure 9 28 Example of nondistributive transfer functions

9 4 6 Interpretation of the Results

The value UNDEF is used in the iterative algorithm for two purposes to initialize the ENTRY node and to initialize the interior points of the program before the iterations. The meaning is slightly different in the two cases. The first says that variables are underned at the beginning of the program execution, the second says that for lack of information at the beginning of the iterative process, we approximate the solution with the top element UNDEF. At the end of the iterative process, the variables at the exit of the ENTRY node will still hold the UNDEF value since OUT ENTRY never changes.

It is possible that UNDEFs may show up at some other program points. When they do it means that no de nitions have been observed for that variable along any of the paths leading up to that program point. Notice that with the way we de ne the meet operator as long as there exists a path that de ness a variable reaching a program point, the variable will not have an UNDEF value. If all the de nitions reaching a program point have the same constant value the variable is considered a constant even though it may not be de ned along some program path.

By assuming that the program is correct the algorithm can nd more constants than it otherwise would. That is the algorithm conveniently chooses some values for those possibly unde ned variables in order to make the program more e-cient. This change is legal in most programming languages since unde ned variables are allowed to take on any value. If the language semantics requires that all unde ned variables be given some speci-c value, then we must change our problem formulation accordingly. And if instead we are interested in nding possibly unde ned variables in a program, we can formulate a di-erent data—ow analysis to provide that result—see Exercise 9.4.1

Example 9 27 In Fig 9 29 the values of x are 10 and UNDEF at the exit of basic blocks B_2 and B_3 respectively Since UNDEF 10 10 the value of x is 10 on entry to block B_4 Thus block B_5 where x is used can be optimized by replacing x by 10 Had the path executed been B_1 B_3 B_4 B_5 the value of x reaching basic block B_5 would have been unde ned So it appears incorrect to replace the use of x by 10

However if it is impossible for predicate Q to be false while Q' is true then this execution path never occurs. While the programmer may be aware of that fact it may well be beyond the capability of any data ow analysis to determine. Thus if we assume that the program is correct and that all the variables are defined before they are used it is indeed correct that the value of x at the beginning of basic block B_5 can only be 10. And if the program is incorrect to begin with then choosing 10 as the value of x cannot be worse than allowing x to assume some random value.

9 4 7 Exercises for Section 9 4

Exercise 9 4 1 Suppose we wish to detect all possibility of a variable being

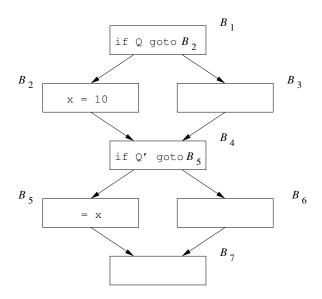

Figure 9 29 Meet of UNDEF and a constant

uninitialized along any path to a point where it is used How would you modify the framework of this section to detect such situations

Exercise 9 4 2 An interesting and powerful data ow analysis framework is obtained by imagining the domain V to be all possible partitions of expressions so that two expressions are in the same class if and only if they are certain to have the same value along any path to the point in question. To avoid having to list an in nity of expressions we can represent V by listing only the minimal pairs of equivalent expressions. For example, if we execute the statements

then the minimal set of equivalences is $\{a \quad b \quad c \quad a \quad d\}$ From these follow other equivalences such as $c \quad b \quad d$ and $a \quad e \quad b \quad e$ but there is no need to list these explicitly

- a What is the appropriate meet operator for this framework
- b Give a data structure to represent domain values and an algorithm to implement the meet operator
- c What are the appropriate functions to associate with statements Explain the e ect that a statement such as a $\,$ b $\,$ c should have on a partition of expressions i.e on a value in V
- d Is this framework monotone Distributive

9 5 Partial Redundancy Elimination

In this section we consider in detail how to minimize the number of expression evaluations. That is we want to consider all possible execution sequences in a ow graph and look at the number of times an expression such as x-y is evaluated. By moving around the places where x-y is evaluated and keeping the result in a temporary variable when necessary we often can reduce the number of evaluations of this expression along many of the execution paths while not increasing that number along any path. Note that the number of di erent places in the ow graph where x-y is evaluated may increase but that is relatively unimportant as long as the number of evaluations of the expression x-y is reduced

Applying the code transformation developed here improves the performance of the resulting code since as we shall see an operation is never applied unless it absolutely has to be Every optimizing compiler implements something like the transformation described here even if it uses a less aggressive algorithm than the one of this section. However, there is another motivation for discussing the problem. Finding the right place or places in the low graph at which to evaluate each expression requires four different kinds of data low analyses. Thus, the study of partial redundancy elimination as minimizing the number of expression evaluations is called will enhance our understanding of the role data low analysis plays in a compiler

Redundancy in programs exists in several forms. As discussed in Section 9.1.4 it may exist in the form of common subexpressions where several evaluations of the expression produce the same value. It may also exist in the form of a loop invariant expression that evaluates to the same value in every iteration of the loop. Redundancy may also be partial if it is found along some of the paths but not necessarily along all paths. Common subexpressions and loop invariant expressions can be viewed as special cases of partial redundancy thus a single partial redundancy elimination algorithm can be devised to eliminate all the various forms of redundancy

In the following we rst discuss the di erent forms of redundancy in order to build up our intuition about the problem. We then describe the generalized redundancy elimination problem and nally we present the algorithm. This algorithm is particularly interesting because it involves solving multiple data ow problems in both the forward and backward directions

9 5 1 The Sources of Redundancy

Figure 9 30 illustrates the three forms of redundancy common subexpressions loop invariant expressions and partially redundant expressions. The gure shows the code both before and after each optimization

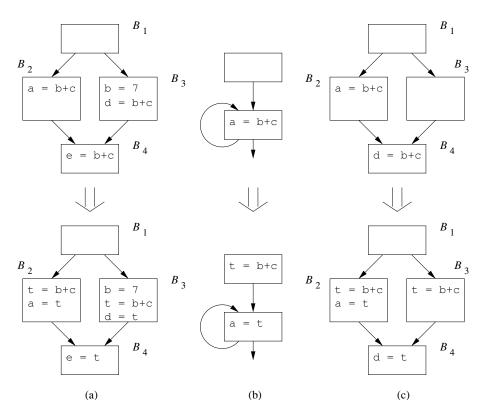

Figure 9 30 Examples of a global common subexpression b loop invariant code motion c partial redundancy elimination

Global Common Subexpressions

In Fig 9 30 a the expression b c computed in block B_4 is redundant it has already been evaluated by the time the ow of control reaches B_4 regardless of the path taken to get there. As we observe in this example, the value of the expression may be different on different paths. We can optimize the code by storing the result of the computations of b c in blocks B_2 and B_3 in the same temporary variable say t and then assigning the value of t to the variable e in block B_4 instead of reevaluating the expression. Had there been an assignment to either b or c after the last computation of b c but before block B_4 the expression in block B_4 would not be redundant

Formally we say that an expression b-c is fully redundant at point p if it is an available expression in the sense of Section 9.2.6 at that point. That is the expression b-c has been computed along all paths reaching p and the variables b and c were not rede ned after the last expression was evaluated. The latter condition is necessary because even though the expression b-c is textually executed before reaching the point p the value of b-c computed at

Finding Deep Common Subexpressions

Using available expressions analysis to identify redundant expressions only works for expressions that are textually identical. For example, an application of common subexpression elimination will recognize that t1 in the code fragment.

t1 b ca t1 d

has the same value as does t2 in

t2 b c e t2 d

as long as the variables b and c have not been rede ned in between. It does not however recognize that a and e are also the same. It is possible to nd such deep common subexpressions by re applying common subexpression elimination until no new common subexpressions are found on one round. It is also possible to use the framework of Exercise 9.4.2 to catch deep common subexpressions

point p would have been dierent because the operands might have changed

Loop Invariant Expressions

Fig 9 30 b shows an example of a loop invariant expression. The expression b c is loop invariant assuming neither the variable b nor c is rede ned within the loop. We can optimize the program by replacing all the re-executions in a loop by a single calculation outside the loop. We assign the computation to a temporary variable say t and then replace the expression in the loop by t. There is one more point we need to consider when performing code motion optimizations such as this. We should not execute any instruction that would not have executed without the optimization. For example, if it is possible to exit the loop without executing the loop invariant instruction at all, then we should not move the instruction out of the loop. There are two reasons

- 1 If the instruction raises an exception then executing it may throw an exception that would not have happened in the original program
- 2 When the loop exits early the optimized program takes more time than the original program

To ensure that loop invariant expressions in while loops can be optimized compilers typically represent the statement

```
while c
```

in the same way as the statement

```
if c
    repeat
    S
    until not c
```

In this way loop invariant expressions can be placed just prior to the repeat until construct

Unlike common subexpression elimination—where a redundant expression computation is simply dropped—loop invariant expression elimination requires an expression from inside the loop to move outside the loop—Thus—this opti mization is generally known as—loop invariant code motion—Loop invariant code motion may need to be repeated—because once a variable is determined to to have a loop invariant value—expressions using that variable may also become loop invariant

Partially Redundant Expressions

An example of a partially redundant expression is shown in Fig 9 30 c. The expression b c in block B_4 is redundant on the path B_1 B_2 B_4 but not on the path B_1 B_3 B_4 We can eliminate the redundancy on the former path by placing a computation of b c in block B_3 . All the results of b c are written into a temporary variable t and the calculation in block B_4 is replaced with t. Thus like loop invariant code motion partial redundancy elimination requires the placement of new expression computations

9 5 2 Can All Redundancy Be Eliminated

Is it possible to eliminate all redundant computations along every path. The answer is no unless we are allowed to change the ow graph by creating new blocks

Example 9 28 In the example shown in Fig 9 31 a the expression of b c is computed redundantly in block B_4 if the program follows the execution path B_1 B_2 B_4 However we cannot simply move the computation of b c to block B_3 because doing so would create an extra computation of b c when the path B_1 B_3 B_5 is taken

What we would like to do is to insert the computation of b c only along the edge from block B_3 to block B_4 We can do so by placing the instruction in a new block say B_6 and making the ow of control from B_3 go through B_6 before it reaches B_4 The transformation is shown in Fig. 9.31 b

95 PARTIAL REDUNDANCY ELIMINATION

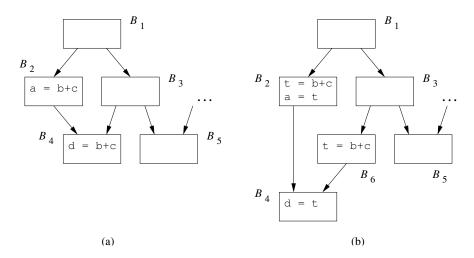

Figure 9 31 B_3 B_4 is a critical edge

We de ne a critical edge of a ow graph to be any edge leading from a node with more than one successor to a node with more than one predecessor. By introducing new blocks along critical edges we can always not a block to accommodate the desired expression placement. For instance, the edge from B_3 to B_4 in Fig. 9.31 a is critical because B_3 has two successors and B_4 has two predecessors

Adding blocks may not be su-cient to allow the elimination of all redundant computations. As shown in Example 9 29 we may need to duplicate code so as to isolate the path where redundancy is found

Example 9 29 In the example shown in Figure 9 32 a the expression of b c is computed redundantly along the path B_1 B_2 B_4 B_6 We would like to remove the redundant computation of b c from block B_6 in this path and compute the expression only along the path B_1 B_3 B_4 B_6 However there is no single program point or edge in the source program that corresponds uniquely to the latter path. To create such a program point, we can duplicate the pair of blocks B_4 and B_6 with one pair reached through B_2 and the other reached through B_3 as shown in Figure 9 32 b. The result of b c is saved in variable t in block B_2 and moved to variable d in B_6' the copy of B_6 reached from B_2 .

Since the number of paths is exponential in the number of conditional branches in the program eliminating all redundant expressions can greatly increase the size of the optimized code We therefore restrict our discussion of redundancy elimination techniques to those that may introduce additional blocks but that do not duplicate portions of the control ow graph

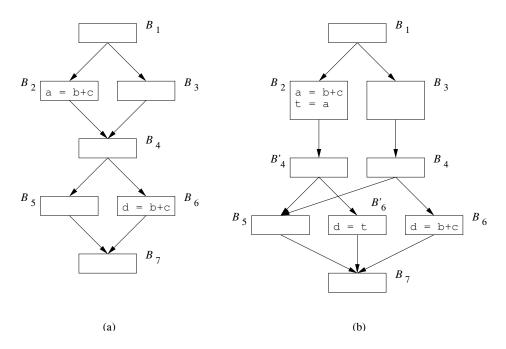

Figure 9 32 Code duplication to eliminate redundancies

9 5 3 The Lazy Code Motion Problem

It is desirable for programs optimized with a partial redundancy elimination algorithm to have the following properties

- $1 \quad \text{All redundant computations of expressions that can be eliminated without code duplication are eliminated} \\$
- 2 The optimized program does not perform any computation that is not in the original program execution
- 3 Expressions are computed at the latest possible time

The last property is important because the values of expressions found to be redundant are usually held in registers until they are used. Computing a value as late as possible minimizes its lifetime—the duration between the time the value is defined and the time it is last used which in turn minimizes its usage of a register. We refer to the optimization of eliminating partial redundancy with the goal of delaying the computations as much as possible as lazy code motion.

To build up our intuition of the problem we rst discuss how to reason about partial redundancy of a single expression along a single path. For convenience we assume for the rest of the discussion that every statement is a basic block of its own

Full Redundancy

An expression e in block B is redundant if along all paths reaching B e has been evaluated and the operands of e have not been rede ned subsequently Let S be the set of blocks each containing expression e that renders e in B redundant. The set of edges leaving the blocks in S must necessarily form a cutset which if removed disconnects block B from the entry of the program Moreover no operands of e are rede ned along the paths that lead from the blocks in S to B

Partial Redundancy

If an expression e in block B is only partially redundant the lazy code motion algorithm attempts to render e fully redundant in B by placing additional copies of the expressions in the ow graph. If the attempt is successful the optimized ow graph will also have a set of basic blocks S each containing expression e and whose outgoing edges are a cutset between the entry and B. Like the fully redundant case no operands of e are rede ned along the paths that lead from the blocks in S to B

9 5 4 Anticipation of Expressions

There is an additional constraint imposed on inserted expressions to ensure that no extra operations are executed. Copies of an expression must be placed only at program points where the expression is anticipated. We say that an expression b-c is anticipated at point p if all paths leading from the point p eventually compute the value of the expression b-c from the values of b and c that are available at that point

Let us now examine what it takes to eliminate partial redundancy along an acyclic path B_1 B_2 B_n Suppose expression e is evaluated only in blocks B_1 and B_n and that the operands of e are not rede ned in blocks along the path. There are incoming edges that join the path and there are outgoing edges that exit the path. We see that e is not anticipated at the entry of block B_i if and only if there exists an outgoing edge leaving block B_j i j n that leads to an execution path that does not use the value of e. Thus, anticipation limits how early an expression can be inserted

We can create a cutset that includes the edge B_{i-1} — B_i and that renders e redundant in B_n if e is either available or anticipated at the entry of B_i If e is anticipated but not available at the entry of B_i we must place a copy of the expression e along the incoming edge

We have a choice of where to place the copies of the expression since there are usually several cutsets in the ow graph that satisfy all the requirements. In the above computation is introduced along the incoming edges to the path of interest and so the expression is computed as close to the use as possible without introducing redundancy. Note that these introduced operations may themselves be partially redundant with other instances of the same expression

in the program Such partial redundancy may be eliminated by moving these computations further up

In summary anticipation of expressions limits how early an expression can be placed you cannot place an expression so early that it is not anticipated where you place it. The earlier an expression is placed the more redundancy can be removed and among all solutions that eliminate the same redundancies the one that computes the expressions the latest minimizes the lifetimes of the registers holding the values of the expressions involved

9 5 5 The Lazy Code Motion Algorithm

This discussion thus motivates a four step algorithm. The rst step uses an ticipation to determine where expressions can be placed the second step and the earliest cutset among those that eliminate as many redundant operations as possible without duplicating code and without introducing any unwanted computations. This step places the computations at program points where the values of their results are rst anticipated. The third step then pushes the cutset down to the point where any further delay would alter the semantics of the program or introduce redundancy. The fourth and analystep is a simple pass to clean up the code by removing assignments to temporary variables that are used only once. Each step is accomplished with a data low pass the rst and fourth are backward low problems the second and third are forward low problems.

Algorithm Overview

- 1 Find all the expressions anticipated at each program point using a back ward data ow pass
- 2 The second step places the computation where the values of the expressions are rst anticipated along some path. After we have placed copies of an expression where the expression is rst anticipated the expression would be available at program point p if it has been anticipated along all paths reaching p. Availability can be solved using a forward data ow pass. If we wish to place the expressions at the earliest possible positions we can simply and those program points where the expressions are anticipated but are not available.
- 3 Executing an expression as soon as it is anticipated may produce a value long before it is used. An expression is *postponable* at a program point if the expression has been anticipated and has yet to be used along any path reaching the program point. Postponable expressions are found using a forward data ow pass. We place expressions at those program points where they can no longer be postponed.
- 4 A simple nal backward data ow pass is used to eliminate assignments to temporary variables that are used only once in the program

Preprocessing Steps

We now present the full lazy code motion algorithm. To keep the algorithm simple we assume that initially every statement is in a basic block of its own and we only introduce new computations of expressions at the beginnings of blocks. To ensure that this simplication does not reduce the electiveness of the technique we insert a new block between the source and the destination of an edge if the destination has more than one predecessor. Doing so obviously also takes care of all critical edges in the program

We abstract the semantics of each block B with two sets e_use_B is the set of expressions computed in B and e_kill_B is the set of expressions killed that is the set of expressions any of whose operands are defined in B. Example 9 30 will be used throughout the discussion of the four data ow analyses whose definitions are summarized in Fig. 9 34

Example 9 30 In the ow graph in Fig 9 33 a the expression b c appears three times Because the block B_9 is part of a loop the expression may be computed many times. The computation in block B_9 is not only loop invariant it is also a redundant expression since its value already has been used in block B_7 . For this example, we need to compute b c only twice once in block B_5 and once along the path after B_2 and before B_7 . The lazy code motion algorithm will place the expression computations at the beginning of blocks B_4 and B_5 .

Anticipated Expressions

Recall that an expression b-c is anticipated at a program point p if all paths leading from point p eventually compute the value of the expression b-c from the values of b and c that are available at that point

In Fig. 9.33 a all the blocks anticipating b c on entry are shown as lightly shaded boxes. The expression b c is anticipated in blocks B_3 B_4 B_5 B_6 B_7 and B_9 . It is not anticipated on entry to block B_2 because the value of c is recomputed within the block and therefore the value of b c that would be computed at the beginning of B_2 is not used along any path. The expression b c is not anticipated on entry to B_1 because it is unnecessary along the branch from B_1 to B_2 although it would be used along the path B_1 B_5 B_6 . Similarly the expression is not anticipated at the beginning of B_8 because of the branch from B_8 to B_{11} . The anticipation of an expression may oscillate along a path as illustrated by B_7 B_8 B_9

The data ow equations for the anticipated expressions problem are shown in Fig 9 34 a. The analysis is a backward pass. An anticipated expression at the exit of a block B is an anticipated expression on entry only if it is not in the e_kill_B set. Also a block B generates as new uses the set of e_use_B expressions. At the exit of the program none of the expressions are anticipated. Since we are interested in inding expressions that are anticipated along every subsequent

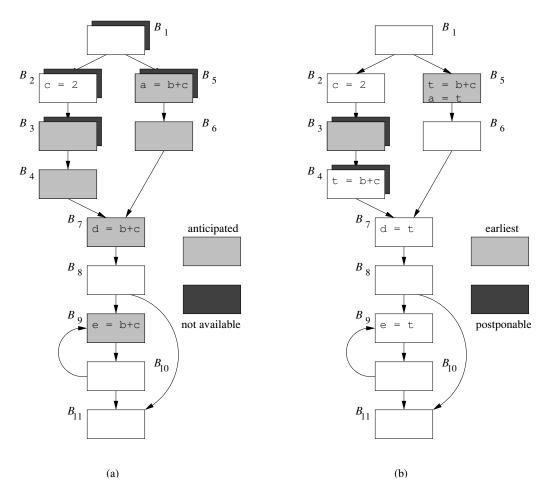

Figure 9 33 $\,$ Flow graph of Example 9 30 $\,$

path the meet operator is set intersection. Consequently the interior points must be initialized to the universal set U as was discussed for the available expressions problem in Section 9 2 6

Available Expressions

At the end of this second step copies of an expression will be placed at program points where the expression is rst anticipated. If that is the case an expression will be available at program point p if it is anticipated along all paths reaching p. This problem is similar to available expressions described in Section 9.2.6 The transfer function used here is slightly dierent though. An expression is available on exit from a block if it is

Completing the Square

Anticipated expressions also called very busy expressions elsewhere is a type of data ow analysis we have not seen previously. While we have seen backwards owing frameworks such as live variable analysis. Sect. 9.2.5 and we have seen frameworks where the meet is intersection such as avail able expressions. Sect. 9.2.6 this is the rst example of a useful analysis that has both properties. Almost all analyses we use can be placed in one of four groups depending on whether they ow forwards or backwards and depending on whether they use union or intersection for the meet. Notice also that the union analyses always involve asking about whether there exists a path along which something is true while the intersection analyses ask whether something is true along all paths.

1 Either

- a Available on entry or
- b In the set of anticipated expressions upon entry ie it *could* be made available if we chose to compute it here

and

2 Not killed in the block

The data ow equations for available expressions are shown in Fig 9 34 b. To avoid confusing the meaning of IN we refer to the result of an earlier analysis by appending B in to the name of the earlier analysis

With the earliest placement strategy the set of expressions placed at block B i e $earliest\ B$ is de ned as the set of anticipated expressions that are not yet available. That is

 $earliest\ B$ $anticipated\ B$ in $available\ B$ in

Example 9 31 The expression b c in the ow graph in Figure 9 35 is not anticipated at the entry of block B_3 but is anticipated at the entry of block B_4 It is however not necessary to compute the expression b c in block B_4 because the expression is already available due to block B_2

Example 9 32 Shown with dark shadows in Fig. 9.33 a are the blocks for which expression b c is not available they are B_1 B_2 B_3 and B_5 . The early placement positions are represented by the lightly shaded boxes with dark shadows and are thus blocks B_3 and B_5 . Note for instance that b c is considered available on entry to B_4 because there is a path B_1 B_2 B_3 B_4 along which b c is anticipated at least once at B_3 in this case and since the beginning of B_3 neither b nor c was recomputed.

95 PARTIAL REDUNDANCY ELIMINATION

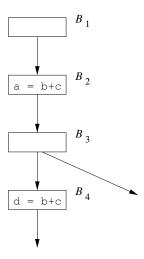

Figure 9 35 Flow graph for Example 9 31 illustrating the use of availability

Postponable Expressions

The third step postpones the computation of expressions as much as possible while preserving the original program semantics and minimizing redundancy Example 9 33 illustrates the importance of this step

Example 9 33 In the ow graph shown in Figure 9 36 the expression b c is computed twice along the path B_1 B_5 B_6 B_7 The expression b c is anticipated even at the beginning of block B_1 If we compute the expression as soon as it is anticipated we would have computed the expression b c in B_1 The result would have to be saved from the beginning through the execution of the loop comprising blocks B_2 and B_3 until it is used in block B_7 Instead we can delay the computation of expression b c until the beginning of B_5 and until the ow of control is about to transition from B_4 to B_7

Formally an expression x y is postponable to a program point p if an early placement of x y is encountered along every path from the entry node to p and there is no subsequent use of x y after the last such placement

Example 9 34 Let us again consider expression b c in Fig 9 33 The two earliest points for b c are B_3 and B_5 note that these are the two blocks that are both lightly and darkly shaded in Fig 9 33 a indicating that b c is both anticipated and not available for these blocks and only these blocks. We cannot postpone b c from B_5 to B_6 because b c is used in B_5 . We can postpone it from B_3 to B_4 however

But we cannot postpone b c from B_4 to B_7 . The reason is that although b c is not used in B_4 placing its computation at B_7 instead would lead to a

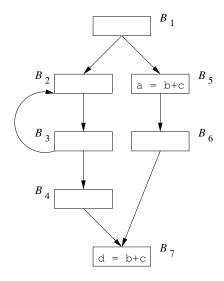

Figure 9 36 Flow graph for Example 9 33 to illustrate the need for postponing an expression

redundant computation of b c along the path B_5 B_6 B_7 As we shall see B_4 is one of the latest places we can compute b c

The data ow equations for the postponable expressions problem are shown in Fig 9 34 c. The analysis is a forward pass. We cannot postpone an expression to the entry of the program so OUT ENTRY. An expression is postponable to the exit of block B if it is not used in the block and either it is postponable to the entry of B or it is in earliest B. An expression is not postponable to the entry of a block unless all its predecessors include the expression in their postponable sets at their exits. Thus the meet operator is set intersection and the interior points must be initialized to the top element of the semilattice. the universal set

Roughly speaking an expression is placed at the *frontier* where an expression transitions from being postponable to not being postponable. More specifically an expression e may be placed at the beginning of a block B only if the expression is in B is expression is in expression is in expression is in expression if the postponement frontier of e if one of the following holds

- 1 e is not in postponable B out In other words e is in e_use_B
- 2 e cannot be postponed to one of its successors. In other words, there exists a successor of B such that e is not in the e arliest or p ostponable set upon entry to that successor

Expression e can be placed at the front of block B in either of the above scenarios because of the new blocks introduced by the preprocessing step in the algorithm

95 PARTIAL REDUNDANCY ELIMINATION

Example 9 35 Fig 9 33 b shows the result of the analysis The light shaded boxes represent the blocks whose earliest set includes b c The dark shadows indicate those that include b c in their postponable set. The latest placements of the expressions are thus the entries of blocks B_4 and B_5 since

- 1 b c is in the postponable set of B_4 but not B_7 and
- 2 B_5 s earliest set includes b-c and it uses b-c

The expression is stored into the temporary variable t in blocks B_4 and B_5 and t is used in place of b c everywhere else as shown in the gure \Box

Used Expressions

Finally a backward pass is used to determine if the temporary variables in troduced are used beyond the block they are in We say that an expression is used at point p if there exists a path leading from p that uses the expression before the value is reevaluated. This analysis is essentially liveness analysis for expressions rather than for variables

The data ow equations for the used expressions problem are shown in Fig 9 34 d. The analysis is a backward pass. A used expression at the exit of a block B is a used expression on entry only if it is not in the latest set A block generates as new uses the set of expressions in e_use_B . At the exit of the program none of the expressions are used. Since we are interested in nding expressions that are used by any subsequent path the meet operator is set union. Thus the interior points must be initialized with the top element of the semilattice.

Putting it All Together

All the steps of the algorithm are summarized in Algorithm 9 36

Algorithm 9 36 Lazy code motion

INPUT A ow graph for which e_use_B and e_kill_B have been computed for each block B

 ${\bf OUTPUT}\,$ A modi $\,$ ed $\,$ ow graph satisfying the four lazy code motion conditions in Section 9 5 3

METHOD

- 1 Insert an empty block along all edges entering a block with more than one predecessor
- 2 Find anticipated B in for all blocks B as defined in Fig. 9.34 a
- 3 Find available B in for all blocks B as defined in Fig. 9.34 b

4 Compute the earliest placements for all blocks B

```
earliest \, B \quad anticipated \, B \ in \quad available \, B \ in
```

- 5 Find postponable B in for all blocks B as de ned in Fig. 9 34 c
- 6 Compute the latest placements for all blocks B

Note that — denotes complementation with respect to the set of all ex pressions computed by the program

- 7 Find $used\ B$ out for all blocks B as de ned in Fig 9 34 d
- 8 For each expression say x y computed by the program do the following
 - a Create a new temporary say t for x = y
 - b For all blocks B such that x y is in latest B used B out add t x y at the beginning of B
 - c For all blocks B such that x y is in

```
e\_use_B   latest B   used out B
```

replace every original x = y by t

Summary

Partial redundancy elimination and many dierent forms of redundant operations in one united algorithm. This algorithm illustrates how multiple data ow problems can be used to and optimal expression placement.

- 1 The placement constraints are provided by the anticipated expressions analysis which is a *backwards* data ow analysis with a set intersection meet operator as it determines if expressions are used *subsequent* to each program point on *all* paths
- 2 The earliest placement of an expression is given by program points where the expression is anticipated but is not available. Available expressions are found with a *forwards* data—ow analysis with a set intersection meet operator that computes if an expression has been anticipated *before* each program point along *all* paths

96 LOOPS IN FLOW GRAPHS

- 3 The latest placement of an expression is given by program points where an expression can no longer be postponed. Expressions are postponable at a program point if for *all* paths *reaching* the program point no use of the expression has been encountered. Postponable expressions are found with a *forwards* data—ow analysis with a set intersection meet operator
- 4 Temporary assignments are eliminated unless they are used by *some* path *subsequently* We nd used expressions with a *backwards* data ow analysis this time with a set union meet operator

9 5 6 Exercises for Section 9 5

Exercise 9 5 1 For the ow graph in Fig 9 37

- a Compute anticipated for the beginning and end of each block
- b Compute available for the beginning and end of each block
- c Compute earliest for each block
- d Compute postponable for the beginning and end of each block
- e Compute used for the beginning and end of each block
- f Compute *latest* for each block
- g Introduce temporary variable t show where it is computed and where it is used

Exercise 9 5 2 Repeat Exercise 9 5 1 for the ow graph of Fig 9 10 see the exercises to Section 9 1 You may limit your analysis to the expressions a b c a and b d

Exercise 9 5 3 The concepts discussed in this section can also be applied to eliminate partially dead code A de nition of a variable is partially dead if the variable is live on some paths and not others. We can optimize the program execution by only performing the de nition along paths where the variable is live. Unlike partial redundancy elimination, where expressions are moved before the original, the new de nitions are placed after the original. Develop an algorithm to move partially dead code, so expressions are evaluated only where they will eventually be used.

9 6 Loops in Flow Graphs

In our discussion so far loops have not been handled di erently they have been treated just like any other kind of control ow However loops are important because programs spend most of their time executing them and optimizations

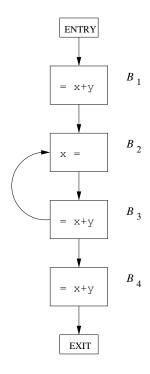

Figure 9 37 Flow graph for Exercise 9 5 1

that improve the performance of loops can have a significant impact. Thus it is essential that we identify loops and treat them specially

Loops also a ect the running time of program analyses If a program does not contain any loops we can obtain the answers to data ow problems by making just one pass through the program For example a forward data ow problem can be solved by visiting all the nodes once in topological order

In this section we introduce the following concepts dominators depth—rst ordering—back edges—graph depth—and reducibility—Each of these is needed for our subsequent discussions on—nding loops and the speed of convergence of iterative data—ow analysis

9 6 1 Dominators

We say node d of a $\$ ow graph dominates node n written d dom n if every path from the entry node of the $\$ ow graph to n goes through d $\$ Note that under this de nition every node dominates itself

Example 9 37 Consider the ow graph of Fig 9 38 with entry node 1 The entry node dominates every node this statement is true for every ow graph Node 2 dominates only itself since control can reach any other node along a path that begins with 1 3 Node 3 dominates all but 1 and 2 Node 4 dominates

96 LOOPS IN FLOW GRAPHS

all but 1 2 and 3 since all paths from 1 must begin with 1 2 3 4 or 1 3 4 Nodes 5 and 6 dominate only themselves since ow of control can skip around either by going through the other Finally 7 dominates 7 8 9 and 10 8 dominates 8 9 and 10 9 and 10 dominate only themselves \Box

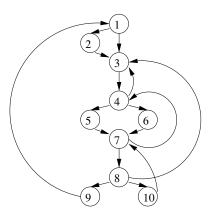

Figure 9 38 A ow graph

A useful way of presenting dominator information is in a tree called the dominator tree in which the entry node is the root and each node d dominates only its descendants in the tree For example Fig 9 39 shows the dominator tree for the ow graph of Fig 9 38

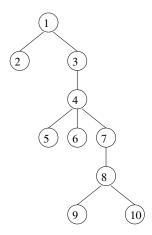

Figure 9 39 Dominator tree for ow graph of Fig 9 38

The existence of dominator trees follows from a property of dominators each node n has a unique $immediate\ dominator\ m$ that is the last dominator of n on any path from the entry node to n. In terms of the dom relation the

immediate dominator m has that property that if d / n and d dom n then d dom m

We shall give a simple algorithm for computing the dominators of every node n in a ow graph based on the principle that if p_1 p_2 p_k are all the predecessors of n and d / n then d dom n if and only if d dom p_i for each i. This problem can be formulated as a forward data—ow analysis. The data—ow values are sets of basic blocks. A node s set of dominators other than itself—is the intersection of the dominators of all its predecessors—thus the meet operator is set intersection. The transfer function for block B simply adds B itself to the set of input nodes. The boundary condition is that the ENTRY node dominates itself. Finally—the initialization of the interior nodes is the universal set—that is the set of all nodes.

Algorithm 9 38 Finding dominators

INPUT A ow graph G with set of nodes N set of edges E and entry node Entry

OUTPUT D n the set of nodes that dominate node n for all nodes n in N

METHOD Find the solution to the data ow problem whose parameters are shown in Fig. 9.40. The basic blocks are the nodes D n OUT n for all n in N

Finding dominators using this data ow algorithm is e cient Nodes in the graph need to be visited only a few times as we shall see in Section 9 6 7

	Dominators
Domain	The power set of N
Direction	Forwards
Transfer function	$f_B x = x - \{B\}$
Boundary	OUT ENTRY {ENTRY}
Meet	
Equations	OUT B f_B in B
	IN $B = \bigwedge_{P \ pred \ B}$ OUT P
Initialization	OUT B N

Figure 9 40 A data ow algorithm for computing dominators

Example 9 39 Let us return to the ow graph of Fig 9 38 and suppose the for loop of lines 4 through 6 in Fig 9 23 visits the nodes in numerical order Let D n be the set of nodes in OUT n Since 1 is the entry node D 1 was assigned $\{1\}$ at line 1 Node 2 has only 1 for a predecessor so

Properties of the dom Relation

A key observation about dominators is that if we take any acyclic path from the entry to node n then all the dominators of n appear along this path and moreover they must appear in the same order along any such path. To see why suppose there were one acyclic path P_1 to n along which dominators a and b appeared in that order and another path P_2 to n along which b preceded a. Then we could follow P_1 to a and P_2 to n thereby avoiding b altogether. Thus b would not really dominate n

This reasoning allows us to prove that dom is transitive if $a\ dom\ b$ and $b\ dom\ c$ then $a\ dom\ c$. Also dom is antisymmetric it is never possible that both $a\ dom\ b$ and $b\ dom\ a$ hold if $a\ /\ b$. Moreover if a and b are two dominators of n then either $a\ dom\ b$ or $b\ dom\ a$ must hold. Finally it follows that each node n except the entry must have a unique immediate dominator—the dominator that appears closest to n along any acyclic path from the entry to n

D 2 {2} D 1 Thus D 2 is set to {1 2} Then node 3 with predecessors 1 2 4 and 8 is considered. Since all the interior nodes are initialized with the universal set N

$$D \ 3 \qquad \{3\} \qquad \{1\} \qquad \{1\ 2\} \qquad \{1\ 2 \qquad \qquad 10\} \qquad \{1\ 2 \qquad \qquad 10\} \qquad \{1\ 3\}$$

The remaining calculations are shown in Fig. 9.41. Since these values do not change in the second iteration through the outer loop of lines 3 through 6 in Fig. 9.23 at they are the nal answers to the dominator problem \Box

9 6 2 Depth First Ordering

As introduced in Section 2 3 4 a depth rst search of a graph visits all the nodes in the graph once by starting at the entry node and visiting the nodes as far away from the entry node as quickly as possible. The route of the search in a depth rst search forms a depth rst spanning tree DFST. Recall from Section 2 3 4 that a preorder traversal visits a node before visiting any of its children which it then visits recursively in left to right order. Also a postorder traversal visits a node schildren recursively in left to right order before visiting the node itself.

There is one more variant ordering that is important for ow graph analysis a depth rst ordering is the reverse of a postorder traversal. That is in a depth rst ordering we visit a node then traverse its rightmost child the child to its left and so on. However, before we build the tree for the ow graph we have choices as to which successor of a node becomes the rightmost child in the tree which node becomes the next child and so on. Before we give the algorithm for depth rst ordering let us consider an example

Example 9 40 One possible depth rst presentation of the ow graph in Fig 9 38 is illustrated in Fig 9 42 Solid edges form the tree dashed edges are the other edges of the ow graph A depth rst traversal of the tree is given by 1 3 4 6 7 8 10 then back to 8 then to 9 We go back to 8 once more retreating to 7 6 and 4 and then forward to 5 We retreat from 5 back to 4 then back to 3 and 1 From 1 we go to 2 then retreat from 2 back to 1 and we have traversed the entire tree

The preorder sequence for the traversal is thus

 $1\ 3\ 4\ 6\ 7\ 8\ 10\ 9\ 5\ 2$

The postorder sequence for the traversal of the tree in Fig 9 42 is

10 9 8 7 6 5 4 3 2 1

The depth rst ordering which is the reverse of the postorder sequence is

 $1\ 2\ 3\ 4\ 5\ 6\ 7\ 8\ 9\ 10$

We now give an algorithm that $\,$ nds a depth $\,$ rst spanning tree and a depth $\,$ rst ordering of a graph. It is this algorithm that $\,$ nds the DFST in Fig. 9.42 from Fig. 9.38

Algorithm 9 41 Depth rst spanning tree and depth rst ordering

INPUT A ow graph G

OUTPUT A DFST T of G and an ordering of the nodes of G

96 LOOPS IN FLOW GRAPHS

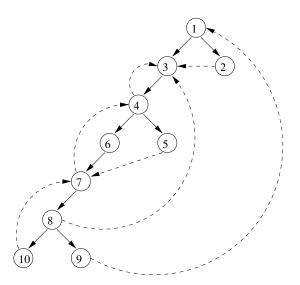

Figure 9 42 A depth rst presentation of the ow graph in Fig 9 38

METHOD We use the recursive procedure search n of Fig 9 43. The algorithm initializes all nodes of G to unvisited then calls search n_0 where n_0 is the entry. When it calls search n it rst marks n visited to avoid adding n to the tree twice. It uses c to count from the number of nodes of G down to 1 assigning depth rst numbers dfn n to nodes n as we go. The set of edges T forms the depth rst spanning tree for G.

Example 9 42 For the ow graph in Fig 9 42 Algorithm 9 41 sets c to 10 and begins the search by calling search 1 The rest of the execution sequence is shown in Fig 9 44 \Box

9 6 3 Edges in a Depth First Spanning Tree

When we construct a DFST for a ow graph the edges of the ow graph fall into three categories

- 1 There are edges called advancing edges that go from a node m to a proper descendant of m in the tree. All edges in the DFST itself are advancing edges. There are no other advancing edges in Fig. 9.42 but for example if 4. 8 were an edge it would be in this category.
- 2 There are edges that go from a node m to an ancestor of m in the tree possibly to m itself. These edges we shall term $retreating\ edges$. For example 4 3 7 4 10 7 8 3 and 9 1 are the retreating edges in Fig. 9 42

```
void search n  {
      \max n visited
      for each successor s of n
            if s is unvisited
                  add edge n
                               s to T
                  search s
      dfn n
      c c 1
}
main
                set of edges
      for each node n of G
            \max n unvisited
          number of nodes of G
      search n_0
}
```

Figure 9 43 Depth rst search algorithm

3 There are edges m n such that neither m nor n is an ancestor of the other in the DFST Edges 2 3 and 5 7 are the only such examples in Fig 9 42. We call these edges $cross\ edges$. An important property of cross edges is that if we draw the DFST so children of a node are drawn from left to right in the order in which they were added to the tree then all cross edges travel from right to left

It should be noted that m n is a retreating edge if and only if $dfn \, m$ $dfn \, n$. To see why note that if m is a descendant of n in the DFST then $search \, m$ terminates before $search \, n$ so $dfn \, m$ $dfn \, n$. Conversely if $dfn \, m$ $dfn \, n$ then $search \, m$ terminates before $search \, n$ or m n But $search \, n$ must have begun before $search \, m$ if there is an edge m n or else the fact that n is a successor of m would have made n a descendant of m in the DFST. Thus the time $search \, m$ is active is a subinterval of the time $search \, n$ is active from which it follows that n is an ancestor of m in the DFST.

9 6 4 Back Edges and Reducibility

A back edge is an edge a b whose head b dominates its tail a. For any ow graph every back edge is retreating but not every retreating edge is a back edge. A ow graph is said to be reducible if all its retreating edges in any depth rst spanning tree are also back edges. In other words if a graph is reducible, then all the DFSTs have the same set of retreating edges and

96 LOOPS IN FLOW GRAPHS

Call search 1	Node 1 has two successors Suppose $s-3$ is considered rst add edge $1-3$ to T
Call search 3	Add edge 3 -4 to T
Call search 4	Node 4 has two successors 4 and 6 Suppose s 6 is considered rst add edge 4 6 to T
Call search 6	Add 6 7 to T
Call search 7	Node 7 has two successors 4 and 8 But 4 is already marked visited by search 4 so do nothing when s 4 For s 8 add edge 7 8 to T
Call search 8	Node 8 has two successors 9 and 10 Suppose s 10 is considered rst add edge 8 10
Call search 10	10 has a successor 7 but 7 is already marked visited Thus $search$ 10 completes by setting dfn 10 10 and c 9
Return to search 8	Set $s=9$ and add edge $8=9$ to T
Call search 9	The only successor of 9 node 1 is already visited
	so set $dfn 9 = 9$ and $c = 8$
Return to search 8	The last successor of 8 node 3 is visited so do nothing for s 3 At this point all successors of 8 have been considered so set dfn 8 8 and c 7
Return to search 7	All of 7 s successors have been considered so set dfn 7 and c 6
Return to search 6	Similarly 6 s successors have been considered so set dfn 6 6 and c 5
Return to search 4	Successor 3 of 4 has been visited but 5 has not so add 4 5 to the tree
Call search 5	Successor 7 of 5 has been visited thus set dfn 5 and c 4
Return to search 4	All successors of 4 have been considered set $dfn \ 4$ and $c = 3$
Return to search 3	Set $dfn 3 = 3$ and $c = 2$
Return to search 1	2 has not been visited yet so add 1 2 to T
Call search 2	Set $dfn 2 \qquad 2 c 1$
Return to search 1	Set $dfn 1 = 1$ and $c = 0$

Figure 9 44 Execution of Algorithm 9 41 on the $\,$ ow graph in Fig 9 42

Why Are Back Edges Retreating Edges

Suppose a b is a back edge i e its head dominates its tail. The sequence of calls of the function search in Fig. 9.43 that lead to node a must be a path in the low graph. This path must of course include any dominator of a. It follows that a call to search b must be open when search a is called. Therefore b is already in the tree when a is added to the tree and a is added as a descendant of b. Therefore a b must be a retreating edge.

those are exactly the back edges in the graph. If the graph is nonreducible not reducible however all the back edges are retreating edges in any DFST but each DFST may have additional retreating edges that are not back edges. These retreating edges may be different from one DFST to another. Thus, if we remove all the back edges of a low graph and the remaining graph is cyclic then the graph is nonreducible, and conversely

Flow graphs that occur in practice are almost always reducible Exclusive use of structured ow of control statements such as if then else while do con tinue and break statements produces programs whose ow graphs are always reducible Even programs written using goto statements often turn out to be reducible as the programmer logically thinks in terms of loops and branches

Example 9 43 The ow graph of Fig 9 38 is reducible. The retreating edges in the graph are all back edges, that is their heads dominate their respective tails \Box

Example 9 44 Consider the ow graph of Fig 9 45 whose initial node is 1 Node 1 dominates nodes 2 and 3 but 2 does not dominate 3 nor vice versa Thus this ow graph has no back edges since no head of any edge dominates its tail. There are two possible depth 1 rst spanning trees depending on whether we choose to call search 2 or search 3 rst from search 1. In the 1 rst case edge 3 2 is a retreating edge but not a back edge in the second case 2 3 is the retreating but not back edge. Intuitively the reason this 1 ow graph is not reducible is that the cycle 2 3 can be entered at two different places nodes 2 and 3 \Box

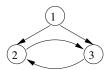

Figure 9 45 The canonical nonreducible ow graph

9 6 5 Depth of a Flow Graph

Given a depth rst spanning tree for the graph the depth is the largest number of retreating edges on any cycle free path. We can prove the depth is never greater than what one would intuitively call the depth of loop nesting in the ow graph. If a ow graph is reducible, we may replace retreating by back in the definition of depth since the retreating edges in any DFST are exactly the back edges. The notion of depth, then becomes independent of the DFST actually chosen, and we may truly speak of the depth of a ow graph rather than the depth of a ow graph in connection with one of its depth, rst spanning trees.

Example 9 45 In Fig 9 42 the depth is 3 since there is a path

10 7 4 3

with three retreating edges but no cycle free path with four or more retreating edges. It is a coincidence that the deepest path here has only retreating edges in general we may have a mixture of retreating advancing and cross edges in a deepest path \Box

966 Natural Loops

Loops can be specified in a source program in many different ways, they can be written as for loops, while loops or repeat loops, they can even be defined using labels and goto statements. From a program analysis point of view, it does not matter how the loops appear in the source code. What matters is whether they have the properties that enable easy optimization. In particular, we care about whether a loop has a single entry node if it does compiler analyses can assume certain initial conditions to hold at the beginning of each iteration through the loop. This opportunity motivates the need for the definition of a natural loop.

A natural loop is de ned by two essential properties

- 1 It must have a single entry node called the *header* This entry node dominates all nodes in the loop or it would not be the sole entry to the loop
- 2 There must be a back edge that enters the loop header Otherwise it is not possible for the ow of control to return to the header directly from the loop ie there really is no loop

Given a back edge n-d we de ne the natural loop of the edge to be d plus the set of nodes that can reach n without going through d Node d is the header of the loop

Algorithm 9 46 Constructing the natural loop of a back edge

INPUT A ow graph G and a back edge n

OUTPUT The set *loop* consisting of all nodes in the natural loop of n - d

METHOD Let loop be $\{n \ d\}$ Mark d as visited so that the search does not reach beyond d Perform a depth rst search on the reverse control ow graph starting with node n Insert all the nodes visited in this search into loop This procedure and all the nodes that reach n without going through d

Example 9 47 In Fig 9 38 there are we back edges those whose heads dominate their tails 10 7 7 4 4 3 8 3 and 9 1 Note that these are exactly the edges that one would think of as forming loops in the ow graph

Back edge 10 7 has natural loop {7 8 10} since 8 and 10 are the only nodes that can reach 10 without going through 7 Back edge 7 4 has a natural loop consisting of {4 5 6 7 8 10} and therefore contains the loop of 10 7 We thus assume the latter is an inner loop contained inside the former

The natural loops of back edges 4 3 and 8 3 have the same header node 3 and they also happen to have the same set of nodes {3 4 5 6 7 8 10} We shall therefore combine these two loops as one This loop contains the two smaller loops discovered earlier

Finally the edge 9 1 has as its natural loop the entire ow graph and therefore is the outermost loop. In this example, the four loops are nested within one another. It is typical however to have two loops neither of which is a subset of the other. \Box

In reducible ow graphs since all retreating edges are back edges we can associate a natural loop with each retreating edge. That statement does not hold for nonreducible graphs. For instance, the nonreducible ow graph in Fig. 9.45 has a cycle consisting of nodes 2 and 3. Neither of the edges in the cycle is a back edge so this cycle does not at the definition of a natural loop. We do not identify the cycle as a natural loop and it is not optimized as such. This situation is acceptable because our loop analyses can be made simpler by assuming that all loops have single entry nodes and nonreducible programs are rare in practice anyway.

By considering only natural loops as loops we have the useful property that unless two loops have the same header they are either disjoint or one is nested within the other. Thus we have a natural notion of *innermost loops* loops that contain no other loops

When two natural loops have the same header as in Fig 9 46 it is hard to tell which is the inner loop. Thus we shall assume that when two natural loops have the same header and neither is properly contained within the other they are combined and treated as a single loop.

Example 9 48 The natural loops of the back edges 3 1 and 4 1 in Fig 9 46 are {1 2 3} and {1 2 4} respectively We shall combine them into a single loop {1 2 3 4}

However were there another back edge 2 1 in Fig 946 its natural loop would be $\{1\ 2\}$ a third loop with header 1 This set of nodes is properly

96 LOOPS IN FLOW GRAPHS

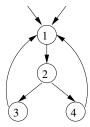

Figure 9 46 Two loops with the same header

contained within $\{1\ 2\ 3\ 4\}$ so it would not be combined with the other natural loops but rather treated as an inner loop nested within \Box

9 6 7 Speed of Convergence of Iterative Data Flow Algorithms

We are now ready to discuss the speed of convergence of iterative algorithms As discussed in Section 9 3 3 the maximum number of iterations the algorithm may take is the product of the height of the lattice and the number of nodes in the ow graph. For many data ow analyses it is possible to order the evaluation such that the algorithm converges in a much smaller number of iterations. The property of interest is whether all events of signic cance at a node will be propagated to that node along some acyclic path. Among the data ow analyses discussed so far reaching de nitions available expressions and live variables have this property but constant propagation does not. More speci cally

If a de nition d is in IN B then there is some acyclic path from the block containing d to B such that d is in the IN s and OUT s all along that path

If an expression x-y is not available at the entrance to block B then there is some acyclic path that demonstrates that either the path is from the entry node and includes no statement that kills or generates x-y or the path is from a block that kills x-y and along the path there is no subsequent generation of x-y

If x is live on exit from block B then there is an acyclic path from B to a use of x along which there are no de nitions of x

We should check that in each of these cases paths with cycles add nothing For example if a use of x is reached from the end of block B along a path with a cycle we can eliminate that cycle to A nd a shorter path along which the use of A is still reached from B

In contrast constant propagation does not have this property Consider a simple program that has one loop containing a basic block with statements

 $\begin{array}{cccc} L & a & b \\ & b & c \\ & c & 1 \\ & goto \ L \end{array}$

The rst time the basic block is visited c is found to have constant value 1 but both a and b are unde ned. Visiting the basic block the second time, we indicate that b and c have constant values 1. It takes three visits of the basic block for the constant value 1 assigned to c to reach a

If all useful information propagates along acyclic paths we have an opportunity to tailor the order in which we visit nodes in iterative data ow algorithms so that after relatively few passes through the nodes we can be sure information has passed along all the acyclic paths

Recall from Section 9 6 3 that if a b is an edge then the depth $\,$ rst number of b is less than that of a only when the edge is a retreating edge $\,$ For forward data $\,$ ow problems it is desirable to visit the nodes according to the depth $\,$ rst ordering $\,$ Speci cally we modify the algorithm in Fig 9 23 $\,$ a by replacing line 4 $\,$ which visits the basic blocks in the $\,$ ow graph with

for each block B other than ENTRY in depth rst order $\{$

Example 9 49 Suppose we have a path along which a denition d propagates such as

3 5 19 35 16 23 45 4 10 17

where integers represent the depth—rst numbers of the blocks along the path Then the—rst time through the loop of lines—4—through 6—in the algorithm in Fig_9_23 a—d will propagate from OUT 3—to IN 5—to OUT 5—and so on—up to OUT 35—It will not reach IN 16—on that round—because as 16 precedes 35—we had already computed IN 16—by the time d was put in OUT 35—However—the next time we run through the loop of lines—4—through—6—when we compute IN 16—d will be included because it is in OUT 35—De—nition d will also propagate to OUT 16—IN 23—and so on—up to OUT 45—where it must wait because IN 4—was already computed on this round—On the third pass—d travels to IN 4—OUT 4—IN 10—OUT 10—and IN 17—so after three passes we establish that d reaches block 17—

It should not be hard to extract the general principle from this example. If we use depth—rst order in Fig. 9.23 a—then the number of passes needed to propagate any reaching de nition along any acyclic path is no more than one greater than the number of edges along that path that go from a higher numbered block to a lower numbered block. Those edges are exactly the retreating edges so the number of passes needed is one plus the depth. Of course Algorithm 9.11 does not detect the fact that all de nitions have reached wherever they can reach until one more pass has yielded no changes. Therefore the upper bound on the number of passes taken by that algorithm with depth—rst

A Reason for Nonreducible Flow Graphs

There is one place where we cannot generally expect a ow graph to be reducible. If we reverse the edges of a program ow graph as we did in Algorithm 9 46 to and natural loops then we may not get a reducible ow graph. The intuitive reason is that while typical programs have loops with single entries those loops sometimes have several exits which become entries when we reverse the edges

block ordering is actually two plus the depth A study¹⁰ has shown that typical ow graphs have an average depth around 2 75 Thus the algorithm converges very quickly

In the case of backward ow problems like live variables we visit the nodes in the reverse of the depth rst order. Thus we may propagate a use of a variable in block 17 backwards along the path

3 5 19 35 16 23 45 4 10 17

in one pass to IN 4 where we must wait for the next pass in order to reach OUT 45 On the second pass it reaches IN 16 and on the third pass it goes from OUT 35 to OUT 3

In general one plus the depth passes su ce to carry the use of a variable backward along any acyclic path. However, we must choose the reverse of depth rst order to visit the nodes in a pass, because then uses propagate along any decreasing sequence in a single pass.

The bound described so far is an upper bound on all problems where cyclic paths add no information to the analysis. In special problems such as dominators the algorithm converges even faster. In the case where the input ow graph is reducible the correct set of dominators for each node is obtained in the rst iteration of a data ow algorithm that visits the nodes in depth rst ordering. If we do not know that the input is reducible ahead of time it takes an extra iteration to determine that convergence has occurred

9 6 8 Exercises for Section 9 6

Exercise 9 6 1 For the ow graph of Fig. 9.10 see the exercises for Section 9.1

- i Compute the dominator relation
- ii Find the immediate dominator of each node

 $^{^{10}\}mathrm{D}$ E Knuth An empirical study of FORTRAN programs $\it Software Practice and \it Experience 1~2~1971~$ pp. 105–133

- iii Construct the dominator tree
- iv Find one depth rst ordering for the ow graph
- v Indicate the advancing retreating cross and tree edges for your answer to iv
- vi Is the ow graph reducible
- vii Compute the depth of the ow graph
- viii Find the natural loops of the ow graph

Exercise 9 6 2 Repeat Exercise 9 6 1 on the following ow graphs

- a Fig 93
- b Fig 89
- c Your ow graph from Exercise 8 4 1
- d Your ow graph from Exercise 8 4 2

Exercise 9 6 3 Prove the following about the dom relation

- a If $a \ dom \ b$ and $b \ dom \ c$ then $a \ dom \ c$ transitivity
- b It is never possible that both $a \ dom \ b$ and $b \ dom \ a$ hold if $a \ / \ b$ anti symmetry
- c If a and b are two dominators of n then either a dom b or b dom a must hold
- d Each node n except the entry has a unique $immediate\ dominator$ the dominator that appears closest to n along any acyclic path from the entry to n
- Exercise 9 6 4 Figure 9 42 is one depth—rst presentation of the—ow graph of Fig 9 38 How many other depth—rst presentations of this—ow graph are there Remember—order of children matters in distinguishing depth—rst presentations
- Exercise 9 6 5 Prove that a ow graph is reducible if and only if when we remove all the back edges those whose heads dominate their tails the resulting ow graph is acyclic
- **Exercise 9 6 6** A complete ow graph on n nodes has arcs i j between any two nodes i and j in both directions. For what values of n is this graph reducible
- Exercise 9 6 7 A complete acyclic ow graph on n nodes 1 2 n has arcs i j for all nodes i and j such that i j Node 1 is the entry

96 LOOPS IN FLOW GRAPHS

- a For what values of n is this graph reducible
- b Does your answer to a change if you add self loops i i for all nodes i

Exercise 9 6 8 The natural loop of a back edge n h was defined to be h plus the set of nodes that can reach n without going through h Show that h dominates all the nodes in the natural loop of n h

Exercise 9 6 9 We claimed that the ow graph of Fig 9 45 is nonreducible If the arcs were replaced by paths of disjoint sets of nodes except for the endpoints of course then the ow graph would still be nonreducible. In fact node 1 need not be the entry it can be any node reachable from the entry along a path whose intermediate nodes are not part of any of the four explicitly shown paths. Prove the converse that every nonreducible ow graph has a subgraph like Fig 9 45 but with arcs possibly replaced by node disjoint paths and node 1 being any node reachable from the entry by a path that is node disjoint from the four other paths

Exercise 9 6 10 Show that every depth rst presentation for every nonre ducible ow graph has a retreating edge that is not a back edge

Exercise 9 6 11 Show that if the following condition

$$fa$$
 ga a fga

holds for all functions f and g and value a then the general iterative algorithm Algorithm 9 25 with iteration following a depth—rst ordering—converges within 2 plus the depth passes

Exercise 9 6 12 Find a nonreducible $\$ ow graph with two di erent DFST s that have di erent depths

Exercise 9 6 13 Prove the following

- a If a definition d is in IN B—then there is some acyclic path from the block containing d to B such that d is in the IN s and OUT s all along that path
- b If an expression x-y is not available at the entrance to block B then there is some acyclic path that demonstrates that fact either the path is from the entry node and includes no statement that kills or generates x-y or the path is from a block that kills x-y and along the path there is no subsequent generation of x-y
- c If x is live on exit from block B then there is an acyclic path from B to a use of x along which there are no de nitions of x

9 7 Region Based Analysis

The iterative data ow analysis algorithm we have discussed so far is just one approach to solving data ow problems. Here we discuss another approach called *region based analysis*. Recall that in the iterative analysis approach we create transfer functions for basic blocks then individual solution by repeated passes over the blocks. Instead of creating transfer functions just for individual blocks a region based analysis individual stransfer functions that summarize the execution of progressively larger regions of the program. Ultimately transfer functions for entire procedures are constructed and then applied to get the desired data ow values directly

While a data ow framework using an iterative algorithm is speci ed by a semilattice of data ow values and a family of transfer functions closed un der composition region based analysis requires more elements. A region based framework includes both a semilattice of data ow values and a semilattice of transfer functions that must possess a meet operator a composition oper ator and a closure operator. We shall see what all these elements entail in Section 9.7.4

A region based analysis is particularly useful for data ow problems where paths that have cycles may change the data ow values. The closure operator allows the e ect of a loop to be summarized more e ectively than does iterative analysis. The technique is also useful for interprocedural analysis where transfer functions associated with a procedure call may be treated like the transfer functions associated with basic blocks

For simplicity we shall consider only forward data ow problems in this section. We rst illustrate how region based analysis works by using the familiar example of reaching de nitions. In Section 9.8 we show a more compelling use of this technique, when we study the analysis of induction variables.

971 Regions

In region based analysis a program is viewed as a hierarchy of regions which are roughly portions of a ow graph that have only one point of entry We should not this concept of viewing code as a hierarchy of regions intuitive because a block structured procedure is naturally organized as a hierarchy of regions Each statement in a block structured program is a region as control ow can only enter at the beginning of a statement Each level of statement nesting corresponds to a level in the region hierarchy

Formally a region of a ow graph is a collection of nodes N and edges E such that

- 1 There is a header h in N that dominates all the nodes in N
- 2 If some node m can reach a node n in N without going through h then m is also in N

97 REGION BASED ANALYSIS

3 E is the set of all the control ow edges between nodes n_1 and n_2 in N except possibly for some that enter h

Example 9 50 Clearly a natural loop is a region but a region does not necessarily have a back edge and need not contain any cycles. For example in Fig. 9 47 nodes B_1 and B_2 together with the edge B_1 B_2 form a region so do nodes B_1 B_2 and B_3 with edges B_1 B_2 B_3 and B_1 B_3

However the subgraph with nodes B_2 and B_3 with edge B_2 — B_3 does not form a region—because control may enter the subgraph at both nodes B_2 and B_3 —More precisely neither B_2 nor B_3 dominates the other—so condition—1—for a region is violated—Even if we picked—say— B_2 to be the—header—we would violate condition—2—since we can reach B_3 from B_1 without going through B_2 and B_1 is not in the—region—

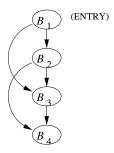

Figure 9 47 Examples of regions

9 7 2 Region Hierarchies for Reducible Flow Graphs

In what follows we shall assume the ow graph is reducible If occasionally we must deal with nonreducible ow graphs then we can use a technique called node splitting that will be discussed in Section 9 7 6

To construct a hierarchy of regions we identify the natural loops Recall from Section 9 6 6 that in a reducible ow graph any two natural loops are either disjoint or one is nested within the other. The process of parsing a reducible ow graph into its hierarchy of loops begins with every block as a region by itself. We call these regions leaf regions. Then we order the natural loops from the inside out it estarting with the innermost loops. To process a loop, we replace the entire loop by a node in two steps.

1 First the body of the loop L all nodes and edges except the back edges to the header is replaced by a node representing a region R Edges to the header of L now enter the node for R An edge from any exit of loop L is replaced by an edge from R to the same destination. However, if the edge is a back edge then it becomes a loop on R. We call R a body region

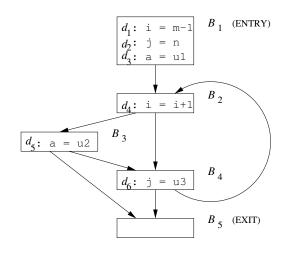

2 Next we construct a region R' that represents the entire natural loop L We call R' a loop region. The only difference between R and R' is that the latter includes the back edges to the header of loop L. Put another way when R' replaces R in the low graph all we have to do is remove the edge from R to itself

We proceed this way reducing larger and larger loops to single nodes—rst with a looping edge and then without—Since loops of a reducible—ow graph are nested or disjoint—the loop region s node can represent all the nodes of the natural loop in the series of—ow graphs that are constructed by this reduction process

Eventually all natural loops are reduced to single nodes At that point the ow graph may be reduced to a single node or there may be several nodes remaining with no loops i.e. the reduced ow graph is an acyclic graph of more than one node. In the former case we are done constructing the region hierarchy while in the latter case we construct one more body region for the entire ow graph.

Example 9 51 Consider the control ow graph in Fig 9 48 a There is one back edge in this ow graph which leads from B_4 to B_2 The hierarchy of regions is shown in Fig 9 48 b the edges shown are the edges in the region ow graphs There are altogether 8 regions

- 1 Regions R_1 R_5 are leaf regions representing blocks B_1 through B_5 respectively Every block is also an exit block in its region
- 2 Body region R_6 represents the body of the only loop in the ow graph it consists of regions R_2 R_3 and R_4 and three interregion edges B_2 B_3 B_2 B_4 and B_3 B_4 It has two exit blocks B_3 and B_4 since they both have outgoing edges not contained in the region Figure 9 49 a shows the ow graph with R_6 reduced to a single node. Notice that although the edges R_3 R_5 and R_4 R_5 have both been replaced by edge R_6 R_5 it is important to remember that the latter edge represents the two former edges since we shall have to propagate transfer functions across this edge eventually and we need to know that what comes out of both blocks B_3 and B_4 will reach the header of R_5
- 3 Loop region R_7 represents the entire natural loop. It includes one subre gion R_6 and one back edge B_4 B_2 . It has also two exit nodes again B_3 and B_4 . Figure 9.49 b. shows the ow graph after the entire natural loop is reduced to R_7 .
- 4 Finally body region R_8 is the top region. It includes three regions R_1 R_7 R_5 and three interregion edges B_1 B_2 B_3 B_5 and B_4 B_5 . When we reduce the ow graph to R_8 it becomes a single node. Since there are no back edges to its header B_1 there is no need for a nal step reducing this body region to a loop region.

(a)

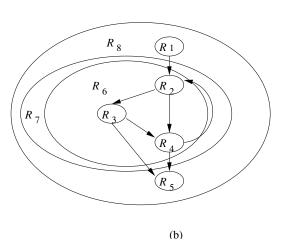

Figure 9 48 $\,$ a $\,$ An example $\,$ ow graph for the reaching de nitions problem and $\,$ b $\,$ Its region hierarchy

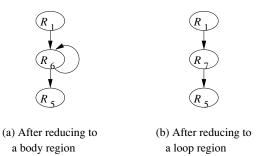

Figure 9 49 $\,$ Steps in the reduction of the $\,$ ow graph of Fig 9 48 to a single region

To summarize the process of decomposing reducible ow graphs hierarchically we over the following algorithm

Algorithm 9 52 Constructing a bottom up order of regions of a reducible ow graph

INPUT A reducible ow graph G

 ${f OUTPUT}$ A list of regions of G that can be used in region based data ow problems

METHOD

- 1 Begin the list with all the leaf regions consisting of single blocks of G in any order
- 2 Repeatedly choose a natural loop L such that if there are any natural loops contained within L then these loops have had their body and loop regions added to the list already. Add set the region consisting of the body of L i.e. L without the back edges to the header of L and then the loop region of L
- 3 If the entire ow graph is not itself a natural loop add at the end of the list the region consisting of the entire ow graph

9 7 3 Overview of a Region Based Analysis

For each region R and for each subregion R' within R we compute a transfer function $f_{R \text{ IN } R'}$ that summarizes the e ect of executing all possible paths

Where Reducible Comes From

We now see why reducible ow graphs were given that name While we shall not prove this fact the de nition of reducible ow graph used in this book involving the back edges of the graph is equivalent to several de nitions in which we mechanically reduce the ow graph to a single node. The process of collapsing natural loops described in Section 9.7.2 is one of them. Another interesting de nition is that the reducible ow graphs are all and only those graphs that can be reduced to a single node by the following two transformations.

- T_1 Remove an edge from a node to itself
- T_2 If node n has a single predecessor m and n is not the entry of the ow graph combine m and n

leading from the entry of R to the entry of R' while staying within R. We say that a block B within R is an $exit\ block$ of region R if it has an outgoing edge to some block outside R. We also compute a transfer function for each exit block B of R denoted $f_{R\ OUT\ B}$ that summarizes the e ect of executing all possible paths within R leading from the entry of R to the exit of B

We then proceed up the region hierarchy computing transfer functions for progressively larger regions. We begin with regions that are single blocks where $f_{B \text{ IN } B}$ is just the identity function and $f_{B \text{ OUT } B}$ is the transfer function for the block B itself. As we move up the hierarchy

If R is a body region then the edges belonging to R form an acyclic graph on the subregions of R. We may proceed to compute the transfer functions in a topological order of the subregions

If R is a loop region then we only need to account for the e ect of the back edges to the header of R

Eventually we reach the top of the hierarchy and compute the transfer functions for region R_n that is the entire ow graph. How we perform each of these computations will be seen in Algorithm 9.53

The next step is to compute the data ow values at the entry and exit of each block. We process the regions in the reverse order starting with region R_n and working our way down the hierarchy. For each region, we compute the data ow values at the entry. For region R_n , we apply $f_{R_n \text{ IN } R}$ IN ENTRY to get the data ow values at the entry of the subregions R in R_n . We repeat until we reach the basic blocks at the leaves of the region hierarchy

9 7 4 Necessary Assumptions About Transfer Functions

In order for region based analysis to work we need to make certain assumptions about properties of the set of transfer functions in the framework Speci cally we need three primitive operations on transfer functions composition meet and closure only the rst is required for data ow frameworks that use the iterative algorithm

Composition

The transfer function of a sequence of nodes can be derived by composing the functions representing the individual nodes. Let f_1 and f_2 be transfer functions of nodes n_1 and n_2 . The e ect of executing n_1 followed by n_2 is represented by f_2 f_1 . Function composition has been discussed in Section 9.2.2 and an example using reaching de nitions was shown in Section 9.2.4. To review let gen_i and $kill_i$ be the gen and kill sets for f_i . Then

Thus the gen and kill sets for f_2 f_1 are gen_2 gen_1 $kill_2$ and $kill_1$ $kill_2$ respectively. The same idea works for any transfer function of the gen kill form. Other transfer functions may also be closed but we have to consider each case separately.

Meet

That is the gen and kill sets for f_1 f_2 are gen_1 gen_2 and $kill_1$ $kill_2$ respectively. Again the same argument applies to any set of gen kill transfer functions

97 REGION BASED ANALYSIS

Closure

If f represents the transfer function of a cycle then f^n represents the e ect of going around the cycle n times. In the case where the number of iterations is not known we have to assume that the loop may be executed 0 or more times. We represent the transfer function of such a loop by f the closure of f which is defined by

$$f$$
 f^n

Note that f^0 must be the identity transfer function—since it represents the e ect of going zero times around the loop—i e—starting at the entry and not moving. If we let I represent the identity transfer function—then we can write

Suppose the transfer function f in a reaching de nitions framework has a gen set and a kill set. Then

and so on any f^n x is gen x kill That is going around a loop doesn t a ect the transfer function if it is of the gen kill form. Thus

That is the gen and kill sets for f are gen and respectively. Intuitively since we might not go around a loop at all anything in x will reach the entry to the loop. In all subsequent iterations, the reaching definitions include those in the gen set

9 7 5 An Algorithm for Region Based Analysis

The following algorithm solves a forward data ow analysis problem on a reducible ow graph according to some framework that satis es the assumptions of Section 9.7.4 Recall that $f_{R \text{ IN } R'}$ and $f_{R \text{ OUT } B}$ refer to transfer functions that transform data ow values at the entry to region R into the correct value at the entry of subregion R' and the exit of the exit block R' respectively

Algorithm 9 53 Region based analysis

INPUT A data ow framework with the properties outlined in Section 9.7.4 and a reducible ow graph G

OUTPUT Data ow values in B for each block B of G

METHOD

- 1 Use Algorithm 9 52 to construct the bottom up sequence of regions of G say R_1 R_2 R_n where R_n is the topmost region
- 2 Perform the bottom up analysis to compute the transfer functions sum marizing the e ect of executing a region For each region R_1 R_2 in the bottom up order do the following
 - a If R is a leaf region corresponding to block B let $f_{R \text{ IN } B}$ I and $f_{R \text{ OUT } B}$ f_{B} the transfer function associated with block B
 - b If R is a body region perform the computation of Fig. 9.50 a
 - c If R is a loop region perform the computation of Fig. 9.50 b
- 3 Perform the top down pass to nd the data ow values at the beginning of each region
 - a in R_n in entry
 - b For each region R in $\{R_1 \ R_{n-1}\}$ in the top down order compute IN R $f_{R'}$ IN R' where R' is the immediate enclosing region of R

Let us rst look at the details of how the bottom up analysis works. In line 1 of Fig. 9.50 a we visit the subregions of a body region in some topolog ical order. Line 2 computes the transfer function representing all the possible paths from the header of R to the header of S then in lines 3 and 4 we compute the transfer functions representing all the possible paths from the header of R to the exits of R—that is to the exits of all blocks that have successors outside S. Notice that all the predecessors B' in R must be in regions that precede S in the topological order constructed at line 1. Thus $f_{R \text{ OUT } B'}$ will have been computed already in line 4 of a previous iteration through the outer loop

97 REGION BASED ANALYSIS

For loop regions we perform the steps of lines 1 through 4 in Fig 9 50 b Line 2 computes the e ect of going around the loop body region S zero or more times Lines 3 and 4 compute the e ect at the exits of the loop after one or more iterations

In the top down pass of the algorithm step 3 a —rst assigns the boundary condition to the input of the top most region—Then if R is immediately contained in R'—we can simply apply the transfer function $f_{R'}$ —IN R—to the data—ow value IN R'—to compute IN R—

```

```

Figure 9 50 Details of region based data ow computations

Example 9 54 Let us apply Algorithm 9 53 to nd reaching de nitions in the ow graph in Fig 9 48 a Step 1 constructs the bottom up order in which the regions are visited this order will be the numerical order of their subscripts R_1 R_2 R_n

The values of the gen and kill sets for the ve blocks are summarized below

B	B_1	B_2	B_3	B_4	B_5
gen_B	$\{d_1 \ d_2 \ d_3\}$	$\{d_4\}$	$\{d_5\}$	$\{d_6\}$	
$kill_B$	$\{d_4 \ d_5 \ d_6\}$	$\{d_1\}$	$\{d_3\}$	$\{d_2\}$	

Remember the simpli ed rules for $gen\ kill$ transfer functions from Section 9.7.4

To take the meet of transfer functions take the union of the gen s and the intersection of the kill s

To compose transfer functions take the union of both the gen s and the kill s. However as an exception an expression that is generated by the rst function not generated by the second but killed by the second is not in the gen of the result

To take the closure of a transfer function $\$ retain its $\$ gen and $\$ replace the $\$ kill by

The rst ve regions R_1 R_5 are blocks B_1 B_5 respectively For 1 i 5 $f_{R_i \text{ IN } B_i}$ is the identity function and $f_{R_i \text{ OUT } B_i}$ is the transfer function for block B_i

 $f_{B_i \text{ OUT } B_i} \quad x \quad x \quad kill_{B_i} \quad gen_{B_i}$

		Transfer Function	n	gen	kill
R_6	$f_{R_6 \text{ IN } R_2}$	I			
	f_{R_6} OUT $_{B_2}$	f_{R_2} OUT $_{B_2}$	$f_{R_6 \; { m IN} \; R_2}$	$\{d_4\}$	$\{d_1\}$
	$f_{R_6 \text{ IN } R_3}$	$f_{R_6 \; \mathrm{OUT} \; B_2}$		$\{d_4\}$	$\{d_1\}$
	f_{R_6} OUT $_{B_3}$	f_{R_3} OUT $_{B_3}$	$f_{R_6 \; { m IN} \; R_3}$	$\{d_4 \ d_5\}$	$\{d_1 \ d_3\}$
	$f_{R_6 \text{ IN } R_4}$	f_{R_6} OUT $_{B_2}$	f_{R_6} OUT $_{B_3}$	$\{d_4 \ d_5\}$	$\{d_1\}$
	f_{R_6} OUT $_{B_4}$	f_{R_4} OUT $_{B_4}$	$f_{R_6 \; { m IN} \; R_4}$	$\{d_4 \ d_5 \ d_6\}$	$\{d_1 \ d_2\}$
R_7	$f_{R_7 \text{ IN } R_6}$	f_{R_6} OUT $_{B_4}$		$\{d_4 \ d_5 \ d_6\}$	
	$f_{R_7 \text{ OUT } B_3}$	f_{R_6} OUT $_{B_3}$	$f_{R_7 \; { m IN} \; R_6}$	$\{d_4\ d_5\ d_6\}$	$\{d_1 \ d_3\}$
	f_{R_7} OUT $_{B_4}$	f_{R_6} OUT $_{B_4}$	$f_{R_7 \; { m IN} \; R_6}$	$\{d_4\ d_5\ d_6\}$	$\{d_1 \ d_2\}$
R_8	$f_{R_8 \text{ IN } R_1}$	I			
	$f_{R_8 \text{ OUT } B_1}$	$f_{R_1 \; \mathrm{OUT} \; B_1}$		$\{d_1 \ d_2 \ d_3\}$	$\{d_4 \ d_5 \ d_6\}$
	$f_{R_8 \text{ IN } R_7}$	f_{R_8} OUT $_{B_1}$		$\{d_1 \ d_2 \ d_3\}$	$\{d_4 \ d_5 \ d_6\}$
	f_{R_8} OUT $_{B_3}$	f_{R_7} OUT $_{B_3}$	$f_{R_8 \; { m IN} \; R_7}$	$\{d_2 \ d_4 \ d_5 \ d_6\}$	$\{d_1 \ d_3\}$
	f_{R_8} OUT $_{B_4}$	f_{R_7} OUT $_{B_4}$	$f_{R_8 \; { m IN} \; R_7}$	$\{d_3 \ d_4 \ d_5 \ d_6\}$	$\{d_1 \ d_2\}$
	$f_{R_8 \text{ IN } R_5}$	$f_{R_8 \; { m OUT} \; B_3}$	f_{R_8} OUT $_{B_4}$	$\{d_2\ d_3\ d_4\ d_5\ d_6\}$	$\{d_1\}$
	$f_{R_8 ext{ OUT } B_5}$	$f_{R_5 \; { m OUT} \; B_5}$	$f_{R_8 \; { m IN} \; R_5}$	$\{d_2 \ d_3 \ d_4 \ d_5 \ d_6\}$	$\{d_1\}$

Figure 9 51 Computing transfer functions for the ow graph in Fig 9 48 a using region based analysis

The rest of the transfer functions constructed in Step 2 of Algorithm 9 53 are summarized in Fig 9 51 Region R_6 consisting of regions R_2 R_3 and R_4

represents the loop body and thus does not include the back edge B_4 B_2 The order of processing these regions will be the only topological order R_2 R_3 R_4 First R_2 has no predecessors within R_6 remember that the edge B_4 B_2 goes outside R_6 Thus $f_{R_6 \text{ IN } B_2}$ is the identity function 11 and $f_{R_6 \text{ OUT } B_2}$ is the transfer function for block B_2 itself

The header of region B_3 has one predecessor within R_6 namely R_2 . The transfer function to its entry is simply the transfer function to the exit of B_2 $f_{R_6 \ \rm OUT \ B_2}$ which has already been computed. We compose this function with the transfer function of B_3 within its own region to compute the transfer function to the exit of B_3

Last for the transfer function to the entry of R_4 we must compute

$$f_{R_6 \text{ OUT } B_2}$$
 $f_{R_6 \text{ OUT } B_3}$

because both B_2 and B_3 are predecessors of B_4 the header of R_4 . This transfer function is composed with the transfer function $f_{R_4 \ {\rm OUT} \ B_4}$ to get the desired function $f_{R_6 \ {\rm OUT} \ B_4}$. Notice for example that d_3 is not killed in this transfer function because the path B_2 . B_4 does not rede ne variable a

Now consider loop region R_7 It contains only one subregion R_6 which represents its loop body. Since there is only one back edge B_4 B_2 to the header of R_6 the transfer function representing the execution of the loop body 0 or more times is just $f_{R_6 \text{ OUT } B_4}$ the gen set is $\{d_4 \ d_5 \ d_6\}$ and the kill set is. There are two exits out of region R_7 blocks B_3 and B_4 . Thus this transfer function is composed with each of the transfer functions of R_6 to get the corresponding transfer functions of R_7 . Notice for instance how d_6 is in the gen set for $f_{R_7 \text{ OUT } B_3}$ because of paths like B_2 B_4 B_2 B_3 or even B_2 B_3 B_4 B_2 B_3

Finally consider R_8 the entire ow graph Its subregions are R_1 R_7 and R_5 which we shall consider in that topological order. As before the transfer function $f_{R_8 \text{ IN } B_1}$ is simply the identity function and the transfer function $f_{R_8 \text{ OUT } B_1}$ is just $f_{R_1 \text{ OUT } B_1}$ which in turn is f_{B_1}

The header of R_7 which is B_2 has only one predecessor B_1 so the transfer function to its entry is simply the transfer function out of B_1 in region R_8 We compose $f_{R_8 \text{ OUT } B_1}$ with the transfer functions to the exits of B_3 and B_4 within R_7 to obtain their corresponding transfer functions within R_8 Lastly we consider R_5 Its header B_5 has two predecessors within R_8 namely B_3 and B_4 Therefore we compute $f_{R_8 \text{ OUT } B_3}$ $f_{R_8 \text{ OUT } B_4}$ to get $f_{R_8 \text{ IN } B_5}$ Since the transfer function of block B_5 is the identity function $f_{R_8 \text{ OUT } B_5}$ $f_{R_8 \text{ IN } B_5}$

Step 3 computes the actual reaching denitions from the transfer functions. In step 3 a \times IN R_8 since there are no reaching denitions at the beginning of the program. Figure 9.52 shows how step 3 b computes the rest of the data ow values. The step starts with the subregions of R_8 . Since the transfer function from the start of R_8 to the start of each of its subregion has been

 $^{^{11}{\}rm Strictly}$ speaking we mean $f_{R_6~{\rm IN}~R_2}~$ but when a region like R_2 is a single block it is often clearer if we use the block name rather than the region name in this context

computed a single application of the transfer function $\,$ nds the data $\,$ ow value at the start each subregion. We repeat the steps until we get the data $\,$ ow values of the leaf regions which are simply the individual basic blocks. Note that the data $\,$ ow values shown in Figure 9.52 are exactly what we would get had we applied iterative data $\,$ ow analysis to the same $\,$ ow graph as must be the case of course. $\,$ $\,$

                         f_{R_6 \text{ IN } R_2} IN R_6
```

Figure 9 52 Final steps of region based ow analysis

9 7 6 Handling Nonreducible Flow Graphs

If nonreducible ow graphs are expected to be common for the programs to be processed by a compiler or other program processing software then we recommend using an iterative rather than a hierarchy based approach to data ow analysis. However, if we need only to be prepared for the occasional nonreducible ow graph then the following node splitting technique is adequate.

Construct regions from natural loops to the extent possible If the ow graph is nonreducible we shall nd that the resulting graph of regions has cycles but no back edges so we cannot parse the graph any further A typical situation is suggested in Fig 9 53 a which has the same structure as the nonreducible ow graph of Fig 9 45 but the nodes in Fig 9 53 may actually be complex regions as suggested by the smaller nodes within

We pick some region R that has more than one predecessor and is not the header of the entire—ow graph. If R has k predecessors make k copies of the entire—ow graph R—and connect each predecessor of R s header to a different copy of R—Remember that only the header of a region could possibly have a predecessor outside that region. It turns out although we shall not prove it that such node splitting results in a reduction by at least one in the number of regions after new back edges are identified and their regions constructed. The resulting graph may still not be reducible but by alternating a splitting phase with a phase where new natural loops are identified and collapsed to regions we eventually are left with a single region if each ow graph has been reduced

97 REGION BASED ANALYSIS

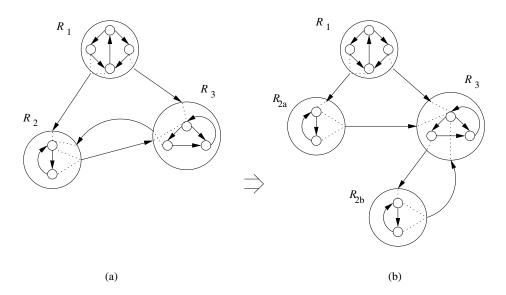

Figure 9 53 Duplicating a region to make a nonreducible ow graph become reducible

Example 9 55 The splitting shown in Fig 9 53 b has turned the edge R_{2b} R_3 into a back edge since R_3 now dominates R_{2b} These two regions may thus be combined into one The resulting three regions R_1 R_{2a} and the new region—form an acyclic graph—and therefore may be combined into a single body region—We thus have reduced the entire—ow graph to a single region—In general additional splits may be necessary and in the worst case the total number of basic blocks could become exponential in the number of blocks in the original—ow graph—

We must also think about how the result of the data ow analysis on the split ow graph relates to the answer we desire for the original ow graph. There are two approaches we might consider

- 1 Splitting regions may be bene cial for the optimization process and we can simply revise the ow graph to have copies of certain blocks Since each duplicated block is entered along only a subset of the paths that reached the original the data ow values at these duplicated blocks will tend to contain more speci-c information than was available at the original For instance fewer de nitions may reach each of the duplicated blocks that reach the original block
- 2 If we wish to retain the original ow graph with no splitting then after analyzing the split ow graph we look at each split block B and its corresponding set of blocks B_1 B_2 B_k We may compute IN B IN B_1 IN B_2 IN B_k and similarly for the OUT s

9 7 7 Exercises for Section 9 7

Exercise 9 7 1 For the ow graph of Fig 9 10 see the exercises for Section 9 1

- *i* Find all the possible regions You may however omit from the list the regions consisting of a single node and no edges
- ii Give the set of nested regions constructed by Algorithm 9 52
- iii Give a T_1 T_2 reduction of the ow graph as described in the box on Where Reducible Comes From in Section 9 7 2

Exercise 9 7 2 Repeat Exercise 9 7 1 on the following ow graphs

- a Fig 93
- b Fig 89
- c Your ow graph from Exercise 8 4 1
- d Your ow graph from Exercise 8 4 2

Exercise 9 7 3 Prove that every natural loop is a region

Exercise 9 7 4 Show that a ow graph is reducible if and only it can be transformed to a single node using

- a The operations T_1 and T_2 described in the box in Section 9.7.2
- b The region de nition introduced in Section 9 7 2

Exercise 9 7 5 Show that when you apply node splitting to a nonreducible ow graph and then perform T_1 T_2 reduction on the resulting split graph you wind up with strictly fewer nodes than you started with

Exercise 9 7 6 What happens if you apply node splitting and T_1 reduction alternately to reduce a complete directed graph of n nodes

98 Symbolic Analysis

We shall use symbolic analysis in this section to illustrate the use of region based analysis. In this analysis we track the values of variables in programs symbolically as expressions of input variables and other variables which we call reference variables. Expressing variables in terms of the same set of reference variables draws out their relationships. Symbolic analysis can be used for a range of purposes such as optimization parallelization and analyses for program understanding.

98 SYMBOLIC ANALYSIS

```
1 x input
2 y x 1
3 z y 1
4 A x 10
5 A y 11
6 if z x
7 z x
```

Figure 9 54 An example program motivating symbolic analysis

Example 9 56 Consider the simple example program in Fig 9 54 Here we use x as the sole reference variable. Symbolic analysis will and that y has the value x 1 and z has the value x 2 after their respective assignment statements in lines 2 and 3. This information is useful for example in determining that the two assignments in lines 4 and 5 write to discrete memory locations and can thus be executed in parallel. Furthermore, we can tell that the condition z x is never true, thus allowing the optimizer to remove the conditional statement in lines 6 and 7 all together. \Box

9 8 1 A ne Expressions of Reference Variables

Since we cannot create succinct and closed form symbolic expressions for all values computed we choose an abstract domain and approximate the computations with the most precise expressions within the domain. We have already seen an example of this strategy before constant propagation. In constant propagation our abstract domain consists of the constants an UNDEF symbol if we have not yet determined if the value is a constant and a special NAC symbol that is used whenever a variable is found not to be a constant

The symbolic analysis we present here expresses values as a ne expressions of reference variables whenever possible. An expression is a ne with respect to variables v_1 v_2 v_n if it can be expressed as c_0 c_1v_1 c_nv_n where c_0 c_1 c_n are constants. Such expressions are informally known as linear expressions. Strictly speaking an anne expression is linear only if c_0 is zero. We are interested in a ne expressions because they are often used to index arrays in loops—such information is useful for optimizations and parallelization. Much more will be said about this topic in Chapter 11

Induction Variables

Instead of using program variables as reference variables an a ne expression can also be written in terms of the count of iterations through the loop Vari ables whose values can be expressed as c_1i c_0 where i is the count of iterations through the closest enclosing loop are known as *induction variables*

Example 9 57 Consider the code fragment

for m 10 m 20 m
$$\times$$
 m 3 A \times 0

Suppose we introduce for the loop a variable say i representing the number of iterations executed. The value i is 0 in the first iteration of the loop 1 in the second and so on. We can express variable m as an anne expression of i namely m in 10. Variable x which is 3m takes on values 30. 33. 57 during successive iterations of the loop. Thus x has the anne expression x 30. 3i. We conclude that both m and x are induction variables of this loop.

Expressing variables as a ne expressions of loop indexes makes the series of values being computed explicit and enables several transformations. The series of values taken on by an induction variable can be computed with additions rather than multiplications. This transformation is known as strength reduction and was introduced in Sections 8.7 and 9.1. For instance, we can eliminate the multiplication x m 3 from the loop of Example 9.57 by rewriting the loop as

In addition notice that the locations assigned 0 in that loop A=30 A=33 A=57 are also a ne expressions of the loop index. In fact this series of integers is the only one that needs to be computed. We do not need both m and x for instance the code above can be replaced by

Besides speeding up the computation symbolic analysis is also useful for parallelization. When the array indexes in a loop are an expressions of loop indexes we can reason about relations of data accessed across the iterations. For example, we can tell that the locations written are different in each iteration and therefore all the iterations in the loop can be executed in parallel on different processors. Such information is used in Chapters 10 and 11 to extract parallelism from sequential programs.

Other Reference Variables

If a variable is not a linear function of the reference variables already chosen we have the option of treating its value as reference for future operations. For example, consider the code fragment

98 SYMBOLIC ANALYSIS

While the value held by a after the function call cannot itself be expressed as a linear function of any reference variables it can be used as reference for subsequent statements. For example, using a as a reference variable, we can discover that c is one larger than b at the end of the program

```
1
2
     for
            f
                              200
3
                  a
4
             b
                   10
5
                  0
             С
             for
                         10
                    g
7
                    d
                          b
                               С
8
     }
```

Figure 9 55 Source code for Example 9 58

Example 9 58 Our running example for this section is based on the source code shown in Fig 9 55. The inner and outer loops are easy to understand since f and g are not modi ed except as required by the for loops. It is thus possible to replace f and g by reference variables i and j that count the number of iterations of the outer and inner loops respectively. That is we can let f in 99 and g in 9 and substitute for f and g throughout. When translating to intermediate code, we can take advantage of the fact that each loop iterates at least once and so postpone the test for g 100 and g 10 to the ends of the loops. Figure 9 56 shows the loops as if they were repeat loops

It turns out that a b c and d are all induction variables. The sequences of values assigned to the variables in each line of the code are shown in Figure 9.57. As we shall see it is possible to discover the annexpressions for these variables in terms of the reference variables i and j. That is at line 4 a i at line 7. d 10i j 1 and at line 8. c j \square

9 8 2 Data Flow Problem Formulation

This analysis nds a ne expressions of reference variables introduced 1 to count the number of iterations executed in each loop and 2 to hold values at the entry of regions where necessary. This analysis also nds induction variables loop invariants as well as constants as degenerate a ne expressions. Note that this analysis cannot nd all constants because it only tracks a ne expressions of reference variables.

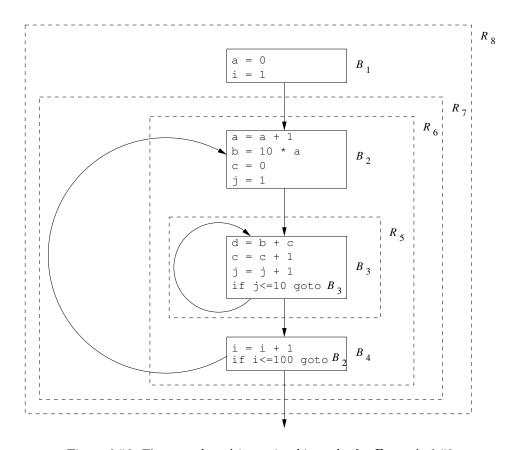

Figure 9 56 Flow graph and its region hierarchy for Example 9 58

Data Flow Values Symbolic Maps

The domain of data ow values for this analysis is symbolic maps which are functions that map each variable in the program to a value. The value is either an a ne function of reference values or the special symbol NAA to represent a non a ne expression. If there is only one variable the bottom value of the semilattice is a map that sends the variable to NAA. The semilattice for n variables is simply the product of the individual semilattices. We use $m_{\rm NAA}$ to denote the bottom of the semilattice which maps all variables to NAA. We can de ne the symbolic map that sends all variables to an unknown value to be the top data ow value as we did for constant propagation. However, we do not need top values in region based analysis

Example 9 59 The symbolic maps associated with each block for the code in Example 9 58 are shown in Figure 9 58 We shall see later how these maps are discovered they are the result of doing region based data ow analysis on the ow graph of Fig 9 56

		i	1		i	2		1	i	100		i 1	.00

Figure 9 58 Symbolic maps of the program in Example 9 58

The symbolic map associated with the entry of the program is $m_{\rm NAA}$. At the exit of B_1 the value of a is set to 0. Upon entry to block B_2 a has value 0 in the first iteration and increments by one in each subsequent iteration of the outer loop. Thus a has value i 1 at the entry of the ith iteration and value i at the end. The symbolic map at the entry of B_2 maps variables b c d to NAA because the variables have unknown values on entry to the outer loop. Their values depend on the number of iterations of the outer loop so far. The symbolic map on exit from B_2 rejects the assignment statements to a b and c in that block. The rest of the symbolic maps can be deduced in a similar manner. Once we have established the validity of the maps in Fig. 9.58 we can replace each of the assignments to a b c and d in Fig. 9.55 by the appropriate a ne expressions. That is we can replace Fig. 9.55 by the code in Fig. 9.59.

Transfer Function of a Statement

The transfer functions in this data ow problem send symbolic maps to symbolic maps. To compute the transfer function of an assignment statement we interpret the semantics of the statement and determine if the assigned variable can be expressed as an a ne expression of the values on the right of the

```

                     j
          }
```

Figure 9 59 The code of Fig 9 55 with assignments replaced by a $\,$ ne expres sions of the reference variables i and j

Cautions Regarding Transfer Functions on Value Maps

A subtlety in the way we de ne the transfer functions on symbolic maps is that we have options regarding how the e ects of a computation are expressed. When m is the map for the input of a transfer function m x is really just—whatever value variable x happens to have on entry—We try very hard to express the result of the transfer function as an anne expression of reference variables used by the input map

You should observe the proper interpretation of expressions like $f \ m \ x$ where f is a transfer function m a map and x a variable. As is conventional in mathematics we apply functions from the left meaning that we rst compute $f \ m$ which is a map. Since a map is a function we may then apply it to variable x to produce a value

assignment The values of all other variables remain unchanged The transfer function of statement s denoted f_s is defined as follows

- 1 If s is not an assignment statement then f_s is the identity function
- 2 If s is an assignment statement to variable x then

```
f_s\ m\ x for all variables v\ /\ x c_0\ c_1 m\ y \qquad c_2 m\ z \qquad \text{if}\ x\ \text{is assigned}\ c_0\ c_1 y \quad c_2 z c_1\ 0\ \text{or}\ m\ y\ /\ \text{NAA} \qquad \text{and} c_2\ 0\ \text{or}\ m\ z\ /\ \text{NAA} otherwise
```

98 SYMBOLIC ANALYSIS

The expression c_0 c_1m y c_2m z is intended to represent all the possible forms of expressions involving arbitrary variables y and z that may appear on the right side of an assignment to x and that give x a value that is an a ne transformation on prior values of variables. These expressions are c_0 c_0 y c_0 y y z x y c_1 y and y 1 c_1 . Note that in many cases one or more of c_0 c_1 and c_2 are 0

Example 9 60 If the assignment is \mathbf{x} \mathbf{y} \mathbf{z} then c_0 0 and c_1 c_2 1 If the assignment is \mathbf{x} \mathbf{y} 5 then c_0 c_2 0 and c_1 1 5

Composition of Transfer Functions

To compute f_2 f_1 where f_1 and f_2 are defined in terms of input map m we substitute the value of m v_i in the definition of f_2 with the definition of f_1 m v_i . We replace all operations on NAA values with NAA. That is

1 If
$$f_2$$
 m v NAA then f_2 f_1 m v NAA
$$2 \text{ If } f_2$$
 m v c_0 $\sum_i c_i m$ v_i then
$$f_2$$
 f_1 m v
$$\text{NAA} \qquad \qquad \text{if } f_1$$
 m v_i NAA for some i / 0 c_i / 0
$$c_0$$
 $\sum_i c_i f_1$ m v_i otherwise

Example 9 61 The transfer functions of the blocks in Example 9 58 can be computed by composing the transfer functions of their constituent statements These transfer functions are defined in Fig. 9 60 \Box

f	f m a	f m b	f m c	f m d
f_{B_1}	0	m b	m c	m d
f_{B_2}	$m \ a = 1$	$10m \ a = 10$	0	m d
f_{B_3}	m a	m b	$m \ c \qquad 1$	$m \ b \ m \ c$
$f_{B_1} \\ f_{B_2} \\ f_{B_3} \\ f_{B_4}$	m a	m b	m c	m d

Figure 9 60 Transfer Functions of Example 9 58

Solution to Data Flow Problem

We use the notation $\text{IN}_{i\,j}\ B_3$ and $\text{OUT}_{i\,j}\ B_3$ to refer to the input and output data ow values of block B_3 in iteration j of the inner loop and iteration i of the outer loop. For the other blocks we use $\text{IN}_i\ B_k$ and $\text{OUT}_i\ B_k$ to refer to these values in the ith iteration of the outer loop. Also we can see that

```
f_B in B_k
                                          for all B_k
     OUT B_k
     OUT B_1
                        IN_1 B_2
    \mathrm{OUT}_i \ B_2
                        IN _{i 1} B_3
                                                     10
                                          1
OUT_{i j 1} B_3
                                                     100 \ 2
                        IN_{ij} B_3
 OUT_{i \ 10} B_3
                                          2
                        IN _i B_4
                                                     100
                                                     100
 OUT_{i-1} B_4
                        IN_i B_2
```

Figure 9 61 Constraints satis ed on each iteration of the nested loops

the symbolic maps shown in Fig. 9.58 satisfy the constraints imposed by the transfer functions $\,$ listed in Fig. 9.61

The rst constraint says that the output map of a basic block is obtained by applying the blocks transfer function to the input map. The rest of the constraints say that the output map of a basic block must be greater than or equal to the input map of a successor block in the execution

Note that our iterative data ow algorithm cannot produce the above solution because it lacks the concept of expressing data ow values in terms of the number of iterations executed Region based analysis can be used to not such solutions as we shall see in the next section

9 8 3 Region Based Symbolic Analysis

We can extend the region based analysis described in Section 9 7 to $\,$ nd ex pressions of variables in the ith iteration of a loop. A region based symbolic analysis has a bottom up pass and a top down pass like other region based al gorithms. The bottom up pass summarizes the e ect of a region with a transfer function that sends a symbolic map at the entry to an output symbolic map at the exit. In the top down pass values of symbolic maps are propagated down to the inner regions

The di erence lies in how we handle loops In Section 9.7 the e ect of a loop is summarized with a closure operator. Given a loop with body f its closure f is defined as an infinite meet of all possible numbers of applications of f. However to an induction variables we need to determine if a value of a variable is an ane function of the number of iterations executed so far. The symbolic map must be parameterized by the number of the iteration being executed. Furthermore, whenever we know the total number of iterations executed in a loop we can use that number to and the values of induction variables after the loop. For instance, in Example 9.58, we claimed that a has the value of i after executing the ith iteration. Since the loop has 100 iterations, the value of a must be 100 at the end of the loop.

In what follows we rst de ne the primitive operators meet and composition of transfer functions for symbolic analysis. Then show how we use them to perform region based analysis of induction variables

Meet of Transfer Functions

When computing the meet of two functions the value of a variable is NAA unless the two functions map the variable to the same value and the value is not NAA Thus

$$f_1$$
 f_2 m v f_1 m v if f_1 m v f_2 m v NAA otherwise

Parameterized Function Compositions

To express a variable as an a ne function of a loop index we need to compute the e ect of composing a function some given number of times. If the e ect of one iteration is summarized by transfer function f then the e ect of executing i iterations for some i 0 is denoted f^i . Note that when i 0 f^i f^0 I the identify function

Variables in the program are divided into four categories

- 1 If f m x m x c where c is a constant then f^i m x m x ci for every value of i 0. We say that x is a basic induction variable of the loop whose body is represented by the transfer function f
- 2 If f m x m x then f i m x m x for all i 0 The variable x is not modily ed and it remains unchanged at the end of any number of iterations through the loop with transfer function f. We say that x is a $symbolic \ constant$ in the loop
- 3 If $f m x c_0 c_1 m x_1 c_n m x_n$ where each x_k is either a basic induction variable or a symbolic constant then for i = 0

$$f^i m x c_0 c_1 f^i m x_1 c_n f^i m x_n$$

We say that x is also an induction variable though not a basic one. Note that the formula above does not apply if i=0

4 In all other cases $f^i m x$ NAA

To nd the e ect of executing a xed number of iterations we simply replace i above by that number. In the case where the number of iterations is unknown the value at the start of the last iteration is given by f. In this case, the only variables whose values can still be expressed in the anne form are the loop invariant variables.

Example 9 62 For the innermost loop in Example 9 58 the e ect of executing i iterations i 0 is summarized by $f_{B_3}^i$ From the de nition of f_{B_3} we see that a and b are symbolic constants c is a basic induction variable as it is

incremented by one every iteration d is an induction variable because it is an a ne function the symbolic constant b and basic induction variable c. Thus

$$f_{B_3}^i \ m \ v \ egin{pmatrix} f \ m \ a \ & & ext{if} \ v \ a \ & & ext{if} \ v \ b \ & & ext{if} \ v \ c \ & & ext{if} \ v \ c \ & & ext{if} \ v \ d \ \end{pmatrix}$$

If we could not tell how many times the loop of block B_3 iterated then we could not use f^i and would have to use f to express the conditions at the end of the loop. In this case, we would have

$$f_{B_3} \ m \ \ v$$
 $egin{pmatrix} f \ m \ a & ext{if} \ v & a \ m \ b & ext{if} \ v & b \ ext{NAA} & ext{if} \ v & c \ ext{NAA} & ext{if} \ v & d \end{pmatrix}$

A Region Based Algorithm

Algorithm 9 63 Region based symbolic analysis

INPUT A reducible ow graph G

OUTPUT Symbolic maps in B for each block B of G

METHOD We make the following modi cations to Algorithm 9 53

1 We change how we construct the transfer function for a loop region. In the original algorithm we use the $f_{R \; {\rm IN} \; S}$ transfer function to map the symbolic map at the entry of loop region R to a symbolic map at the entry of loop body S after executing an unknown number of iterations. It is defined to be the closure of the transfer function representing all paths leading back to the entry of the loop as shown in Fig. 9.50 b. Here we define $f_{R \; i \; {\rm IN} \; S}$ to represent the effect of execution from the start of the loop region to the entry of the ith iteration. Thus

$$f_{R \ i \ \text{IN} \ S}$$
 $f_{S \ \text{OUT} \ B}$ $f_{S \ \text{OUT} \ B}$

- 2 If the number of iterations of a region is known the summary of the region is computed by replacing i with the actual count
- 3 In the top down pass we compute $f_{R\ i\ {\rm IN}\ B}$ to $\ {\rm nd}$ the symbolic map associated with the entry of the $i{\rm th}$ iteration of a loop

98 SYMBOLIC ANALYSIS

4 In the case where the input value of a variable $m\ v$ is used on the right hand side of a symbolic map in region R and $m\ v$ NAA upon entry to the region we introduce a new reference variable t add assignment t v to the beginning of region R and all references of $m\ v$ are replaced by t If we did not introduce a reference variable at this point the NAA value held by v would penetrate into inner loops

Figure 9 62 Transfer function relations in the bottom up pass for Example 9 58

Example 9 64 For Example 9 58 we show how the transfer functions for the program are computed in the bottom up pass in Fig 9 62 Region R_5 is the inner loop with body B_5 The transfer function representing the path from the entry of region R_5 to the beginning of the jth iteration j-1 is $f_{B_3}^{j-1}$ The transfer function representing the path to the end of the jth iteration j-1 is $f_{B_3}^{j}$

Region R_6 consists of blocks B_2 and B_4 with loop region R_5 in the middle. The transfer functions from the entry of B_2 and R_5 can be computed in the same way as in the original algorithm. Transfer function f_{R_6} OUT B_3 represents the composition of block B_2 and the entire execution of the inner loop since f_{B_4} is the identity function. Since the inner loop is known to iterate 10 times we can replace j by 10 to summarize the elect of the inner loop precisely. The

\overline{f}	f m a	f m b	f m c	f m d
$f_{R_5 \ j \ \text{IN} \ B_3}$	m a	m b	$m \ c j 1$	NAA
$f_{R_5\ j\ { m OUT}\ B_3}$	m a	m b	$m \ c j$	$m \ b \ m \ c$
, and the second				j 1
$f_{R_6 \text{ IN } B_2}$	m a	m b	m c	m d
$f_{R_6 \; { m IN} \; R_5}$	$m \ a = 1$	$10m \ a = 10$	0	m d
f_{R_6} out $_{B_4}$	$m \ a = 1$	$10m \ a = 10$	10	$10m \ a \qquad 9$
$f_{R_7 \ i \ { m IN} \ R_6}$	$m\ a i 1$	NAA	NAA	NAA
$f_{R_7\ i\ { m OUT}\ B_4}$	$m \ a = i$	$10m \ a \qquad 10i$	10	$10m \ a$
				10i - 9
$f_{R_8 \text{ IN } B_1}$	m a	m b	m c	m d
$f_{R_8 \; { m IN} \; R_7}$	0	m b	m c	m d
$f_{R_8 \text{ OUT } B_4}$	100	1000	10	1009

Figure 9 63 Transfer functions computed in the bottom up pass for Exam ple $9\,58$

rest of the transfer functions can be computed in a similar manner The actual transfer functions computed are shown in Fig. 9 63

The symbolic map at the entry of the program is simply m_{NAA} We use the top down pass to compute the symbolic map to the entry to successively nested regions until we nd all the symbolic maps for every basic block. We start by computing the data—ow values for block B_1 in region R_8

$$\begin{array}{ccc} \text{in } B_1 & & m_{\text{naa}} \\ \text{out } B_1 & & f_{B_1} \text{ in } B_1 \end{array}$$

Descending down to regions R_7 and R_6 we get

$$egin{array}{lll} \operatorname{IN}_i \ B_2 & & f_{R_7 \ i \ \operatorname{IN} \ R_6} & \operatorname{OUT} B_1 \ & \operatorname{OUT}_i \ B_2 & & f_{B_2 \ \operatorname{IN}_i \ B_2} \ & \end{array}$$

Finally in region R_5 we get

$$\operatorname{IN}_{i\;j}B_3 \qquad \qquad f_{R_5\;j\operatorname{IN}\,B_3} \quad \operatorname{OUT}_iB_2 \\ \operatorname{OUT}_{i\;j}B_3 \qquad \qquad f_{B_3} \,\operatorname{IN}_{i\;j}B_3$$

Not surprisingly these equations produce the results we showed in Fig. 9.58 \Box

Example 958 shows a simple program where every variable used in the symbolic map has an a ne expression. We use Example 965 to illustrate why and how we introduce reference variables in Algorithm 963

98 SYMBOLIC ANALYSIS

```
for i
                      n i
1
              1 i

b A reference variable t makes b an induction variable

Figure 9 64 The need to introduce reference variables

Example 9 65 Consider the simple example in Fig 9 64 a Let f_j be the transfer function summarizing the e ect of executing j iterations of the inner loop. Even though the value of a may uctuate during the execution of the loop we see that b is an induction variable based on the value of a on entry of the loop that is f_j m b m a 1 j Because a is assigned an input value the symbolic map upon entry to the inner loop maps a to NAA. We introduce a new reference variable t to save the value of a upon entry and perform the substitutions as in Fig 9 64 b.

9 8 4 Exercises for Section 9 8

Exercise 9 8 1 For the ow graph of Fig 9 10 see the exercises for Section 9 1 give the transfer functions for

- a Block B_2
- b Block B_4
- c Block B_5

Exercise 9 8 2 Consider the inner loop of Fig 9 10 consisting of blocks B_3 and B_4 If i represents the number of times around the loop and f is the transfer function for the loop body i e excluding the edge from B_4 to B_3 from the entry of the loop i e the beginning of B_3 to the exit from B_4 then what is f^i Remember that f takes as argument a map m and m assigns a value to each of variables a b d and e We denote these values m a and so on although we do not know their values

Exercise 9 8 3 Now consider the outer loop of Fig. 9 10 consisting of blocks B_2 B_3 B_4 and B_5 Let g be the transfer function for the loop body from the entry of the loop at B_2 to its exit at B_5 Let i measure the number of iterations of the inner loop of B_3 and B_4 which count of iterations we cannot know and let j measure the number of iterations of the outer loop—which we also cannot know—What is g^j

9 9 Summary of Chapter 9

- ♦ Global Common Subexpressions An important optimization is nding computations of the same expression in two di erent basic blocks If one precedes the other we can store the result the rst time it is computed and use the stored result on subsequent occurrences
- ightharpoonup Copy Propagation A copy statement u-v assigns one variable v to another u In some circumstances we can replace all uses of u by v thus eliminating both the assignment and u
- ◆ Code Motion Another optimization is to move a computation outside the loop in which it appears This change is only correct if the computation produces the same value each time around the loop
- ◆ Induction Variables Many loops have induction variables variables that take on a linear sequence of values each time around the loop Some of these are used only to count iterations and they often can be eliminated thus reducing the time it takes to go around the loop
- → Data Flow Analysis A data ow analysis schema de nes a value at each point in the program Statements of the program have associated transfer functions that relate the value before the statement to the value after Statements with more than one predecessor must have their value de ned by combining the values at the predecessors using a meet or con uence operator
- ◆ Data Flow Analysis on Basic Blocks Because the propagation of data ow values within a block is usually quite simple data ow equations are generally set up to have two variables for each block called IN and OUT that represent the data ow values at the beginning and end of the

99 SUMMARY OF CHAPTER 9

block respectively The transfer functions for the statements in a block are composed to get the transfer function for the block as a whole

- ◆ Reaching De nitions The reaching de nitions data ow framework has values that are sets of statements in the program that de ne values for one or more variables The transfer function for a block kills de nitions of variables that are de nitely rede ned in the block and adds generates those de nitions of variables that occur within the block The con u ence operator is union since de nitions reach a point if they reach any predecessor of that point
- ◆ Live Variables Another important data ow framework computes the variables that are live will be used before rede nition at each point. The framework is similar to reaching de nitions except that the transfer function runs backward. A variable is live at the beginning of a block if it is either used before de nition in the block or is live at the end of the block and not rede ned in the block.
- ◆ Available Expressions To discover global common subexpressions we determine the available expressions at each point expressions that have been computed and neither of the expression s arguments were rede ned after the last computation The data ow framework is similar to reaching de nitions but the con uence operator is intersection rather than union
- ◆ Abstraction of Data Flow Problems Common data ow problems such as those already mentioned can be expressed in a common mathematical structure. The values are members of a semilattice whose meet is the con uence operator. Transfer functions map lattice elements to lattice elements. The set of allowed transfer functions must be closed under composition and include the identity function.
- ♦ Monotone Frameworks A semilattice has a relation de ned by a b if and only if a b a Monotone frameworks have the property that each transfer function preserves the relationship that is a b implies f a f b for all lattice elements a and b and transfer function f
- ◆ Distributive Frameworks These frameworks satisfy the condition that f a b f a f b for all lattice elements a and b and transfer function f It can be shown that the distributive condition implies the monotone condition
- ◆ Iterative Solution to Abstract Frameworks All monotone data ow frame works can be solved by an iterative algorithm in which the IN and OUT values for each block are initialized appropriately depending on the framework and new values for these variables are repeatedly computed by applying the transfer and con uence operations This solution is always safe optimizations that it suggests will not change what the

program does but the solution is certain to be the best possible only if the framework is distributive

- ◆ The Constant Propagation Framework While the basic frameworks such as reaching de nitions are distributive there are interesting monotone but not distributive frameworks as well One involves propagating constants by using a semilattice whose elements are mappings from the program variables to constants plus two special values that represent no information and de nitely not a constant
- ◆ Partial Redundancy Elimination Many useful optimizations such as code motion and global common subexpression elimination can be generalized to a single problem called partial redundancy elimination Expressions that are needed but are available along only some of the paths to a point are computed only along the paths where they are not available The correct application of this idea requires the solution to a sequence of four different data ow problems plus other operations
- ◆ Dominators A node in a ow graph dominates another if every path to the latter must go through the former A proper dominator is a dominator other than the node itself Each node except the entry node has an imme diate dominator that one of its proper dominators that is dominated by all the other proper dominators
- ◆ Depth First Ordering of Flow Graphs If we perform a depth—rst search of a ow graph starting at its entry we produce a depth—rst spanning tree—The depth—rst order of the nodes is the reverse of a postorder traversal of this tree
- ◆ Classi cation of Edges When we construct a depth rst spanning tree all the edges of the ow graph can be divided into three groups advanc ing edges those that go from ancestor to proper descendant retreating edges those from descendant to ancestor and cross edges others. An important property is that all the cross edges go from right to left in the tree. Another important property is that of these edges only the retreat ing edges have a head lower than its tail in the depth rst order reverse postorder.
- ♦ Back Edges A back edge is one whose head dominates its tail Every back edge is a retreating edge regardless of which depth rst spanning tree for its ow graph is chosen
- ◆ Reducible Flow Graphs If every retreating edge is a back edge regardless of which depth—rst spanning tree is chosen—then the—ow graph is said to be reducible—The vast majority of—ow graphs are reducible—those whose only control—ow statements are the usual loop forming and branching statements are certainly reducible

9 10 REFERENCES FOR CHAPTER 9

- ◆ Natural Loops A natural loop is a set of nodes with a header node that dominates all the nodes in the set and has at least one back edge entering that node Given any back edge we can construct its natural loop by taking the head of the edge plus all nodes that can reach the tail of the edge without going through the head Two natural loops with di erent headers are either disjoint or one is completely contained in the other this fact lets us talk about a hierarchy of nested loops as long as loops are taken to be natural loops
- ◆ Depth First Order Makes the Iterative Algorithm E cient The iterative algorithm requires few passes as long as propagation of information along acyclic paths is su cient ie cycles add nothing If we visit nodes in depth rst order any data ow framework that propagates information forward eg reaching de nitions will converge in no more than 2 plus the largest number of retreating edges on any acyclic path The same holds for backward propagating frameworks like live variables if we visit in the reverse of depth rst order ie in postorder
- ◆ Regions Regions are sets of nodes and edges with a header h that dominates all nodes in the region. The predecessors of any node other than h in the region must also be in the region. The edges of the region are all that go between nodes of the region with the possible exception of some or all that enter the header.
- ♦ Regions and Reducible Flow Graphs Reducible ow graphs can be parsed into a hierarchy of regions These regions are either loop regions which include all the edges into the header or body regions that have no edges into the header
- ◆ Region Based Data Flow Analysis An alternative to the iterative ap proach to data ow analysis is to work up and down the region hierarchy computing transfer functions from the header of each region to each node in that region
- ◆ Region Based Induction Variable Detection An important application of region based analysis is in a data ow framework that tries to compute formulas for each variable in a loop region whose value is an an elinear function of the number of times around the loop

Chapter 10

Instruction Level Parallelism

Every modern high performance processor can execute several operations in a single clock cycle. The billion dollar question is how fast can a program be run on a processor with instruction level parallelism. The answer depends on

- 1 The potential parallelism in the program
- 2 The available parallelism on the processor
- 3 Our ability to extract parallelism from the original sequential program
- 4 Our ability to nd the best parallel schedule given scheduling constraints

If all the operations in a program are highly dependent upon one another then no amount of hardware or parallelization techniques can make the program run fast in parallel. There has been a lot of research on understanding the limits of parallelization. Typical nonnumeric applications have many inherent dependences. For example, these programs have many data dependent branches that make it hard even to predict which instructions are to be executed, let alone decide which operations can be executed in parallel. Therefore, work in this area has focused on relaxing the scheduling constraints including the introduction of new architectural features, rather than the scheduling techniques themselves

Numeric applications such as scientic computing and signal processing tend to have more parallelism. These applications deal with large aggregate data structures operations on distinct elements of the structure are often independent of one another and can be executed in parallel. Additional hardware resources can take advantage of such parallelism and are provided in high performance general purpose machines and digital signal processors. These programs tend to have simple control structures and regular data access pat terns and static techniques have been developed to extract the available parallelism from these programs. Code scheduling for such applications is interesting

and signi cant as they o er a large number of independent operations to be mapped onto a large number of resources

Both parallelism extraction and scheduling for parallel execution can be performed either statically in software or dynamically in hardware. In fact even machines with hardware scheduling can be aided by software scheduling. This chapter starts by explaining the fundamental issues in using instruction level parallelism which is the same regardless of whether the parallelism is managed by software or hardware. We then motivate the basic data dependence analyses needed for the extraction of parallelism. These analyses are useful for many optimizations other than instruction level parallelism as we shall see in Chapter 11

Finally we present the basic ideas in code scheduling. We describe a technique for scheduling basic blocks a method for handling highly data dependent control ow found in general purpose programs and nally a technique called software pipelining that is used primarily for scheduling numeric programs

10.1 Processor Architectures

When we think of instruction level parallelism we usually imagine a processor issuing several operations in a single clock cycle. In fact, it is possible for a machine to issue just one operation per clock¹ and yet achieve instruction level parallelism using the concept of *pipelining*. In the following we shall rst explain pipelining then discuss multiple instruction issue

10 1 1 Instruction Pipelines and Branch Delays

Practically every processor be it a high performance supercomputer or a stan dard machine uses an instruction pipeline With an instruction pipeline a new instruction can be fetched every clock while preceding instructions are still going through the pipeline Shown in Fig 10 1 is a simple 5 stage instruction pipeline it rst fetches the instruction IF decodes it ID executes the operation EX accesses the memory MEM and writes back the result WB The gure shows how instructions i i 1 i 2 i 3 and i 4 can execute at the same time Each row corresponds to a clock tick and each column in the gure speci es the stage each instruction occupies at each clock tick

If the result from an instruction is available by the time the succeeding in struction needs the data the processor can issue an instruction every clock Branch instructions are especially problematic because until they are fetched decoded and executed the processor does not know which instruction will execute next. Many processors speculatively fetch and decode the immediately succeeding instructions in case a branch is not taken. When a branch is found to be taken the instruction pipeline is emptied and the branch target is fetched

 $^{^{1}\}mathrm{We}$ shall refer to a clock tick or clock cycle simply as a clock when the intent is clear

10.1 PROCESSOR ARCHITECTURES

7			WB	MEM	$\mathbf{E}\mathbf{X}$
8				WB	MEM
9					WB

Figure 10.1 Five consecutive instructions in a 5 stage instruction pipeline

Thus taken branches introduce a delay in the fetch of the branch target and introduce hiccups in the instruction pipeline Advanced processors use hard ware to predict the outcomes of branches based on their execution history and to prefetch from the predicted target locations Branch delays are nonetheless observed if branches are mispredicted

10 1 2 Pipelined Execution

Some instructions take several clocks to execute One common example is the memory load operation. Even when a memory access hits in the cache it usu ally takes several clocks for the cache to return the data. We say that the execution of an instruction is pipelined if succeeding instructions not dependent on the result are allowed to proceed. Thus, even if a processor can issue only one operation per clock several operations might be in their execution stages at the same time. If the deepest execution pipeline has n stages potentially n operations can be in light at the same time. Note that not all instructions are fully pipelined. While loating point adds and multiplies often are fully pipelined oating point divides being more complex and less frequently executed often are not

Most general purpose processors dynamically detect dependences between consecutive instructions and automatically stall the execution of instructions if their operands are not available. Some processors especially those embedded in hand held devices leave the dependence checking to the software in order to keep the hardware simple and power consumption low. In this case, the compiler is responsible for inserting no op instructions in the code if necessary to assure that the results are available when needed

10 1 3 Multiple Instruction Issue

By issuing several operations per clock processors can keep even more operations in light. The largest number of operations that can be executed simultaneously can be computed by multiplying the instruction issue width by the average number of stages in the execution pipeline.

Like pipelining parallelism on multiple issue machines can be managed either by software or hardware. Machines that rely on software to manage their parallelism are known as VLIW Very Long Instruction Word machines while those that manage their parallelism with hardware are known as superscalar machines. VLIW machines as their name implies have wider than normal instruction words that encode the operations to be issued in a single clock. The compiler decides which operations are to be issued in parallel and encodes the information in the machine code explicitly. Superscalar machines on the other hand have a regular instruction set with an ordinary sequential execution semantics. Superscalar machines automatically detect dependences among in structions and issue them as their operands become available. Some processors include both VLIW and superscalar functionality

Simple hardware schedulers execute instructions in the order in which they are fetched—If a scheduler comes across a dependent instruction—it and all instructions that follow must wait until the dependences are resolved—i e—the needed results are available—Such machines obviously can bene—t from having a static scheduler that places independent operations next to each other in the order of execution

More sophisticated schedulers can execute instructions out of order. Op erations are independently stalled and not allowed to execute until all the values they depend on have been produced. Even these schedulers bene t from static scheduling because hardware schedulers have only a limited space in which to bu er operations that must be stalled. Static scheduling can place independent operations close together to allow better hardware utilization. More importantly regardless how sophisticated a dynamic scheduler is it cannot execute instructions it has not fetched. When the processor has to take an unexpected branch it can only and parallelism among the newly fetched instructions. The compiler can enhance the performance of the dynamic scheduler by ensuring that these newly fetched instructions can execute in parallel

10 2 Code Scheduling Constraints

Code scheduling is a form of program optimization that applies to the machine code that is produced by the code generator. Code scheduling is subject to three kinds of constraints

1 Control dependence constraints All the operations executed in the original program must be executed in the optimized one

10 2 CODE SCHEDULING CONSTRAINTS

- 2 Data dependence constraints The operations in the optimized program must produce the same results as the corresponding ones in the original program
- 3 Resource constraints The schedule must not oversubscribe the resources on the machine

These scheduling constraints guarantee that the optimized program produces the same results as the original. However because code scheduling changes the order in which the operations execute the state of the memory at any one point may not match any of the memory states in a sequential execution. This situation is a problem if a program s execution is interrupted by for example a thrown exception or a user inserted breakpoint. Optimized programs are therefore harder to debug. Note that this problem is not specied to code scheduling but applies to all other optimizations including partial redundancy elimination. Section 9.5 and register allocation. Section 8.8

10 2 1 Data Dependence

It is easy to see that if we change the execution order of two operations that do not touch any of the same variables we cannot possibly a ect their results. In fact, even if these two operations read the same variable, we can still permute their execution. Only if an operation writes to a variable read or written by another can changing their execution order alter their results. Such pairs of operations are said to share a data dependence and their relative execution order must be preserved. There are three, avors of data dependence.

- 1 True dependence read after write If a write is followed by a read of the same location the read depends on the value written such a dependence is known as a true dependence
- 2 Antidependence write after read If a read is followed by a write to the same location we say that there is an antidependence from the read to the write The write does not depend on the read per se but if the write happens before the read then the read operation will pick up the wrong value Antidependence is a byproduct of imperative programming where the same memory locations are used to store di erent values It is not a true dependence and potentially can be eliminated by storing the values in di erent locations
- 3 Output dependence write after write Two writes to the same location share an output dependence If the dependence is violated the value of the memory location written will have the wrong value after both operations are performed

Antidependence and output dependences are referred to as *storage related de pendences* These are not true dependences and can be eliminated by using

CHAPTER 10 INSTRUCTION LEVEL PARALLELISM

di erent locations to store di erent values Note that data dependences apply to both memory accesses and register accesses

10 2 2 Finding Dependences Among Memory Accesses

To check if two memory accesses share a data dependence we only need to tell if they can refer to the same location we do not need to know which location is being accessed. For example, we can tell that addresses given by a pointer p and an o set from the same pointer p 4 cannot refer to the same location even though we may not know what p points to. Data dependence is generally undecidable at compile time. The compiler must assume that operations may refer to the same location unless it can prove otherwise.

Example 10 1 Given the code sequence

unless the compiler knows that p cannot possibly point to a it must conclude that the three operations need to execute serially. There is an output dependence owing from statement 1 to statement 2 and there are two true dependences owing from statements 1 and 2 to statement 3.

Data dependence analysis is highly sensitive to the programming language used in the program. For type unsafe languages like C and C — where a pointer can be cast to point to any kind of object sophisticated analysis is necessary to prove independence between any pair of pointer based memory ac cesses. Even local or global scalar variables can be accessed indirectly unless we can prove that their addresses have not been stored anywhere by any instruction in the program. In type safe languages like Java objects of different types are necessarily distinct from each other. Similarly local primitive variables on the stack cannot be aliased with accesses through other names

A correct discovery of data dependences requires a number of di-erent forms of analysis. We shall focus on the major questions that must be resolved if the compiler is to detect all the dependences that exist in a program and how to use this information in code scheduling. Later chapters show how these analyses are performed

Array Data Dependence Analysis

Array data dependence is the problem of disambiguating between the values of indexes in array element accesses For example the loop

10 2 CODE SCHEDULING CONSTRAINTS

copies odd elements in the array A to the even elements just preceding them Because all the read and written locations in the loop are distinct from each other there are no dependences between the accesses and all the iterations in the loop can execute in parallel Array data dependence analysis often referred to simply as data dependence analysis is very important for the optimization of numerical applications. This topic will be discussed in detail in Section 11 6.

Pointer Alias Analysis

We say that two pointers are aliased if they can refer to the same object Pointer alias analysis is di-cult because there are many potentially aliased pointers in a program and they can each point to an unbounded number of dynamic objects over time. To get any precision pointer alias analysis must be applied across all the functions in a program. This topic is discussed starting in Section 12.4

Interprocedural Analysis

For languages that pass parameters by reference interprocedural analysis is needed to determine if the same variable is passed as two or more di erent arguments. Such aliases can create dependences between seemingly distinct parameters. Similarly global variables can be used as parameters and thus create dependences between parameter accesses and global variable accesses. Interprocedural analysis discussed in Chapter 12 is necessary to determine these aliases.

10 2 3 Tradeo Between Register Usage and Parallelism

In this chapter we shall assume that the machine independent intermediate representation of the source program uses an unbounded number of *pseudoregisters* to represent variables that can be allocated to registers. These variables include scalar variables in the source program that cannot be referred to by any other names as well as temporary variables that are generated by the compiler to hold the partial results in expressions. Unlike memory locations registers are uniquely named. Thus precise data dependence constraints can be generated for register accesses easily

The unbounded number of pseudoregisters used in the intermediate repre sentation must eventually be mapped to the small number of physical registers available on the target machine. Mapping several pseudoregisters to the same physical register has the unfortunate side elect of creating artificial storage dependences that constrain instruction level parallelism. Conversely executing instructions in parallel creates the need for more storage to hold the values being computed simultaneously. Thus, the goal of minimizing the number of registers used condicts directly with the goal of maximizing instruction level parallelism. Examples 10.2 and 10.3 below illustrate this classic trade of between storage and parallelism.

Hardware Register Renaming

Instruction level parallelism was rst used in computer architectures as a means to speed up ordinary sequential machine code. Compilers at the time were not aware of the instruction level parallelism in the machine and were designed to optimize the use of registers. They deliberately reordered instructions to minimize the number of registers used and as a result also minimized the amount of parallelism available. Example 10-3 illustrates how minimizing register usage in the computation of expression trees also limits its parallelism.

There was so little parallelism left in the sequential code that computer architects invented the concept of hardware register renaming to undo the e ects of register optimization in compilers. Hardware register renaming dynamically changes the assignment of registers as the program runs. It interprets the machine code stores values intended for the same register in different internal registers and updates all their uses to refer to the right registers accordingly

Since the arti cial register dependence constraints were introduced by the compiler in the rst place they can be eliminated by using a register allocation algorithm that is cognizant of instruction level paral lelism. Hardware register renaming is still useful in the case when a machine s instruction set can only refer to a small number of registers. This capability allows an implementation of the architecture to map the small number of architectural registers in the code to a much larger number of internal registers dynamically.

Example 10 2 The code below copies the values of variables in locations a and c to variables in locations b and d respectively using pseudoregisters t1 and t2

LD	t1	a		t1	a
ST	b	t1	1	b	t1
LD	t2	С	-	t2	С
ST	d	t2	(d	t.2

If all the memory locations accessed are known to be distinct from each other then the copies can proceed in parallel. However, if $\tt t1$ and $\tt t2$ are assigned the same register so as to minimize the number of registers used, the copies are necessarily serialized. \Box

Example 10 3 Traditional register allocation techniques aim to minimize the number of registers used when performing a computation Consider the expression

10 2 CODE SCHEDULING CONSTRAINTS

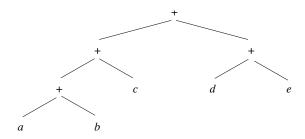

Figure 10 2 Expression tree in Example 10 3

a b c d e

shown as a syntax tree in Fig 10.2 It is possible to perform this computation using three registers as illustrated by the machine code in Fig 10.3

LD r1	a		r1	a	
LD r2	b		r2	b	
ADD r1	r1	r2	r1	r1	r2
LD r2	С		r2	С	
ADD r1	r1	r2	r1	r1	r2
LD r2	d		r2	d	
LD r3	е		r3	е	
ADD r2	r2	r3	r2	r2	r3
ADD r1	r1	r2	r1	r1	r2

Figure 10 3 $\,$ Machine code for expression of Fig. 10 2

The reuse of registers however serializes the computation. The only oper ations allowed to execute in parallel are the loads of the values in locations a and b and the loads of the values in locations d and e. It thus takes a total of 7 steps to complete the computation in parallel

Had we used di erent registers for every partial sum the expression could be evaluated in 4 steps which is the height of the expression tree in Fig $\,10\,2$ The parallel computation is suggested by Fig $\,10\,4$ $\,\Box$

r1	a	r2	b	r3	O	r4	d	r5	е
r6	r1 r2	r7	b r4 r5		•		•		
r8	r6 r3			•					
r9	r8 r7								

Figure 10 4 Parallel evaluation of the expression of Fig 10 2

10 2 4 Phase Ordering Between Register Allocation and Code Scheduling

If registers are allocated before scheduling the resulting code tends to have many storage dependences that limit code scheduling. On the other hand if code is scheduled before register allocation the schedule created may require so many registers that register *spilling* storing the contents of a register in a memory location so the register can be used for some other purpose may negate the advantages of instruction level parallelism. Should a compiler allocate registers are rest before it schedules the code. Or should it be the other way round. Or do we need to address these two problems at the same time

To answer the questions above we must consider the characteristics of the programs being compiled Many nonnumeric applications do not have that much available parallelism. It success to dedicate a small number of registers for holding temporary results in expressions. We can rest apply a coloring algorithm as in Section 8.8.4 to allocate registers for all the nontemporary variables then schedule the code and nally assign registers to the temporary variables.

This approach does not work for numeric applications where there are many more large expressions. We can use a hierarchical approach where code is optimized inside out starting with the innermost loops. Instructions are rst scheduled assuming that every pseudoregister will be allocated its own physical register. Register allocation is applied after scheduling and spill code is added where necessary and the code is then rescheduled. This process is repeated for the code in the outer loops. When several inner loops are considered together in a common outer loop, the same variable may have been assigned different registers. We can change the register assignment to avoid having to copy the values from one register to another. In Section 10.5 we shall discuss the interaction between register allocation and scheduling further in the context of a special calculation algorithm.

10 2 5 Control Dependence

Scheduling operations within a basic block is relatively easy because all the instructions are guaranteed to execute once control ow reaches the beginning of the block Instructions in a basic block can be reordered arbitrarily as long as all the data dependences are satis ed Unfortunately basic blocks especially in nonnumeric programs are typically very small on average there are only about ve instructions in a basic block In addition operations in the same block are often highly related and thus have little parallelism Exploiting parallelism across basic blocks is therefore crucial

An optimized program must execute all the operations in the original program. It can execute more instructions than the original as long as the extra instructions do not change what the program does. Why would executing extra instructions speed up a program's execution. If we know that an instruction

10.2 CODE SCHEDULING CONSTRAINTS

is likely to be executed and an idle resource is available to perform the operation for free we can execute the instruction *speculatively* The program runs faster when the speculation turns out to be correct

An instruction i_1 is said to be *control dependent* on instruction i_2 if the outcome of i_2 determines whether i_1 is to be executed. The notion of control dependence corresponds to the concept of nesting levels in block structured programs. Specifically in the if else statement

```
if c s1 else s2
```

s1 and s2 are control dependent on c Similarly in the while statement

the body s is control dependent on c

Example 10 4 In the code fragment

the statements b a a and d a c have no data dependence with any other part of the fragment. The statement b a a depends on the comparison a t. The statement d a c however does not depend on the comparison and can be executed any time. Assuming that the multiplication a a does not cause any side e ects it can be performed speculatively as long as b is written only after a is found to be greater than t. \Box

10 2 6 Speculative Execution Support

Memory loads are one type of instruction that can bene t greatly from specula tive execution Memory loads are quite common of course. They have relatively long execution latencies addresses used in the loads are commonly available in advance and the result can be stored in a new temporary variable without destroying the value of any other variable. Unfortunately memory loads can raise exceptions if their addresses are illegal so speculatively accessing illegal addresses may cause a correct program to halt unexpectedly. Besides mispre dicted memory loads can cause extra cache misses and page faults which are extremely costly

Example 10 5 In the fragment

$$\begin{array}{ccc} \text{if} & p & \text{null} \\ & q & p \end{array}$$

dereferencing p speculatively will cause this correct program to halt in error if p is null \square

Many high performance processors provide special features to support speculative memory accesses We mention the most important ones next

Prefetching

The *prefetch* instruction was invented to bring data from memory to the cache before it is used. A *prefetch* instruction indicates to the processor that the program is likely to use a particular memory word in the near future. If the location specified is invalid or if accessing it causes a page fault, the processor can simply ignore the operation. Otherwise, the processor will bring the data from memory to the cache if it is not already there

Poison Bits

Another architectural feature called *poison bits* was invented to allow speculative load of data from memory into the register le Each register on the machine is augmented with a *poison* bit If illegal memory is accessed or the accessed page is not in memory the processor does not raise the exception im mediately but instead just sets the poison bit of the destination register. An exception is raised only if the contents of the register with a marked poison bit are used

Predicated Execution

Because branches are expensive and mispredicted branches are even more so see Section 10.1 predicated instructions were invented to reduce the number of branches in a program. A predicated instruction is like a normal instruction but has an extra predicate operand to guard its execution, the instruction is executed only if the predicate is found to be true.

As an example a conditional move instruction CMOVZ R2 R3 R1 has the semantics that the contents of register R3 are moved to register R2 only if register R1 is zero. Code such as

$$\begin{array}{ccc} \text{if} & \text{a} & \text{0} \\ & \text{b} & \text{c} & \text{d} \end{array}$$

can be implemented with two machine instructions assuming that $a\ b\ c$ and d are allocated to registers R1 R2 R4 R5 respectively as follows

This conversion replaces a series of instructions sharing a control dependence with instructions sharing only data dependences. These instructions can then be combined with adjacent basic blocks to create a larger basic block. More importantly with this code, the processor does not have a chance to mispredict thus guaranteeing that the instruction pipeline will run smoothly

Predicated execution does come with a cost Predicated instructions are fetched and decoded even though they may not be executed in the end Static schedulers must reserve all the resources needed for their execution and ensure

Dynamically Scheduled Machines

The instruction set of a statically scheduled machine explicitly de nes what can execute in parallel However recall from Section 10 1 2 that some machine architectures allow the decision to be made at run time about what can be executed in parallel With dynamic scheduling the same machine code can be run on dierent members of the same family machines that implement the same instruction set that have varying amounts of parallel execution support. In fact, machine code compatibility is one of the major advantages of dynamically scheduled machines.

Static schedulers implemented in the compiler by software can help dynamic schedulers implemented in the machine s hardware better utilize machine resources. To build a static scheduler for a dynamically scheduled machine we can use almost the same scheduling algorithm as for statically scheduled machines except that ${\tt no}$ op instructions left in the schedule need not be generated explicitly. The matter is discussed further in Section 10 4 7

that all the potential data dependences are satis ed Predicated execution should not be used aggressively unless the machine has many more resources than can possibly be used otherwise

10 2 7 A Basic Machine Model

Many machines can be represented using the following simple model A machine $M = \langle R | T \rangle$ consists of

- 1 A set of operation types T such as loads stores arithmetic operations and so on
- 2 A vector R r_1 r_2 representing hardware resources where r_i is the number of units available of the ith kind of resource Examples of typical resource types include memory access units ALUs and oating point functional units

Each operation has a set of input operands a set of output operands and a resource requirement. Associated with each input operand is an input latency indicating when the input value must be available relative to the start of the operation. Typical input operands have zero latency meaning that the values are needed immediately at the clock when the operation is issued. Similarly associated with each output operand is an output latency which indicates when the result is available relative to the start of the operation.

Resource usage for each machine operation type t is modeled by a two dimensional resource reservation table RT_t . The width of the table is the

number of kinds of resources in the machine and its length is the duration over which resources are used by the operation Entry $RT_t i j$ is the number of units of the jth resource used by an operation of type t i clocks after it is issued. For notational simplicity, we assume $RT_t i j = 0$ if i refers to a nonex istent entry in the table i e i is greater than the number of clocks it takes to execute the operation. Of course for any t i and j $RT_t i j$ must be less than or equal to R j, the number of resources of type j that the machine has

Typical machine operations occupy only one unit of resource at the time an operation is issued. Some operations may use more than one functional unit. For example, a multiply and add operation may use a multiplier in the rst clock and an adder in the second. Some operations such as a divide may need to occupy a resource for several clocks. Fully pipelined operations are those that can be issued every clock, even though their results are not available until some number of clocks later. We need not model the resources of every stage of a pipeline explicitly one single unit to represent the rst stage will do. Any operation occupying the rst stage of a pipeline is guaranteed the right to proceed to subsequent stages in subsequent clocks.

10 3 Basic Block Scheduling

We are now ready to start talking about code scheduling algorithms. We start with the easiest problem scheduling operations in a basic block consisting of machine instructions. Solving this problem optimally is NP complete. But in practice a typical basic block has only a small number of highly constrained operations so simple scheduling techniques sure we shall introduce a simple but highly elective algorithm called *list scheduling* for this problem

10 3 1 Data Dependence Graphs

We represent each basic block of machine instructions by a data dependence graph G N E having a set of nodes N representing the operations in the machine instructions in the block and a set of directed edges E representing the data dependence constraints among the operations. The nodes and edges of G are constructed as follows

- 1 Each operation n in N has a resource reservation table RT_n whose value is simply the resource reservation table associated with the operation type of n
- 2 Each edge e in E is labeled with delay d_e indicating that the destination node must be issued no earlier than d_e clocks after the source node is issued Suppose operation n_1 is followed by operation n_2 and the same location is accessed by both with latencies l_1 and l_2 respectively. That is the location s value is produced l_1 clocks after the rst instruction begins and the value is needed by the second instruction l_2 clocks after that instruction begins note l_1 1 and l_2 0 is typical. Then there is an edge n_1 n_2 in E labeled with delay l_1 l_2

Example 10 6 Consider a simple machine that can execute two operations every clock. The rst must be either a branch operation or an ALU operation of the form

```
OP dst src1 src2
```

The second must be a load or store operation of the form

```
LD dst addr
ST addr src
```

The load operation LD is fully pipelined and takes two clocks However a load can be followed immediately by a store ST that writes to the memory location read All other operations complete in one clock

Shown in Fig 10 7 is the dependence graph of an example of a basic block and its resources requirement. We might imagine that R1 is a stack pointer used to access data on the stack with o sets such as 0 or 12. The rst instruction loads register R2 and the value loaded is not available until two clocks later. This observation explains the label 2 on the edges from the rst instruction to the second and fth instructions each of which needs the value of R2. Similarly there is a delay of 2 on the edge from the third instruction to the fourth, the value loaded into R3 is needed by the fourth instruction, and not available until two clocks after the third begins.

Since we do not know how the values of R1 and R7 relate we have to consider the possibility that an address like $8\ R1$ is the same as the address $0\ R7$

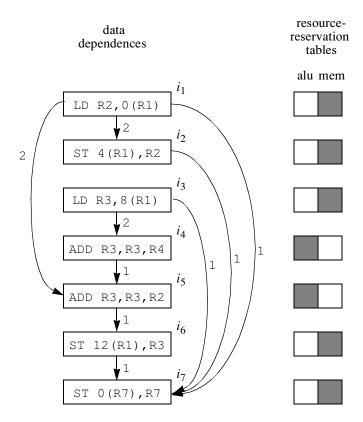

Figure 10 7 Data dependence graph for Example 10 6

That is the last instruction may be storing into the same address that the third instruction loads from The machine model we are using allows us to store into a location one clock after we load from that location even though the value to be loaded will not appear in a register until one clock later. This observation explains the label 1 on the edge from the third instruction to the last. The same reasoning explains the edge and label from the rist instruction to the last. The other edges with label 1 are explained by a dependence or possible dependence conditioned on the value of R7. \Box

10 3 2 List Scheduling of Basic Blocks

The simplest approach to scheduling basic blocks involves visiting each node of the data dependence graph in prioritized topological order. Since there can be no cycles in a data dependence graph, there is always at least one topological order for the nodes. However, among the possible topological orders, some may be preferable to others. We discuss in Section 10 3 3 some of the strategies for

Pictorial Resource Reservation Tables

It is frequently useful to visualize a resource reservation table for an oper ation by a grid of solid and open squares. Each column corresponds to one of the resources of the machine and each row corresponds to one of the clocks during which the operation executes. Assuming that the operation never needs more than one unit of any one resource we may represent 1 s by solid squares and 0 s by open squares. In addition if the operation is fully pipelined, then we only need to indicate the resources used at the rst row and the resource reservation table becomes a single row

This representation is used for instance in Example 10 6 In Fig 10 7 we see resource reservation tables as rows. The two addition operations require the alu resource while the loads and stores require the mem resource.

picking a topological order but for the moment we just assume that there is some algorithm for picking a preferred order

The list scheduling algorithm we shall describe next visits the nodes in the chosen prioritized topological order. The nodes may or may not wind up being scheduled in the same order as they are visited. But the instructions are placed in the schedule as early as possible, so there is a tendency for instructions to be scheduled in approximately the order visited.

In more detail the algorithm computes the earliest time slot in which each node can be executed according to its data dependence constraints with the previously scheduled nodes. Next, the resources needed by the node are checked against a resource reservation table that collects all the resources committed so far. The node is scheduled in the earliest time slot that has sudicient resources.

Algorithm 10 7 List scheduling a basic block

INPUT A machine resource vector R r_1 r_2 where r_i is the number of units available of the ith kind of resource and a data dependence graph G N E Each operation n in N is labeled with its resource reservation table RT_n each edge e n_1 n_2 in E is labeled with d_e indicating that n_2 must execute no earlier than d_e clocks after n_1

OUTPUT A schedule S that maps the operations in N into time slots in which the operations can be initiated satisfying all the data and resources constraints

METHOD Execute the program in Fig. 10.8. A discussion of what the prior itized topological order might be follows in Section 10.3.3. \Box

             RT s
                          RTs = i
                                      RT_n i
}
```

Figure 10 8 A list scheduling algorithm

10 3 3 Prioritized Topological Orders

List scheduling does not backtrack it schedules each node once and only once It uses a heuristic priority function to choose among the nodes that are ready to be scheduled next Here are some observations about possible prioritized orderings of the nodes

Without resource constraints the shortest schedule is given by the critical path the longest path through the data dependence graph. A metric useful as a priority function is the height of the node which is the length of a longest path in the graph originating from the node

On the other hand if all operations are independent then the length of the schedule is constrained by the resources available. The critical resource is the one with the largest ratio of uses to the number of units of that resource available. Operations using more critical resources may be given higher priority

Finally we can use the source ordering to break ties between operations the operation that shows up earlier in the source program should be scheduled rst

Example 10 8 For the data dependence graph in Fig 10 7 the critical path including the time to execute the last instruction is 6 clocks. That is the critical path is the last ve nodes from the load of R3 to the store of R7. The total of the delays on the edges along this path is 5 to which we add 1 for the clock needed for the last instruction.

Using the height as the priority function Algorithm 10 7 nds an optimal schedule as shown in Fig 10 9 Notice that we schedule the load of R3 rst since it has the greatest height. The add of R3 and R4 has the resources to be

sc	resource- reservation table	
		alu mem

- c Assuming unlimited MEM resources what are all the possible schedules for the seven instructions

10 4 Global Code Scheduling

For a machine with a moderate amount of instruction level parallelism sched ules created by compacting individual basic blocks tend to leave many resources idle. In order to make better use of machine resources it is necessary to consider code generation strategies that move instructions from one basic block to another. Strategies that consider more than one basic block at a time are referred to as global scheduling algorithms. To do global scheduling correctly we must consider not only data dependences but also control dependences. We must ensure that

- 1 All instructions in the original program are executed in the optimized program and
- 2 While the optimized program may execute extra instructions specula tively these instructions must not have any unwanted side e ects

10 4 1 Primitive Code Motion

Let us rst study the issues involved in moving operations around by way of a simple example

Example 10 9 Suppose we have a machine that can execute any two oper ations in a single clock Every operation executes with a delay of one clock except for the load operation which has a latency of two clocks. For simplicity we assume that all memory accesses in the example are valid and will hit in the cache. Figure 10 12 a shows a simple ow graph with three basic blocks. The code is expanded into machine operations in Figure 10 12 b. All the instructions in each basic block must execute serially because of data dependences in fact a no op instruction has to be inserted in every basic block.

Assume that the addresses of variables $a\ b\ c\ d$ and e are distinct and that those addresses are stored in registers R1 through R5 respectively. The computations from different basic blocks therefore share no data dependences. We observe that all the operations in block B_3 are executed regardless of whether the branch is taken and can therefore be executed in parallel with operations from block B_1 . We cannot move operations from B_1 down to B_3 because they are needed to determine the outcome of the branch

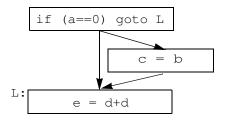

Operations in block B_2 are control dependent on the test in block B_1 We can perform the load from B_2 speculatively in block B_1 for free and shave two clocks from the execution time whenever the branch is taken

Stores should not be performed speculatively because they overwrite the old value in a memory location. It is possible however to delay a store operation. We cannot simply place the store operation from block B_2 in block B_3 because it should only be executed if the low of control passes through block B_2 . However, we can place the store operation in a duplicated copy of B_3 . Figure 10.12 c. shows such an optimized schedule. The optimized code executes in 4 clocks, which is the same as the time it takes to execute B_3 alone.

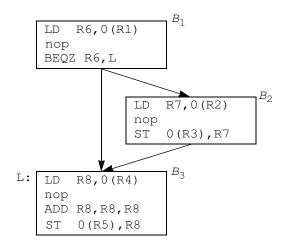

Example 10 9 shows that it is possible to move operations up and down an execution path. Every pair of basic blocks in this example has a different dominance relation, and thus the considerations of when and how instructions can be moved between each pair are different. As discussed in Section 9.6.1 a block B is said to dominate block B' if every path from the entry of the control low graph to B' goes through B Similarly a block B postdominates block B' if every path from B' to the exit of the graph goes through B When B dominates B' and B' postdominates B we say that B and B' are control equivalent meaning that one is executed when and only when the other is. For the example in Fig. 10.12 assuming B_1 is the entry and B_3 the exit

- 1 B_1 and B_3 are control equivalent B_1 dominates B_3 and B_3 postdominates B_1
- 2 B_1 dominates B_2 but B_2 does not postdominate B_1 and

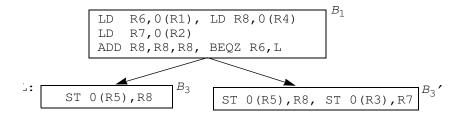

10 4 GLOBAL CODE SCHEDULING

(b) Locally scheduled machine code

(c) Globally scheduled machine code

Figure 10 12 $\,$ Flow graphs before and after global scheduling in Example 10 9

3 B_2 does not dominate B_3 but B_3 postdominates B_2

It is also possible for a pair of blocks along a path to share neither a dominance nor postdominance relation

10 4 2 Upward Code Motion

We now examine carefully what it means to move an operation up a path Suppose we wish to move an operation from block src up a control ow path to block dst. We assume that such a move does not violate any data dependences and that it makes paths through dst and src run faster. If dst dominates src and src postdominates dst then the operation moved is executed once and only once when it should

If src does not postdominate dst

Then there exists a path that passes through dst that does not reach src An extra operation would have been executed in this case. This code motion is illegal unless the operation moved has no unwanted side e.ects. If the moved operation executes for free i.e. it uses only resources that otherwise would be idle then this move has no cost. It is bene cial only if the control ow reaches src

If dst does not dominate src

Then there exists a path that reaches *src* without rst going through *dst* We need to insert copies of the moved operation along such paths. We know how to achieve exactly that from our discussion of partial redundancy elimination in Section 9.5. We place copies of the operation along basic blocks that form a cut set separating the entry block from *src*. At each place where the operation is inserted, the following constraints must be satisfied.

- 1 The operands of the operation must hold the same values as in the original
- 2 The result does not overwrite a value that is still needed and
- 3 It itself is not subsequently overwritten before reaching src

These copies render the original instruction in src fully redundant and it thus can be eliminated

We refer to the extra copies of the operation as compensation code As discussed in Section 9.5 basic blocks can be inserted along critical edges to create places for holding such copies. The compensation code can potentially make some paths run slower. Thus this code motion improves program execution only if the optimized paths are executed more frequently than the nonoptimized ones.

10 4 GLOBAL CODE SCHEDULING

10 4 3 Downward Code Motion

Suppose we are interested in moving an operation from block src down a control ow path to block dst We can reason about such code motion in the same way as above

If src does not dominate dst

Then there exists a path that reaches dst without rst visiting src Again an extra operation will be executed in this case. Unfortunately downward code motion is often applied to writes which have the side elects of overwriting old values. We can get around this problem by replicating the basic blocks along the paths from src to dst and placing the operation only in the new copy of dst Another approach if available is to use predicated instructions. We guard the operation moved with the predicate that guards the src block. Note that the predicated instruction must be scheduled only in a block dominated by the computation of the predicate because the predicate would not be available otherwise.

If dst does not postdominate src

As in the discussion above compensation code needs to be inserted so that the operation moved is executed on all paths not visiting dst This transformation is again analogous to partial redundancy elimination except that the copies are placed below the src block in a cut set that separates src from the exit

Summary of Upward and Downward Code Motion

From this discussion we see that there is a range of possible global code motions which vary in terms of bene t cost and implementation complexity. Figure 10 13 shows a summary of these various code motions the lines correspond to the following four cases

	up src postdom dst	dst dom src	speculation	compensation
	$\operatorname{down} \ src \operatorname{dom} \ dst$	dst postdom src	code dup	code
1	yes	yes	no	no
2	no	yes	yes	no
3	yes	no	no	yes
4	no	no	yes	yes

Figure 10 13 Summary of code motions

1 Moving instructions between control equivalent blocks is simplest and most cost e ective. No extra operations are ever executed and no compensation code is needed.

- 2 Extra operations may be executed if the source does not postdominate dominate the destination in upward downward code motion. This code motion is bene cial if the extra operations can be executed for free and the path passing through the source block is executed.
- 3 Compensation code is needed if the destination does not dominate post dominate the source in upward downward code motion. The paths with the compensation code may be slowed down so it is important that the optimized paths are more frequently executed.
- 4 The last case combines the disadvantages of the second and third case extra operations may be executed and compensation code is needed

10 4 4 Updating Data Dependences

As illustrated by Example 10 10 below code motion can change the data dependence relations between operations Thus data dependences must be updated after each code movement

Example 10 10 For the ow graph shown in Fig 10 14 either assignment to x can be moved up to the top block since all the dependences in the original program are preserved with this transformation. However once we have moved one assignment up we cannot move the other. More specifically we see that variable x is not live on exit in the top block before the code motion but it is live after the motion. If a variable is live at a program point, then we cannot move speculative definitions to the variable above that program point.

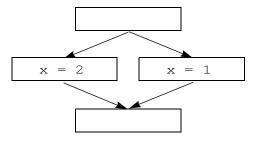

Figure 10 14 $\,$ Example illustrating the change in data dependences due to code motion

10 4 5 Global Scheduling Algorithms

We saw in the last section that code motion can bene t some paths while hurting the performance of others. The good news is that instructions are not all created equal. In fact, it is well established that over 90 of a program s execution time is spent on less than 10 of the code. Thus, we should aim to

10 4 GLOBAL CODE SCHEDULING

make the frequently executed paths run faster while possibly making the less frequent paths run slower

There are a number of techniques a compiler can use to estimate execution frequencies. It is reasonable to assume that instructions in the innermost loops are executed more often than code in outer loops, and that branches that go backward are more likely to be taken than not taken. Also, branch statements found to guard program exits or exception handling routines are unlikely to be taken. The best frequency estimates however come from dynamic procling. In this technique programs are instrumented to record the outcomes of conditional branches as they run. The programs are then run on representative inputs to determine how they are likely to behave in general. The results obtained from this technique have been found to be quite accurate. Such information can be fed back to the compiler to use in its optimizations.

Region Based Scheduling

We now describe a straightforward global scheduler that supports the two eas iest forms of code motion

- 1 Moving operations up to control equivalent basic blocks and
- 2 Moving operations speculatively up one branch to a dominating predeces sor

Recall from Section 9 7 1 that a region is a subset of a control ow graph that can be reached only through one entry block. We may represent any procedure as a hierarchy of regions. The entire procedure constitutes the top level region nested in it are subregions representing the natural loops in the function. We assume that the control ow graph is reducible

Algorithm 10 11 Region based scheduling

INPUT A control ow graph and a machine resource description

 ${\bf OUTPUT}\,$ A schedule S mapping each instruction to a basic block and a time slot

METHOD Execute the program in Fig 10.15 Some shorthand terminology should be apparent $ControlEquiv\ B$ is the set of blocks that are control equivalent to block B and DominatedSucc applied to a set of blocks is the set of blocks that are successors of at least one block in the set and are dominated by all

Code scheduling in Algorithm 10 11 proceeds from the innermost regions to the outermost. When scheduling a region each nested subregion is treated as a black box instructions are not allowed to move in or out of a subregion. They can however move around a subregion provided their data and control dependences are satistically dependences.

```
for each region R in topological order so that inner regions
          are processed before outer regions {
     compute data dependences
     for each basic block B of R in prioritized topological order \{
          CandBlocks
                         ControlEquiv B
               DominatedSucc\ ControlEquiv\ B
          CandInsts
                       ready instructions in CandBlocks
          for t
                  0 1
                           until all instructions from B are scheduled \{
               for each instruction n in CandInsts in priority order
                    if n has no resource conjicts at time t {
                         S n
                                \langle B \ t \rangle
                         update resource commitments
                         update data dependences
               update CandInsts
     }
}
```

Figure 10 15 A region based global scheduling algorithm

All control and dependence edges—owing back to the header of the region are ignored so the resulting control—ow and data dependence graphs are acyclic. The basic blocks in each region are visited in topological order. This ordering guarantees that a basic block is not scheduled until all the instructions it depends on have been scheduled. Instructions to be scheduled in a basic block B are drawn from all the blocks that are control equivalent to B—including B as well as their immediate successors that are dominated by B

A list scheduling algorithm is used to create the schedule for each basic block. The algorithm keeps a list of candidate instructions CandInsts which contains all the instructions in the candidate blocks whose predecessors all have been scheduled. It creates the schedule clock by clock. For each clock, it checks each instruction from the CandInsts in priority order and schedules it in that clock if resources permit. Algorithm 10.11 then updates CandInsts and repeats the process until all instructions from B are scheduled.

The priority order of instructions in CandInsts uses a priority function similar to that discussed in Section 10.3. We make one important modication however. We give instructions from blocks that are control equivalent to B higher priority than those from the successor blocks. The reason is that in structions in the latter category are only speculatively executed in block B.

10 4 GLOBAL CODE SCHEDULING

Loop Unrolling

In region based scheduling the boundary of a loop iteration is a barrier to code motion. Operations from one iteration cannot overlap with those from another. One simple but highly elective technique to mitigate this problem is to unroll the loop a small number of times before code scheduling. A for loop such as

```
for i 0 i N i
S i
```

can be written as in Fig 10 16 a Similarly a repeat loop such as

```
repeat
S
until C
```

can be written as in Fig 1016 b Unrolling creates more instructions in the loop body permitting global scheduling algorithms to nd more parallelism

```
for i 0 i 4 N i 4
S i
S i 1
S i 2
S i 3

for i N i
S i
```

a Unrolling a for loop

```
repeat
S
if C break
S
if C break
S
if C break
S
until C
```

b Unrolling a repeat loop

Figure 10 16 Unrolled loops

Neighborhood Compaction

Algorithm 10 11 only supports the rst two forms of code motion described in Section 10 41 Code motions that require the introduction of compensation code can sometimes be useful. One way to support such code motions is to follow the region based scheduling with a simple pass. In this pass, we can examine each pair of basic blocks that are executed one after the other and check if any operation can be moved up or down between them to improve the execution time of those blocks. If such a pair is found, we check if the instruction to be moved needs to be duplicated along other paths. The code motion is made if it results in an expected net gain.

This simple extension can be quite e ective in improving the performance of loops. For instance, it can move an operation at the beginning of one iteration to the end of the preceding iteration while also moving the operation from the rst iteration out of the loop. This optimization is particularly attractive for tight loops, which are loops that execute only a few instructions per iteration. However, the impact of this technique is limited by the fact that each code motion decision is made locally and independently.

10 4 6 Advanced Code Motion Techniques

If our target machine is statically scheduled and has plenty of instruction level parallelism we may need a more aggressive algorithm. Here is a high level description of further extensions

- 1 To facilitate the extensions below we can add new basic blocks along control ow edges originating from blocks with more than one predecessor. These basic blocks will be eliminated at the end of code scheduling if they are empty. A useful heuristic is to move instructions out of a basic block that is nearly empty so that the block can be eliminated completely.
- 2 In Algorithm 10 11 the code to be executed in each basic block is sched uled once and for all as each block is visited. This simple approach surces because the algorithm can only move operations up to dominating blocks. To allow motions that require the addition of compensation code, we take a slightly different approach. When we visit block B we only schedule instructions from B and all its control equivalent blocks. We great try to place these instructions in predecessor blocks, which have already been visited and for which a partial schedule already exists. We try to find a destination block that would lead to an improvement on a frequently executed path and then place copies of the instruction on other paths to guarantee correctness. If the instructions cannot be moved up, they are scheduled in the current basic block as before
- 3 Implementing downward code motion is harder in an algorithm that visits basic blocks in topological order since the target blocks have yet to be

10 4 GLOBAL CODE SCHEDULING

scheduled However there are relatively fewer opportunities for such code motion anyway We move all operations that

- a can be moved and
- b cannot be executed for free in their native block

This simple strategy works well if the target machine is rich with many unused hardware resources

10 4 7 Interaction with Dynamic Schedulers

A dynamic scheduler has the advantage that it can create new schedules ac cording to the run time conditions without having to encode all these possible schedules ahead of time. If a target machine has a dynamic scheduler the static scheduler s primary function is to ensure that instructions with high latency are fetched early so that the dynamic scheduler can issue them as early as possible

Cache misses are a class of unpredictable events that can make a big di er ence to the performance of a program. If data prefetch instructions are avail able the static scheduler can help the dynamic scheduler signicantly by placing these prefetch instructions early enough that the data will be in the cache by the time they are needed. If prefetch instructions are not available it is useful for a compiler to estimate which operations are likely to miss and try to issue them early

If dynamic scheduling is not available on the target machine the static scheduler must be conservative and separate every data dependent pair of op erations by the minimum delay. If dynamic scheduling is available however, the compiler only needs to place the data dependent operations in the correct order to ensure program correctness. For best performance, the compiler should as sign long delays to dependences that are likely to occur and short ones to those that are not likely

Branch misprediction is an important cause of loss in performance Because of the long misprediction penalty instructions on rarely executed paths can still have a significant election the total execution time. Higher priority should be given to such instructions to reduce the cost of misprediction

10 4 8 Exercises for Section 10 4

Exercise 10 4 1 Show how to unroll the generic while loop

Exercise 10 4 2 Consider the code fragment

```
if x 0 a k
else a c
d a
```

Assume a machine that uses the delay model of Example 10 6 loads take two clocks all other instructions take one clock. Also assume that the machine can execute any two instructions at once. Find a shortest possible execution of this fragment. Do not forget to consider which register is best used for each of the copy steps. Also remember to exploit the information given by register descriptors as was described in Section 8.6 to avoid unnecessary loads and stores.

10 5 Software Pipelining

As discussed in the introduction of this chapter numerical applications tend to have much parallelism. In particular, they often have loops whose iterations are completely independent of one another. These loops known as do all loops are particularly attractive from a parallelization perspective because their iter ations can be executed in parallel to achieve a speed up linear in the number of iterations in the loop. Do all loops with many iterations have enough par allelism to saturate all the resources on a processor. It is up to the scheduler to take full advantage of the available parallelism. This section describes an all gorithm, known as software pipelining that schedules an entire loop at a time taking full advantage of the parallelism across iterations.

10 5 1 Introduction

We shall use the do all loop in Example 10 12 throughout this section to explain software pipelining. We rst show that scheduling across iterations is of great importance because there is relatively little parallelism among operations in a single iteration. Next, we show that loop unrolling improves performance by overlapping the computation of unrolled iterations. However, the boundary of the unrolled loop still poses as a barrier to code motion, and unrolling still leaves a lot of performance on the table. The technique of software pipelining on the other hand, overlaps a number of consecutive iterations continually until it runs out of iterations. This technique allows software pipelining to produce highly excited and compact code.

Example 10 12 Here is a typical do all loop

Iterations in the above loop write to di erent memory locations which are themselves distinct from any of the locations read. Therefore, there are no memory dependences between the iterations and all iterations can proceed in parallel

We adopt the following model as our target machine throughout this section. In this model

10 5 SOFTWARE PIPELINING

The machine can issue in a single clock one load one store one arithmetic operation and one branch operation

The machine has a loop back operation of the form

```
BL R. L
```

which decrements register R and unless the result is 0 branches to location L

Memory operations have an auto increment addressing mode denoted by after the register. The register is automatically incremented to point to the next consecutive address after each access

The arithmetic operations are fully pipelined they can be initiated every clock but their results are not available until 2 clocks later. All other instructions have a single clock latency

If iterations are scheduled one at a time the best schedule we can get on our machine model is shown in Fig 10 17. Some assumptions about the layout of the data also also indicated in that gure registers R1 R2 and R3 hold the addresses of the beginnings of arrays A B and D register R4 holds the constant c and register R10 holds the value n 1 which has been computed outside the loop. The computation is mostly serial taking a total of 7 clocks only the loop back instruction is overlapped with the last operation in the iteration.

Figure 10 17 Locally scheduled code for Example 10 12

In general we get better hardware utilization by unrolling several iterations of a loop. However, doing so also increases the code size which in turn can have a negative impact on overall performance. Thus, we have to compromise picking a number of times to unroll a loop that gets most of the performance improvement, yet doesn't expand the code too much. The next example illustrates the tradeo

Example 10 13 While hardly any parallelism can be found in each iteration of the loop in Example 10 12 there is plenty of parallelism across the iterations Loop unrolling places several iterations of the loop in one large basic block and a simple list scheduling algorithm can be used to schedule the operations to execute in parallel If we unroll the loop in our example four times and apply Algorithm 10 7 to the code we can get the schedule shown in Fig 10 18 For simplicity we ignore the details of register allocation for now The loop executes in 13 clocks or one iteration every 3 25 clocks

A loop unrolled k times takes at least 2k-5 clocks achieving a throughput of one iteration every 2-5 k clocks. Thus the more iterations we unroll the faster the loop runs. As $k-\infty$ a fully unrolled loop can execute on average an iteration every two clocks. However, the more iterations we unroll the larger the code gets. We certainly cannot a ord to unroll all the iterations in a loop. Unrolling the loop 4 times produces code with 13 instructions or 163 of the optimum unrolling the loop 8 times produces code with 21 instructions or 131 of the optimum. Conversely if we wish to operate at say only 110 of the optimum we need to unroll the loop 25 times which would result in code with 55 instructions. \Box

10 5 2 Software Pipelining of Loops

Software pipelining provides a convenient way of getting optimal resource usage and compact code at the same time Let us illustrate the idea with our running example

Example 10 14 In Fig 10 19 is the code from Example 10 12 unrolled ve times Again we leave out the consideration of register usage Shown in row i are all the operations issued at clock i shown in column j are all the operations from iteration j Note that every iteration has the same schedule relative to its beginning and also note that every iteration is initiated two clocks after the preceding one. It is easy to see that this schedule satis es all the resource and data dependence constraints

We observe that the operations executed at clocks 7 and 8 are the same as those executed at clocks 9 and 10 Clocks 7 and 8 execute operations from the rst four iterations in the original program Clocks 9 and 10 also execute operations from four iterations this time from iterations 2 to 5 In fact we can keep executing this same pair of multi operation instructions to get the e ect of retiring the oldest iteration and adding a new one until we run out of iterations

Such dynamic behavior can be encoded succinctly with the code shown in Fig 10 20 if we assume that the loop has at least 4 iterations. Each row in the gure corresponds to one machine instruction. Lines 7 and 8 form a 2 clock loop which is executed n-3 times where n is the number of iterations in the original loop. \square

Figure 10 20 Software pipelined code for Example 10 12

The technique described above is called *software pipelining* because it is the software analog of a technique used for scheduling hardware pipelines. We can think of the schedule executed by each iteration in this example as an 8 stage pipeline. A new iteration can be started on the pipeline every 2 clocks. At the beginning there is only one iteration in the pipeline. As the first iteration proceeds to stage three the second iteration starts to execute in the first pipeline stage.

By clock 7 the pipeline is fully lled with the rst four iterations. In the steady state four consecutive iterations are executing at the same time. A new iteration is started as the oldest iteration in the pipeline retires. When we run out of iterations the pipeline drains and all the iterations in the pipeline run to completion. The sequence of instructions used to all the pipeline lines 1 through 6 in our example is called the prolog lines 7 and 8 are the steady state and the sequence of instructions used to drain the pipeline lines 9 through 14 is called the epilog

For this example we know that the loop cannot be run at a rate faster than 2 clocks per iteration since the machine can only issue one read every clock and there are two reads in each iteration. The software pipelined loop above executes in 2n-6 clocks where n is the number of iterations in the original loop. As $n-\infty$ the throughput of the loop approaches the rate of one iteration every two clocks. Thus software scheduling unlike unrolling can potentially encode the optimal schedule with a very compact code sequence.

Note that the schedule adopted for each individual iteration is not the shortest possible. Comparison with the locally optimized schedule shown in Fig. 10.17 shows that a delay is introduced before the ADD operation. The delay is placed strategically so that the schedule can be initiated every two clocks without resource con icts. Had we stuck with the locally compacted schedule.

10 5 SOFTWARE PIPELINING

the initiation interval would have to be lengthened to 4 clocks to avoid resource con icts and the throughput rate would be halved. This example illustrates an important principle in pipeline scheduling—the schedule must be chosen carefully in order to optimize the throughput—A locally compacted schedule while minimizing the time to complete an iteration—may result in suboptimal throughput when pipelined

10 5 3 Register Allocation and Code Generation

Let us begin by discussing register allocation for the software pipelined loop in Example $10\,14$

Example 10 15 In Example 10 14 the result of the multiply operation in the rst iteration is produced at clock 3 and used at clock 6 Between these clock cycles a new result is generated by the multiply operation in the second iteration at clock 5 this value is used at clock 8 The results from these two iterations must be held in di erent registers to prevent them from interfering with each other Since interference occurs only between adjacent pairs of iterations it can be avoided with the use of two registers one for the odd iterations and one for the even iterations Since the code for odd iterations is di erent from that for the even iterations the size of the steady state loop is doubled This code can be used to execute any loop that has an odd number of iterations greater than or equal to 5

                 Ві
    Dі
           Αi
```

Figure 10 21 Source level unrolling of the loop from Example 10 12

To handle loops that have fewer than 5 iterations and loops with an even number of iterations we generate the code whose source level equivalent is shown in Fig 10 21. The rst loop is pipelined as seen in the machine level equivalent of Fig 10 22. The second loop of Fig 10 21 need not be optimized since it can iterate at most four times \Box

10 5 4 Do Across Loops

Software pipelining can also be applied to loops whose iterations share data dependences. Such loops are known as $do\ across\ loops$

```

Figure 10 22 Code after software pipelining and register allocation in Exam ple $10 \ 15$

Example 10 16 The code

has a data dependence between consecutive iterations because the previous value of sum is added to A i to create a new value of sum It is possible to execute the summation in O $\log n$ time if the machine can deliver su cient parallelism but for the sake of this discussion we simply assume that all the sequential dependences must be obeyed and that the additions must be performed in the original sequential order Because our assumed machine model takes two clocks to complete an ADD the loop cannot execute faster than one iteration every two clocks Giving the machine more adders or multipliers will not make this loop run any faster. The throughput of do across loops like this one is limited by the chain of dependences across iterations

The best locally compacted schedule for each iteration is shown in Fig 10 23 a and the software pipelined code is in Fig 10 23 b. This software pipelined loop starts an iteration every two clocks and thus operates at the optimal rate \Box

b The software pipelined version

Figure 10 23 Software pipelining of a do across loop

10 5 5 Goals and Constraints of Software Pipelining

The primary goal of software pipelining is to maximize the throughput of a long running loop. A secondary goal is to keep the size of the code generated reasonably small. In other words, the software pipelined loop should have a small steady state of the pipeline. We can achieve a small steady state by requiring that the relative schedule of each iteration be the same, and that the iterations be initiated at a constant interval. Since the throughput of the loop is simply the inverse of the initiation interval, the objective of software pipelining is to minimize this interval.

A software pipeline schedule for a data dependence graph G — N E can be specified by

- 1 An initiation interval T and
- 2 A relative schedule S that specifies for each operation when that operation is executed relative to the start of the iteration to which it belongs

Thus an operation n in the ith iteration counting from 0 is executed at clock i T S n Like all the other scheduling problems software pipelining has two kinds of constraints resources and data dependences. We discuss each kind in detail below

Modular Resource Reservation

Let a machine s resources be represented by R r_1 r_2 where r_i is the number of units of the ith kind of resource available. If an iteration of a loop requires n_i units of resource i then the average initiation interval of a pipelined loop is at least $\max_i n_i r_i$ clock cycles. Software pipelining requires that the initiation intervals between any pair of iterations have a constant value. Thus the initiation interval must have at least $\max_i [n_i \ r_i]$ clocks. If $\max_i n_i \ r_i$ is less than 1 it is useful to unroll the source code a small number of times

Example 10 17 Let us return to our software pipelined loop shown in Fig 10 20 Recall that the target machine can issue one load one arithmetic operation one store and one loop back branch per clock. Since the loop has two loads two arithmetic operations and one store operation the minimum initiation interval based on resource constraints is 2 clocks.

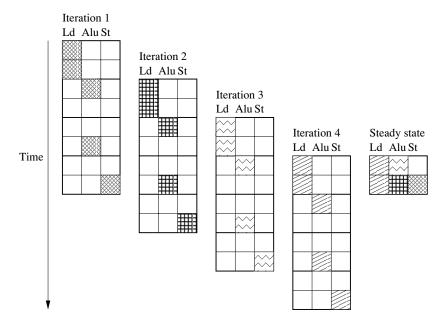

Figure 10 24 $\,$ Resource requirements of four consecutive iterations from the code in Example 10 13

Figure 10 24 shows the resource requirements of four consecutive iterations across time—More resources are used as more iterations get initiated—culmi

10 5 SOFTWARE PIPELINING

nating in maximum resource commitment in the steady state. Let RT be the resource reservation table representing the commitment of one iteration and let $RT_{\rm S}$ represent the commitment of the steady state $RT_{\rm S}$ combines the commitment from four consecutive iterations started T clocks apart. The commitment of row 0 in the table $RT_{\rm S}$ corresponds to the sum of the resources committed in RT 0 RT 2 RT 4 and RT 6. Similarly, the commitment of row 1 in the table corresponds to the sum of the resources committed in RT 1 RT 3 RT 5 and RT 7. That is, the resources committed in the ith row in the steady state are given by

$$RT_{\mathrm{S}} i = \sum_{\{t \mid t \mod 2 = i\}} RT t$$

We refer to the resource reservation table representing the steady state as the modular resource reservation table of the pipelined loop

To check if the software pipeline schedule has any resource con icts we can simply check the commitment of the modular resource reservation table. Surely if the commitment in the steady state can be satisfied so can the commitments in the prolog and epilog, the portions of code before and after the steady state loop. \Box

In general given an initiation interval T and a resource reservation table of an iteration RT the pipelined schedule has no resource conficts on a machine with resource vector R if and only if RT_S i R for all i 0 1 T 1

Data Dependence Constraints

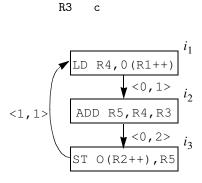

Data dependences in software pipelining are different from those we have en countered so far because they can form cycles. An operation may depend on the result of the same operation from a previous iteration. It is no longer ade quate to label a dependence edge by just the delay we also need to distinguish between instances of the same operation in different iterations. We label a dependence edge n_1 n_2 with label $\langle d \rangle$ if operation n_2 in iteration i must be delayed by at least d clocks after the execution of operation n_1 in iteration i. Let S a function from the nodes of the data dependence graph to integers be the software pipeline schedule, and let T be the initiation interval target. Then

$$T S n_2 S n_1 d$$

The iteration di erence — must be nonnegative Moreover given a cycle of data dependence edges at least one of the edges has a positive iteration di er ence

Example 10 18 Consider the following loop and suppose we do not know the values of p and q

We must assume that any pair of p and q accesses may refer to the same memory location. Thus all the reads and writes must execute in the original sequential order. Assuming that the target machine has the same characteristics as that described in Example 10 12, the data dependence edges for this code are as shown in Fig. 10 25. Note however, that we ignore the loop control instructions that would have to be present, either computing and testing i or doing the test based on the value of R1 or R2.

R1 R2

Figure 10 25 Data dependence graph for Example 10 18

The iteration difference between related operations can be greater than one as shown in the following example

Here the value written in iteration i is used two iterations later. The dependence edge between the store of A i and the load of A i 2 thus has a difference of 2 iterations

The presence of data dependence cycles in a loop imposes yet another limit on its execution throughput. For example, the data dependence cycle in Fig. 10.25 imposes a delay of 4 clock ticks between load operations from consecutive iterations. That is loops cannot execute at a rate faster than one iteration every 4 clocks.

The initiation interval of a pipelined loop is no smaller than

$$\max_{c \text{ a cycle in } G} \frac{\sum_{e \text{ in } c} d_e}{\sum_{e \text{ in } c} e}$$

clocks

In summary the initiation interval of each software pipelined loop is bound ed by the resource usage in each iteration Namely the initiation interval must be no smaller than the ratio of units needed of each resource and the units

10 5 SOFTWARE PIPELINING

available on the machine In addition if the loops have data dependence cycles then the initiation interval is further constrained by the sum of the delays in the cycle divided by the sum of the iteration di erences The largest of these quantities de nes a lower bound on the initiation interval

10 5 6 A Software Pipelining Algorithm

The goal of software pipelining is to and a schedule with the smallest possible initiation interval. The problem is NP complete and can be formulated as an integer linear programming problem. We have shown that if we know what the minimum initiation interval is the scheduling algorithm can avoid resource conicts by using the modular resource reservation table in placing each operation. But we do not know what the minimum initiation interval is until we can a schedule. How do we resolve this circularity

We know that the initiation interval must be greater than the bound computed from a loop's resource requirement and dependence cycles as discussed above. If we can indicate a schedule meeting this bound, we have found the optimal schedule. If we fail to indicate a schedule we can try again with larger initiation intervals until a schedule is found. Note that if heuristics rather than exhaustive search are used this process may not indicate the bound of the optimal schedule.

Whether we can schedule near the lower bound depends on properties of the data dependence graph and the architecture of the target machine. We can easily such the optimal schedule if the dependence graph is acyclic and if every machine instruction needs only one unit of one resource. It is also easy to such data as schedule close to the lower bound if there are more hardware resources than can be used by graphs with dependence cycles. For such cases it is advisable to start with the lower bound as the initial initiation interval target, then keep increasing the target by just one clock with each scheduling attempt. Another possibility is to such the initiation interval using a binary search. We can use as an upper bound on the initiation interval the length of the schedule for one iteration produced by list scheduling.

10 5 7 Scheduling Acyclic Data Dependence Graphs

For simplicity we assume for now that the loop to be software pipelined contains only one basic block. This assumption will be relaxed in Section $10\ 5\ 11$

Algorithm 10 19 Software pipelining an acyclic dependence graph

Figure 10 26 Software pipelining algorithm for acyclic graphs

Algorithm 10 19 software pipelines acyclic data dependence graphs The algorithm rst nds a bound on the initiation interval T_0 based on the resource requirements of the operations in the graph. It then attempts to nd a software pipelined schedule starting with T_0 as the target initiation interval. The algorithm repeats with increasingly larger initiation intervals if it fails to nd a schedule

The algorithm uses a list scheduling approach in each attempt. It uses a modular resource reservation RT to keep track of the resource commitment in the steady state. Operations are scheduled in topological order so that the data dependences can always be satisted by delaying operations. To schedule an operation it right right allower bound s_0 according to the data dependence constraints. It then invokes NodeScheduled to check for possible resource con icts in the steady state. If there is a resource con ict the algorithm tries to schedule the operation in the next clock. If the operation is found to con ict for

10 5 SOFTWARE PIPELINING

T consecutive clocks because of the modular nature of resource con ict detection further attempts are guaranteed to be futile. At that point the algorithm considers the attempt a failure, and another initiation interval is tried.

The heuristics of scheduling operations as soon as possible tends to minimize the length of the schedule for an iteration Scheduling an instruction as early as possible however can lengthen the lifetimes of some variables. For example loads of data tend to be scheduled early sometimes long before they are used. One simple heuristic is to schedule the dependence graph backwards because there are usually more loads than stores

10 5 8 Scheduling Cyclic Dependence Graphs

Dependence cycles complicate software pipelining signi cantly When schedul ing operations in an acyclic graph in topological order data dependences with scheduled operations can impose only a lower bound on the placement of each operation. As a result it is always possible to satisfy the data dependence con straints by delaying operations. The concept of topological order does not apply to cyclic graphs. In fact, given a pair of operations sharing a cycle placing one operation will impose both a lower and upper bound on the placement of the second.

Let n_1 and n_2 be two operations in a dependence cycle S be a software pipeline schedule and T be the initiation interval for the schedule A dependence edge n_1 with label $\langle \ _1 \ d_1 \rangle$ imposes the following constraint on S n_1 and S n_2

$$_1$$
 T S n_2 S n_1 d_1

Similarly a dependence edge n_1 n_2 with label $\langle 2 d_2 \rangle$ imposes constraint

$$_2$$
 T S n_1 S n_2 d_2

Thus

$$S \ n_1 \quad d_1 \quad {}_1 \quad T \quad S \ n_2 \quad S \ n_1 \quad d_2 \quad {}_2 \quad T$$

A strongly connected component SCC in a graph is a set of nodes where every node in the component can be reached by every other node in the component Scheduling one node in an SCC will bound the time of every other node in the component both from above and from below Transitively if there exists a path p leading from n_1 to n_2 then

$$S n_2 S n_1 \sum_{e \text{ in } p} d_e e T 101$$

Observe that

Around any cycle the sum of the s must be positive If it were 0 or negative then it would say that an operation in the cycle either had to precede itself or be executed at the same clock for all iterations

The schedule of operations within an iteration is the same for all iterations that requirement is essentially the meaning of a software pipeline. As a result, the sum of the delays second components of edge labels in a data dependence graph, around a cycle is a lower bound on the initiation interval T

From these two points if path p is a cycle then for any feasible initiation interval T the value of the right side of Equation 10.1 is negative or zero. As a result, the strongest constraints on the placement of nodes is obtained from the simple paths—those paths that contain no cycles

Thus for each feasible T computing the transitive e ect of data dependences on each pair of nodes is equivalent to inding the length of the longest simple path from the irst node to the second. Moreover since cycles cannot increase the length of a path we can use a simple dynamic programming algorithm to indicate the longest paths without the simple path requirement and be sure that the resulting lengths will also be the lengths of the longest simple paths see Exercise 10.5.7

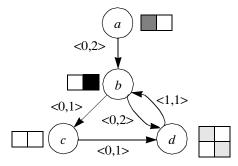

Figure 10 27 Dependence graph and resource requirement in Example 10 20

Example 10 20 Figure 10 27 shows a data dependence graph with four nodes $a\ b\ c\ d$ Attached to each node is its resource reservation table attached to each edge is its iteration difference and delay. Assume for this example that the target machine has one unit of each kind of resource. Since there are three uses of the first resource and two of the second, the initiation interval must be no less than 3 clocks. There are two SCCs in this graph, the first is a trivial component consisting of the node a alone, and the second consists of nodes $b\ c$ and d. The longest cycle $b\ c\ d\ b$ has a total delay of 3 clocks connecting nodes that are 1 iteration apart. Thus, the lower bound on the initiation interval provided by data dependence cycle constraints is also 3 clocks.

10 5 SOFTWARE PIPELINING

Placing any of b c or d in a schedule constrains all the other nodes in the component. Let T be the initiation interval. Figure 10.28 shows the transitive dependences. Part a shows the delay and the iteration difference for each edge. The delay is represented directly but is represented by adding to the delay the value. T

Figure 10 28 b shows the length of the longest simple path between two nodes when such a path exists its entries are the sums of the expressions given by Fig 10 28 a for each edge along the path. Then in c and d we see the expressions of b with the two relevant values of T that is 3 and 4 substituted for T. The difference between the schedule of two nodes S n_2 S n_1 must be no less than the value given in entry n_1 n_2 in each of the tables c or d depending on the value of T chosen

For instance consider the entry in Fig 10 28 for the longest simple path from c to b which is 2 T The longest simple path from c to b is c d b The total delay is 2 along this path and the sum of the s is 1 representing the fact that the iteration number must increase by 1 Since T is the time by which each iteration follows the previous the clock at which b must be scheduled is at least 2 T clocks after the clock at which c is scheduled Since T is at least 3 we are really saying that b may be scheduled T 2 clocks before c or later than that clock but not earlier

Notice that considering nonsimple paths from c to b does not produce a stronger constraint. We can add to the path c d b any number of iterations of the cycle involving d and b. If we add k such cycles, we get a path length of b and b is b and the sum of the b sis b and the sum of the b sis b and the sum of the b sis b and the clock of b relative to the clock of b and b and the sum of the sis b and the sum of the b sis b and the sum of the sis b are since b and the sum of the sis b are since b and the sum of the sis b and the sum of the sis b are since b and the sum of the sis b and the sis b and the sum of the sis b and the sis b

For example from entries b c and c b we see that

That is

$$S b \quad 1 \quad S c \quad S b \quad 2 \quad T$$

If T = 3

$$S b \quad 1 \quad S c \quad S b \quad 1$$

Put equivalently c must be scheduled one clock after b If T 4 however

$$S b \quad 1 \quad S c \quad S b \quad 2$$

That is c is scheduled one or two clocks after b

Given the all points longest path information we can easily compute the range where it is legal to place a node due to data dependences. We see that there is no slack in the case when T-3 and the slack increases as T increases

Algorithm 10 21 Software pipelining

INPUT A machine resource vector R r_1 r_2 where r_i is the number of units available of the ith kind of resource and a data dependence graph G N E Each operation n in N is labeled with its resource reservation table RT_n each edge e n_1 n_2 in E is labeled with $\langle e d_e \rangle$ indicating that n_2 must execute no earlier than d_e clocks after node n_1 from the eth preceding iteration

OUTPUT A software pipelined schedule S and an initiation interval T

METHOD Execute the program in Fig 10 29 □

Algorithm 10 21 has a high level structure similar to that of Algorithm 10 19 which only handles acyclic graphs. The minimum initiation interval in this case is bounded not just by resource requirements but also by the data dependence cycles in the graph. The graph is scheduled one strongly connected component at a time. By treating each strongly connected component as a unit edges be tween strongly connected components necessarily form an acyclic graph. While the top level loop in Algorithm 10 19 schedules nodes in the graph in topological order the top level loop in Algorithm 10 21 schedules strongly connected components in topological order. As before, if the algorithm fails to schedule all the components, then a larger initiation interval is tried. Note that Algorithm 10 21 behaves exactly like Algorithm 10 19 if given an acyclic data dependence graph.

Algorithm 10 21 computes two more sets of edges E' is the set of all edges whose iteration difference is 0 E is the all points longest path edges. That is

```

Figure 10 29 A software pipelining algorithm for cyclic dependence graphs

for each pair of nodes p n there is an edge e in E whose associated distance d_e is the length of the longest simple path from p to n provided that there is at least one path from p to n E is computed for each value of T the initiation interval target. It is also possible to perform this computation just once with a symbolic value of T and then substitute for T in each iteration as we did in Example 10.20

Algorithm 10 21 uses backtracking If it fails to schedule a SCC it tries to reschedule the entire SCC a clock later. These scheduling attempts continue for up to T clocks. Backtracking is important because as shown in Example 10 20 the placement of the rist node in an SCC can fully dictate the schedule of all other nodes. If the schedule happens not to the with the schedule created thus far the attempt fails

To schedule a SCC the algorithm determines the earliest time each node in the component can be scheduled satisfying the transitive data dependences in E . It then picks the one with the earliest start time as the $\ rst$ node to schedule. The algorithm then invokes $\ SccScheduled$ to try to schedule the component at the earliest start time. The algorithm makes at most T attempts with successively greater start times. If it fails then the algorithm tries another initiation interval

The SccScheduled algorithm resembles Algorithm 10 19 but has three major di erences

- 1 The goal of SccScheduled is to schedule the strongly connected component at the given time slot s If the rst node of the strongly connected component cannot be scheduled at s SccScheduled returns false. The main function can invoke SccScheduled again with a later time slot if that is desired
- 2 The nodes in the strongly connected component are scheduled in topolog ical order based on the edges in E' Because the iteration differences on all the edges in E' are 0 these edges do not cross any iteration boundaries and cannot form cycles—Edges that cross iteration boundaries are known as loop carried—Only loop carried dependences place upper bounds on where operations can be scheduled—So—this scheduling order—along with the strategy of scheduling each operation as early as possible—maximizes the ranges in which subsequent nodes can be scheduled
- 3 For strongly connected components dependences impose both a lower and upper bound on the range in which a node can be scheduled SccSched uled computes these ranges and uses them to further limit the scheduling attempts

Example 10 22 Let us apply Algorithm 10 21 to the cyclic data dependence graph in Example 10 20 The algorithm rst computes that the bound on the initiation interval for this example is 3 clocks. We note that it is not possible to meet this lower bound. When the initiation interval T is 3 the transitive

10 5 SOFTWARE PIPELINING

dependences in Fig. 10 28 dictate that S d S b 2 Scheduling nodes b and d two clocks apart will produce a conject in a modular resource reservation table of length 3

Attempt	Initiation Interval	Node	Range	Schedule	Modular Resource Reservation
1	T-3	$egin{array}{c} a \\ b \\ c \end{array}$	$egin{array}{ccc} 0 & \infty & & \ 2 & \infty & & \ 3 & 3 & & \end{array}$	0 2	
2	T 3	$egin{array}{c} a \\ b \\ c \\ d \end{array}$	$\begin{array}{c} 0 \ \infty \\ 2 \ \infty \\ 4 \ 4 \\ 5 \ 5 \end{array}$	0 3 4

5	T 4	$egin{array}{c} a \\ b \\ c \\ d \end{array}$	$\begin{array}{ccc} 0 & \infty & & \\ 2 & \infty & & \\ 4 & 5 & & \\ 5 & 5 & & \end{array}$	0 3 5	
6	T 4	$egin{array}{c} a \\ b \\ c \\ d \end{array}$	$egin{array}{ccc} 0 & \infty & & & \ 2 & \infty & & & \ 5 & 6 & & \ 6 & 7 & & & \end{array}$	0 4 5 6	

Figure 10 30 Behavior of Algorithm 10 21 on Example 10 20

Figure 10 30 shows how Algorithm 10 21 behaves with this example. It is tries to ind a schedule with a 3 clock initiation interval. The attempt starts by scheduling nodes a and b as early as possible. However once node b is placed in clock 2 node c can only be placed at clock 3 which conficts with the resource usage of node a. That is a and c both need the instructions at clocks that have a remainder of 0 modulo 3.

The algorithm backtracks and tries to schedule the strongly connected component $\{b\ c\ d\}$ a clock later. This time node b is scheduled at clock 3, and node c is scheduled successfully at clock 4. Node d however, cannot be scheduled in

clock 5 That is both b and d need the second resource at clocks that have a remainder of 0 modulo 3 Note that it is just a coincidence that the two con icts discovered so far are at clocks with a remainder of 0 modulo 3 the con ict might have occurred at clocks with remainder 1 or 2 in another example

The algorithm repeats by delaying the start of the SCC $\{b\ c\ d\}$ by one more clock. But as discussed earlier this SCC can never be scheduled with an initiation interval of 3 clocks so the attempt is bound to fail. At this point the algorithm gives up and tries to $\$ nd a schedule with an initiation interval of 4 clocks. The algorithm eventually $\$ nds the optimal schedule on its sixth attempt. $\$ \square

10 5 9 Improvements to the Pipelining Algorithms

Algorithm 10 21 is a rather simple algorithm although it has been found to work well on actual machine targets. The important elements in this algorithm are

- 1 The use of a modular resource reservation table to check for resource con icts in the steady state
- 2 The need to compute the transitive dependence relations to nd the legal range in which a node can be scheduled in the presence of dependence cycles
- 3 Backtracking is useful and nodes on *critical cycles* cycles that place the highest lower bound on the initiation interval T must be rescheduled together because there is no slack between them

There are many ways to improve Algorithm 10 21 For instance the all gorithm takes a while to realize that a 3 clock initiation interval is infeasible for the simple Example 10 22 We can schedule the strongly connected components independently rst to determine if the initiation interval is feasible for each component

We can also modify the order in which the nodes are scheduled. The order used in Algorithm 10 21 has a few disadvantages. First because nontrivial SCCs are harder to schedule it is desirable to schedule them - rst. Second some of the registers may have unnecessarily long lifetimes. It is desirable to pull the de nitions closer to the uses. One possibility is to start with scheduling strongly connected components with critical cycles - rst. then extend the schedule on both ends

10 5 10 Modular Variable Expansion

A scalar variable is said to be *privatizable* in a loop if its live range falls within an iteration of the loop. In other words, a privatizable variable must not be live upon either entry or exit of any iteration. These variables are so named because

Are There Alternatives to Heuristics

We can formulate the problem of simultaneously nding an optimal software pipeline schedule and register assignment as an integer linear programming problem. While many integer linear programs can be solved quickly some of them can take an exorbitant amount of time. To use an integer linear programming solver in a compiler, we must be able to abort the procedure if it does not complete within some preset limit.

Such an approach has been tried on a target machine the SGI R8000 empirically and it was found that the solver could nd the optimal solution for a large percentage of the programs in the experiment within a reason able amount of time. It turned out that the schedules produced using a heuristic approach were also close to optimal. The results suggest that at least for that machine it does not make sense to use the integer linear programming approach especially from a software engineering perspective. Because the integer linear solver may not nish it is still necessary to implement some kind of a heuristic scheduler in the compiler. Once such a heuristic scheduler is in place, there is little incentive to implement a scheduler based on integer programming techniques as well.

di erent processors executing di erent iterations in a loop can have their own private copies and thus not interfere with one another

Variable expansion refers to the transformation of converting a privatizable scalar variable into an array and having the *i*th iteration of the loop read and write the *i*th element. This transformation eliminates the antidependence constraints between reads in one iteration and writes in the subsequent iterations as well as output dependences between writes from different iterations. If all loop carried dependences can be eliminated all the iterations in the loop can be executed in parallel

Eliminating loop carried dependences and thus eliminating cycles in the data dependence graph can greatly improve the e-ectiveness of software pipe lining. As illustrated by Example 10.15 we need not expand a privatizable variable fully by the number of iterations in the loop. Only a small number of iterations can be executing at a time-and privatizable variables may simultane ously be live in an even smaller number of iterations. The same storage can thus be reused to hold variables with nonoverlapping lifetimes. More specifically if the lifetime of a register is l clocks and the initiation interval is l then only l l values can be live at any one point. We can allocate l registers to the variable with the variable in the lth iteration using the l mod l th register. We refer to this transformation as l modular variable expansion.

Algorithm 10 23 Software pipelining with modular variable expansion INPUT A data dependence graph and a machine resource description

 ${\bf OUTPUT}$ Two loops one software pipelined and one unpipelined ${\bf METHOD}$

- 1 Remove the loop carried antidependences and output dependences asso ciated with privatizable variables from the data dependence graph
- 2 Software pipeline the resulting dependence graph using Algorithm 10 21 Let T be the initiation interval for which a schedule is found and L be the length of the schedule for one iteration
- 3 From the resulting schedule compute q_v the minimum number of regis ters needed by each privatizable variable v Let $Q = \max_v q_v$
- 4 Generate two loops a software pipelined loop and an unpipelined loop The software pipelined loop has

$$\frac{L}{T}$$
 Q 1

copies of the iterations placed T clocks apart. It has a prolog with

$$\frac{L}{T}$$
 1 T

instructions a steady state with QT instructions and an epilog of L T instructions. Insert a loop back instruction that branches from the bottom of the steady state to the top of the steady state

The number of registers assigned to privatizable variable v is

$$q'_v = egin{array}{ccc} q_v & ext{if } Q mod q_v & 0 \ Q & ext{otherwise} \end{array}$$

The variable v in iteration i uses the $i \mod q_i'$ th register assigned Let n be the variable representing the number of iterations in the source loop. The software pipelined loop is executed if

$$n = \frac{L}{T} = Q = 1$$

The number of times the loop back branch is taken is

$$n_1 \qquad \frac{n \qquad \frac{L}{T} \qquad 1}{Q}$$

Thus the number of source iterations executed by the software pipelined loop is

$$n_2$$
 $\begin{array}{ccccc} \frac{L}{T} & 1 & Qn_1 & \text{if } n & \frac{L}{T} & Q & 1 \\ & 0 & & \text{otherwise} \end{array}$

The number of iterations executed by the unpipelined loop is $n_3 - n - n_2$

Example 10 24 For the software pipelined loop in Fig 10 22 L 8 T 2 and Q 2 The software pipelined loop has 7 copies of the iterations with the prolog steady state and epilog having 6 4 and 6 instructions respectively Let n be the number of iterations in the source loop. The software pipelined loop is executed if n 5 in which case the loop back branch is taken

$$\frac{n-3}{2}$$

times and the software pipelined loop is responsible for

$$3 \quad 2 \qquad \frac{n-3}{2}$$

of the iterations in the source loop

Modular expansion increases the size of the steady state by a factor of Q Despite this increase the code generated by Algorithm 10 23 is still fairly compact. In the worst case the software pipelined loop would take three times as many instructions as that of the schedule for one iteration. Roughly together with the extra loop generated to handle the left over iterations the total code size is about four times the original. This technique is usually applied to tight inner loops so this increase is reasonable.

Algorithm 10 23 minimizes code expansion at the expense of using more registers. We can reduce register usage by generating more code. We can use the minimum q_v registers for each variable v if we use a steady state with

$$T \quad LCM_v q_v$$

instructions Here LCM_v represents the operation of taking the least common multiple of all the q_v s as v ranges over all the privatizable variables i.e. the smallest integer that is an integer multiple of all the q_v s. Unfortunately the least common multiple can be quite large even for a few small q_v s

10 5 11 Conditional Statements

If predicated instructions are available we can convert control dependent in structions into predicated ones Predicated instructions can be software pipe lined like any other operations However if there is a large amount of data dependent control ow within the loop body scheduling techniques described in Section 10 4 may be more appropriate

If a machine does not have predicated instructions we can use the concept of hierarchical reduction described below to handle a small amount of data dependent control ow Like Algorithm 10 11 in hierarchical reduction the control constructs in the loop are scheduled inside out starting with the most

deeply nested structures As each construct is scheduled the entire construct is reduced to a single node representing all the scheduling constraints of its components with respect to the other parts of the program. This node can then be scheduled as if it were a simple node within the surrounding control construct. The scheduling process is complete when the entire program is reduced to a single node.

In the case of a conditional statement with then and else branches we schedule each of the branches independently Then

- 1 The constraints of the entire conditional statement are conservatively taken to be the union of the constraints from both branches
- 2 Its resource usage is the maximum of the resources used in each branch
- 3 Its precedence constraints are the union of those in each branch obtained by pretending that both branches are executed

This node can then be scheduled like any other node. Two sets of code cor responding to the two branches are generated. Any code scheduled in parallel with the conditional statement is duplicated in both branches. If multiple conditional statements are overlapped separate code must be generated for each combination of branches executed in parallel.

10 5 12 Hardware Support for Software Pipelining

Specialized hardware support has been proposed for minimizing the size of software pipelined code. The rotating register—le in the Itanium architecture is one such example. A rotating register—le has a base register—which is added to the register number speci—ed in the code to derive the actual register accessed. We can get di—erent iterations in a loop to use di—erent registers simply by changing the contents of the base register at the boundary of each iteration. The Itanium architecture also has extensive predicated instruction support. Not only can predication be used to convert control dependence to data dependence but it also can be used to avoid generating the prologs and epilogs. The body of a software pipelined loop contains a superset of the instructions issued in the prolog and epilog. We can simply generate the code for the steady state and use predication appropriately to suppress the extra operations to get the e—ects of having a prolog and an epilog.

While Itanium s hardware support improves the density of software pipe lined code we must also realize that the support is not cheap. Since software pipelining is a technique intended for tight innermost loops pipelined loops tend to be small anyway. Specialized support for software pipelining is warranted principally for machines that are intended to execute many software pipelined loops and in situations where it is very important to minimize code size.

Figure 10 31 Machine code for Exercise 10 5 2

10 5 13 Exercises for Section 10 5

Exercise 10 5 1 In Example 10 20 we showed how to establish the bounds on the relative clocks at which b and c are scheduled. Compute the bounds for each of ve other pairs of nodes i for general T ii for T 3 iii for T 4

Exercise 10 5 2 In Fig 10 31 is the body of a loop Addresses such as a R9 are intended to be memory locations where a is a constant and R9 is the register that counts iterations through the loop. You may assume that each iteration of the loop accesses di erent locations because R9 has a di erent value. Using the machine model of Example 10 12 schedule the loop of Fig 10 31 in the following ways

- a Keeping each iteration as tight as possible i e only introduce one nop af ter each arithmetic operation unroll the loop twice Schedule the second iteration to commence at the earliest possible moment without violating the constraint that the machine can only do one load one store one arithmetic operation and one branch at any clock
- b Repeat part a but unroll the loop three times Again start each itera tion as soon as you can subject to the machine constraints
- c Construct fully pipelined code subject to the machine constraints In this part you can introduce extra nop s if needed but you must start a new iteration every two clock ticks

Exercise 10 5 3 A certain loop requires 5 loads 7 stores and 8 arithmetic operations What is the minimum initiation interval for a software pipelining of this loop on a machine that executes each operation in one clock tick and has resources enough to do in one clock tick

- a 3 loads 4 stores and 5 arithmetic operations
- b 3 loads 3 stores and 3 arithmetic operations

Exercise 10 5 4 Using the machine model of Example 10 12 nd the min imum initiation interval and a uniform schedule for the iterations for the following loop

Remember that the counting of iterations is handled by auto increment of reg isters and no operations are needed solely for the counting associated with the for loop

Exercise 10 5 5 Prove that Algorithm 10 19 in the special case where every operation requires only one unit of one resource can always nd a software pipeline schedule meeting the lower bound

Exercise 10 5 6 Suppose we have a cyclic data dependence graph with nodes a b c and d There are edges from a to b and from c to d with label $\langle 0 1 \rangle$ and there are edges from b to c and from d to a with label $\langle 1 1 \rangle$ There are no other edges

- a Draw the cyclic dependence graph
- b Compute the table of longest simple paths among the nodes
 - Show the lengths of the longest simple paths if the initiation interval T is 2
- d Repeat c if T=3
- e For T-3 what are the constraints on the relative times that each of the instructions represented by a-b-c and d may be scheduled

Exercise 10 5 7 Give an O n^3 algorithm to n d the length of the longest simple path in an n node graph on the assumption that no cycle has a positive length Hint Adapt Floyd's algorithm for shortest paths see e.g. A. V. Aho and J. D. Ullman Foundations of Computer Science Computer Science Press New York 1992

Exercise 10 5 8 Suppose we have a machine with three instruction types which we ll call A B and C All instructions require one clock tick and the machine can execute one instruction of each type at each clock. Suppose a loop consists of six instructions two of each type. Then it is possible to execute the loop in a software pipeline with an initiation interval of two. However some sequences of the six instructions require insertion of one delay and some require insertion of two delays. Of the 90 possible sequences of two A s. two B s and two C s. how many require no delay. How many require one delay

Hint There is symmetry among the three instruction types so two sequences that can be transformed into one another by permuting the names A B and C must require the same number of delays. For example ABBCAC must be the same as BCCABA

10 6 Summary of Chapter 10

- ◆ Architectural Issues Optimized code scheduling takes advantage of fea tures of modern computer architectures Such machines often allow pipe lined execution where several instructions are in di erent stages of exe cution at the same time Some machines also allow several instructions to begin execution at the same time
- ◆ Data Dependences When scheduling instructions we must be aware of the e ect instructions have on each memory location and register True data dependences occur when one instruction must read a location after another has written it Antidependences occur when there is a write after a read and output dependences occur when there are two writes to the same location
- ♦ Eliminating Dependences By using additional locations to store data antidependences and output dependences can be eliminated Only true dependences cannot be eliminated and must surely be respected when the code is scheduled
- igspace Data Dependence Graphs for Basic Blocks These graphs represent the timing constraints among the statements of a basic block Nodes correspond to the statements An edge from n to m labeled d says that the instruction m must start at least d clock cycles after instruction n starts
- ◆ Prioritized Topological Orders The data dependence graph for a basic block is always acyclic and there usually are many topological orders consistent with the graph One of several heuristics can be used to select a preferred topological order for a given graph e g choose nodes with the longest critical path rst
- ◆ List Scheduling Given a prioritized topological order for a data depend ence graph we may consider the nodes in that order Schedule each node at the earliest clock cycle that is consistent with the timing constraints im plied by the graph edges the schedules of all previously scheduled nodes and the resource constraints of the machine
- ◆ Interblock Code Motion Under some circumstances it is possible to move statements from the block in which they appear to a predecessor or suc cessor block The advantage is that there may be opportunities to execute instructions in parallel at the new location that do not exist at the orig inal location If there is not a dominance relation between the old and

new locations it may be necessary to insert compensation code along certain paths in order to make sure that exactly the same sequence of instructions is executed regardless of the ow of control

- ◆ Do All Loops A do all loop has no dependences across iterations so any iterations may be executed in parallel
- ◆ Software Pipelining of Do All Loops Software pipelining is a technique for exploiting the ability of a machine to execute several instructions at once We schedule iterations of the loop to begin at small intervals per haps placing no op instructions in the iterations to avoid conficts between iterations for the machines resources. The result is that the loop can be executed quickly with a preamble a coda and usually a tiny inner loop.
- ◆ Do Across Loops Most loops have data dependences from each iteration to later iterations These are called do across loops
- ◆ Data Dependence Graphs for Do Across Loops To represent the dependences among instructions of a do across loop requires that the edges be labeled by a pair of values the required delay as for graphs representing basic blocks and the number of iterations that elapse between the two instructions that have a dependence
- ◆ List Scheduling of Loops To schedule a loop we must choose the one schedule for all the iterations and also choose the initiation interval at which successive iterations commence The algorithm involves deriving the constraints on the relative schedules of the various instructions in the loop by nding the length of the longest acyclic paths between the two nodes These lengths have the initiation interval as a parameter and thus put a lower bound on the initiation interval

Chapter 11

Optimizing for Parallelism and Locality

This chapter shows how a compiler can enhance parallelism and locality in computationally intensive programs involving arrays to speed up target programs running on multiprocessor systems. Many sciential computational cycles and commercial applications have an insatiable need for computational cycles. Examples include weather prediction protein folding for designing drugs and dynamics for designing aeropropulsion systems and quantum chromodynamics for studying the strong interactions in high energy physics.

One way to speed up a computation is to use parallelism Unfortunately it is not easy to develop software that can take advantage of parallel machines Dividing the computation into units that can execute on di erent processors in parallel is already hard enough yet that by itself does not guarantee a speedup We must also minimize interprocessor communication because communication overhead can easily make the parallel code run even slower than the sequential execution

Minimizing communication can be thought of as a special case of improving a program s data locality. In general, we say that a program has good data locality if a processor often accesses the same data it has used recently. Surely if a processor on a parallel machine has good locality, it does not need to communicate with other processors frequently. Thus, parallelism and data locality need to be considered hand in hand. Data locality by itself, is also important for the performance of individual processors. Modern processors have one or more level of caches in the memory hierarchy, a memory access can take tens of machine cycles whereas a cache hit would only take a few cycles. If a program does not have good data locality and misses in the cache often its performance will sufer

Another reason why parallelism and locality are treated together in this same chapter is that they share the same theory If we know how to optimize for data locality we know where the parallelism is You will see in this chapter that the

CHAPTER 11 OPTIMIZING FOR PARALLELISM AND LOCALITY

program model we used for data ow analysis in Chapter 9 is inadequate for parallelization and locality optimization. The reason is that work on data ow analysis assumes we don't distinguish among the ways a given statement is reached and in fact these Chapter 9 techniques take advantage of the fact that we don't distinguish among dierent executions of the same statement eige in a loop. To parallelize a code, we need to reason about the dependences among dierent dynamic executions of the same statement to determine if they can be executed on dierent processors simultaneously

This chapter focuses on techniques for optimizing the class of numerical applications that use arrays as data structures and access them with simple regular patterns. More specifically we study programs that have a ne array accesses with respect to surrounding loop indexes. For example, if i and j are the index variables of surrounding loops, then Zi j and Zi i j are an exaccesses. A function of one or more variables x_1 x_2 x_n is a ne if it can be expressed as a sum of a constant plus constant multiples of the variables i.e. c_0 c_1x_1 c_2x_2 c_nx_n where c_0 c_1 c_n are constants. A ne functions are usually known as linear functions although strictly speaking linear functions do not have the c_0 term

Here is a simple example of a loop in this domain

Because iterations of the loop write to di erent locations di erent processors can execute di erent iterations concurrently. On the other hand if there is another statement Z j $\,$ 1 being executed we need to worry about whether i could ever be the same as j and if so in which order do we execute those instances of the two statements that share a common value of the array index

Knowing which iterations can refer to the same memory location is important. This knowledge lets us specify the data dependences that must be honored when scheduling code for both uniprocessors and multiprocessors. Our objective is to and a schedule that honors all the data dependences such that operations that access the same location and cache lines are performed close together if possible and on the same processor in the case of multiprocessors.

The theory we present in this chapter is grounded in linear algebra and integer programming techniques. We model iterations in an n deep loop nest as an n dimensional polyhedron, whose boundaries are specified by the bounds of the loops in the code. As ne functions map each iteration to the array locations it accesses. We can use integer linear programming to determine if there exist two iterations that can refer to the same location.

The set of code transformations we discuss here fall into two categories a ne partitioning and blocking. A ne partitioning splits up the polyhedra of iterations into components to be executed either on di erent machines or one by one sequentially. On the other hand, blocking creates a hierarchy of iterations. Suppose we are given a loop that sweeps through an array row by

11 1 BASIC CONCEPTS

row We may instead subdivide the array into blocks and visit all elements in a block before moving to the next The resulting code will consist of outer loops traversing the blocks and then inner loops to sweep the elements within each block Linear algebra techniques are used to determine both the best a ne partitions and the best blocking schemes

In the following we rst start with an overview of the concepts in parallel computation and locality optimization in Section 11.1. Then Section 11.2 is an extended concrete example matrix multiplication that shows how *loop transformations* that reorder the computation inside a loop can improve both locality and the e ectiveness of parallelization

Sections 11 3 to Sections 11 6 present the preliminary information necessary for loop transformations. Section 11 3 shows how we model the individual iterations in a loop nest. Section 11 4 shows how we model array index functions that map each loop iteration to the array locations accessed by the iteration Section 11 5 shows how to determine which iterations in a loop refer to the same array location or the same cache line using standard linear algebra algorithms and Section 11 6 shows how to indicate the data dependences among array references in a program

The rest of the chapter applies these preliminaries in coming up with the optimizations Section 11.7 rst looks at the simpler problem of inding par allelism that requires no synchronization. To indicate that operations are partitioning we simply indicate the solution to the constraint that operations that share a data dependence must be assigned to the same processor.

Well not too many programs can be parallelized without requiring any synchronization. Thus in Sections 11.8 through 11.9.9 we consider the general case of inding parallelism that requires synchronization. We introduce the concept of pipelining show how to indicate the animal network of pipelining allowed by a program. We show how to optimize for locality in Section 11.10. Finally, we discuss how a net ransforms are useful for optimizing for other forms of parallelism.

11 1 Basic Concepts

This section introduces the basic concepts related to parallelization and local ity optimization. If operations can be executed in parallel, they also can be reordered for other goals such as locality. Conversely, if data dependences in a program dictate that instructions in a program must execute serially there is obviously no parallelism nor is there any opportunity to reorder instructions to improve locality. Thus parallelization analysis also and the available opportunities for code motion to improve data locality.

To minimize communication in parallel code we group together all related operations and assign them to the same processor. The resulting code must therefore have data locality. One crude approach to getting good data locality on a uniprocessor is to have the processor execute the code assigned to each processor in succession

In this introduction we start by presenting an overview of parallel computer architectures. We then show the basic concepts in parallelization the kind of transformations that can make a big difference as well as the concepts useful for parallelization. We then discuss how similar considerations can be used to optimize locality. Finally, we introduce informally the mathematical concepts used in this chapter.

11 1 1 Multiprocessors

The most popular parallel machine architecture is the symmetric multiproces sor SMP High performance personal computers often have two processors and many server machines have four eight and some even tens of processors Moreover as it has become feasible for several high performance processors to t on a single chip multiprocessors have become even more widely used

Processors on a symmetric multiprocessor share the same address space. To communicate a processor can simply write to a memory location, which is then read by any other processor. Symmetric multiprocessors are so named because all processors can access all of the memory in the system with a uniform access time. Fig. 11.1 shows the high level architecture of a multiprocessor. The processors may have their own arst level second level and in some cases even a third level cache. The highest level caches are connected to physical memory through typically a shared bus

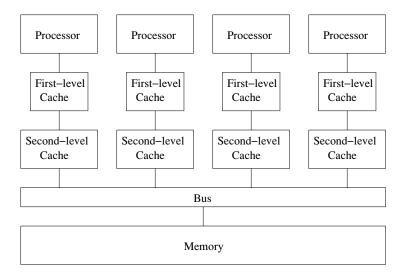

Figure 11.1 The symmetric multi processor architecture

Symmetric multiprocessors use a *coherent cache protocol* to hide the presence of caches from the programmer Under such a protocol several processors are

11 1 BASIC CONCEPTS

allowed to keep copies of the same cache line¹ at the same time provided that they are only reading the data. When a processor wishes to write to a cache line copies from all other caches are removed. When a processor requests data not found in its cache, the request goes out on the shared bus, and the data will be fetched either from memory or from the cache of another processor.

The time taken for one processor to communicate with another is about twice the cost of a memory access. The data in units of cache lines must rst be written from the rst processor's cache to memory and then fetched from the memory to the cache of the second processor. You may think that interprocessor communication is relatively cheap since it is only about twice as slow as a memory access. However, you must remember that memory accesses are very expensive when compared to cache hits they can be a hundred times slower. This analysis brings home the similarity between excient parallelization and locality analysis. For a processor to perform well either on its own or in the context of a multiprocessor it must and most of the data it operates on in its cache.

In the early 2000 s the design of symmetric multiprocessors no longer scaled beyond tens of processors because the shared bus or any other kind of inter connect for that matter could not operate at speed with the increasing number of processors. To make processor designs scalable architects introduced yet an other level in the memory hierarchy. Instead of having memory that is equally far away for each processor they distributed the memories so that each processor could access its local memory quickly as shown in Fig. 11.2. Remote memories thus constituted the next level of the memory hierarchy they are collectively bigger but also take longer to access. Analogous to the principle in memory hierarchy design that fast stores are necessarily small machines that support fast interprocessor communication necessarily have a small number of processors.

There are two variants of a parallel machine with distributed memories NUMA nonuniform memory access machines and message passing machines NUMA architectures provide a shared address space to the software allowing processors to communicate by reading and writing shared memory. On message passing machines however processors have disjoint address spaces and processors communicate by sending messages to each other. Note that even though it is simpler to write code for shared memory machines the software must have good locality for either type of machine to perform well

11 1 2 Parallelism in Applications

We use two high level metrics to estimate how well a parallel application will perform parallelism coverage which is the percentage of the computation that runs in parallel granularity of parallelism which is the amount of computation that each processor can execute without synchronizing or communicating with others. One particularly attractive target of parallelization is loops a loop may

¹You may wish to review the discussion of caches and cache lines in Section 7 4

CHAPTER 11 OPTIMIZING FOR PARALLELISM AND LOCALITY

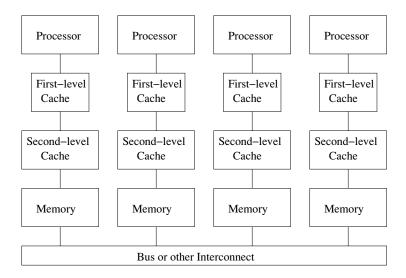

Figure 11 2 Distributed memory machines

have many iterations and if they are independent of each other we have found a great source of parallelism

Amdahl s Law

The signi-cance of parallelism coverage is succinctly captured by Amdahl s Law $Amdahl\ s\ Law$ states that if f is the fraction of the code parallelized and if the parallelized version runs on a p processor machine with no communication or parallelization overhead the speedup is

$$\frac{1}{1 \quad f \quad f \quad p}$$

For example if half of the computation remains sequential the computation can only double in speed regardless of how many processors we use The speedup achievable is a factor of 1 6 if we have 4 processors. Even if the parallelism coverage is 90 — we get at most a factor of 3 speed up on 4 processors and a factor of 10 on an unlimited number of processors

Granularity of Parallelism

It is ideal if the entire computation of an application can be partitioned into many independent coarse grain tasks because we can simply assign the di er ent tasks to di erent processors. One such example is the SETI Search for Extra Terrestrial Intelligence project which is an experiment that uses home computers connected over the Internet to analyze di erent portions of radio telescope data in parallel. Each unit of work requiring only a small amount

11 1 BASIC CONCEPTS

of input and generating a small amount of output can be performed indepen dently of all others. As a result such a computation runs well on machines over the Internet which has relatively high communication latency delay and low bandwidth

Most applications require more communication and interaction between processors yet still allow coarse grained parallelism. Consider for example the web server responsible for serving a large number of mostly independent requests out of a common database. We can run the application on a multiprocessor with a thread implementing the database and a number of other threads servicing user requests. Other examples include drug design or airfoil simulation where the results of many different parameters can be evaluated independently. Sometimes the evaluation of even just one set of parameters in a simulation takes so long that it is desirable to speed it up with parallelization. As the granularity of available parallelism in an application decreases better interprocessor communication support and more programming effort are needed.

Many long running scientic and engineering applications with their simple control structures and large data sets can be more readily parallelized at a ner grain than the applications mentioned above. Thus, this chapter is devoted primarily to techniques that apply to numerical applications and in particular to programs that spend most of their time manipulating data in multidimensional arrays. We shall examine this class of programs next

11 1 3 Loop Level Parallelism

Loops are the main target for parallelization especially in applications using arrays Long running applications tend to have large arrays which lead to loops that have many iterations one for each element in the array. It is not uncommon to nd loops whose iterations are independent of one another. We can divide the large number of iterations of such loops among the processors. If the amount of work performed in each iteration is roughly the same simply dividing the iterations evenly across processors will achieve maximum paral lelism. Example 11-1 is an extremely simple example showing how we can take advantage of loop level parallelism.

Example 11 1 The loop

computes the square of di erences between elements in vectors X and Y and stores it into Z. The loop is parallelizable because each iteration accesses a di erent set of data. We can execute the loop on a computer with M processors by giving each processor an unique ID p = 0.1 M = 1 and having each processor execute the same code

Task Level Parallelism

It is possible to nd parallelism outside of iterations in a loop For example we can assign two different function invocations or two independent loops to two processors. This form of parallelism is known as task parallelism. The task level is not as attractive a source of parallelism as is the loop level. The reason is that the number of independent tasks is a constant for each program and does not scale with the size of the data as does the number of iterations of a typical loop. Moreover, the tasks generally are not of equal size, so it is hard to keep all the processors busy all the time

```
b ceil n M
for i b p i min n b p 1 i
Z i X i Y i
Z i Z i Z i
```

We divide the iterations in the loop evenly among the processors the pth processor is given the pth swath of iterations to execute. Note that the number of iterations may not be divisible by M so we assure that the last processor does not execute past the bound of the original loop by introducing a minimum operation. \Box

The parallel code shown in Example 11 1 is an SPMD Single Program Multiple Data program The same code is executed by all processors but it is parameterized by an identi er unique to each processor so di erent processors can take di erent actions Typically one processor known as the master executes all the serial part of the computation. The master processor upon reaching a parallelized section of the code wakes up all the slave processors. All the processors execute the parallelized regions of the code. At the end of each parallelized region of code all the processors participate in a barrier synchronization. Any operation executed before a processor enters a synchronization barrier is guaranteed to be completed before any other processors are allowed to leave the barrier and execute operations that come after the barrier

If we parallelize only little loops like those in Example 11.1 then the resulting code is likely to have low parallelism coverage and relatively negrain parallelism. We prefer to parallelize the outermost loops in a program as that yields the coarsest granularity of parallelism. Consider for example, the application of a two dimensional FFT transformation that operates on an n-n data set. Such a program performs n FFT s on the rows of the data, then another n FFT s on the columns. It is preferable to assign each of the n independent FFT s to one processor each rather than trying to use several processors to collaborate on one FFT. The code is easier to write the parallelism coverage

11 1 BASIC CONCEPTS

for the algorithm is 100 — and the code has good data locality as it requires no communication at all while computing an FFT

Many applications do not have large outermost loops that are parallelizable. The execution time of these applications however is often dominated by time consuming *kernels* which may have hundreds of lines of code consisting of loops with different nesting levels. It is sometimes possible to take the kernel reorganize its computation and partition it into mostly independent units by focusing on its locality.

11 1 4 Data Locality

There are two somewhat di erent notions of data locality that need to be con sidered when parallelizing programs Temporal locality occurs when the same data is used several times within a short time period Spatial locality occurs when di erent data elements that are located near to each other are used within a short period of time An important form of spatial locality occurs when all the elements that appear on one cache line are used together. The reason is that as soon as one element from a cache line is needed all the elements in the same line are brought to the cache and will probably still be there if they are used soon. The elect of this spatial locality is that cache misses are minimized with a resulting important speedup of the program.

Kernels can often be written in many semantically equivalent ways but with widely varying data localities and performances Example 11 2 shows an alter native way of expressing the computation in Example 11 1

Example 11 2 Like Example 11 1 the following also $\,$ nds the squares of di erences between elements in vectors X and Y

The rst loop and the di erences the second and the squares Code like this appears often in real programs because that is how we can optimize a program for *vector machines* which are supercomputers which have instructions that perform simple arithmetic operations on vectors at a time. We see that the bodies of the two loops here are *fused* as one in Example 11 1

Given that the two programs perform the same computation which performs better. The fused loop in Example 11.1 has better performance because it has better data locality. Each difference is squared immediately as soon as it is produced in fact, we can hold the difference in a register square it and write the result just once into the memory location Zi. In contrast, the code in this example writes Zi long before it uses that value. If the size of the array is larger than the cache Zi needs to be refetched from memory the second time it is used in this example. Thus, this code can run significantly slower.

c Zeroing an array row by row in parallel

Figure 11 3 Sequential and parallel code for zeroing an array

Example 11 3 Suppose we want to set array Z stored in row major order recall Section 6 4 3 to all zeros. Fig. 11 3 a and b sweeps through the array column by column and row by row respectively. We can transpose the loops in Fig. 11 3 a to arrive at Fig. 11 3 b. In terms of spatial locality it is preferable to zero out the array row by row since all the words in a cache line are zeroed consecutively. In the column by column approach even though each cache line is reused by consecutive iterations of the outer loop cache lines will be thrown out before reuse if the size of a colum is greater than the size of the cache. For best performance, we parallelize the outer loop of Fig. 11 3 b. in a manner similar to that used in Example 11 1, see Fig. 11 3 c.

The two examples above illustrate several important characteristics associ ated with numeric applications operating on arrays

Array code often has many parallelizable loops

When loops have parallelism their iterations can be executed in arbitrary order they can be reordered to improve data locality drastically

As we create large units of parallel computation that are independent of each other executing these serially tends to produce good data locality

11 1 5 Introduction to A ne Transform Theory

Writing correct and e cient sequential programs is di cult writing parallel programs that are correct and e cient is even harder. The level of di culty

11 1 BASIC CONCEPTS

increases as the granularity of parallelism exploited decreases. As we see above programmers must pay attention to data locality to get high performance. Fur thermore, the task of taking an existing sequential program and parallelizing it is extremely hard. It is hard to catch all the dependences in the program especially if it is not a program with which we are familiar. Debugging a parallel program is harder yet because errors can be nondeterministic.

Ideally a parallelizing compiler automatically translates ordinary sequential programs into e cient parallel programs and optimizes the locality of these programs. Unfortunately compilers without high level knowledge about the application can only preserve the semantics of the original algorithm which may not be amenable to parallelization. Furthermore, programmers may have made arbitrary choices that limit the program s parallelism

Successes in parallelization and locality optimizations have been demon strated for Fortran numeric applications that operate on arrays with a ne accesses. Without pointers and pointer arithmetic Fortran is easier to ana lyze. Note that not all applications have a ne accesses most notably many numeric applications operate on sparse matrices whose elements are accessed indirectly through another array. This chapter focuses on the parallelization and optimizations of kernels consisting of mostly tens of lines.

As illustrated by Examples 11 2 and 11 3 parallelization and locality op timization require that we reason about the di erent instances of a loop and their relations with each other This situation is very di erent from data ow analysis where we combine information associated with all instances together

For the problem of optimizing loops with array accesses we use three kinds of spaces Each space can be thought of as points on a grid of one or more dimensions

- 1 The *iteration space* is the set of the dynamic execution instances in a computation that is the set of combinations of values taken on by the loop indexes
- 2 The data space is the set of array elements accessed
- 3 The *processor space* is the set of processors in the system Normally these processors are assigned integer numbers or vectors of integers to distinguish among them

Given as input are a sequential order in which the iterations are executed and a ne array access functions e.g. X i j 1 that specify which instances in the iteration space access which elements in the data space

The output of the optimization again represented as a ne functions de nes what each processor does and when To specify what each processor does we use an a ne function to assign instances in the original iteration space to processors To specify when we use an a ne function to map instances in the iteration space to a new ordering The schedule is derived by analyzing the array access functions for data dependences and reuse patterns

CHAPTER 11 OPTIMIZING FOR PARALLELISM AND LOCALITY

The following example will illustrate the three spaces — iteration—data and processor—It will also introduce informally the important concepts and issues that need to be addressed in using these spaces to parallelize code—The concepts each will be covered in detail in later sections

Example 11 4 Figure 11 4 illustrates the different spaces and their relations used in the following program

The three spaces and the mappings among them are as follows

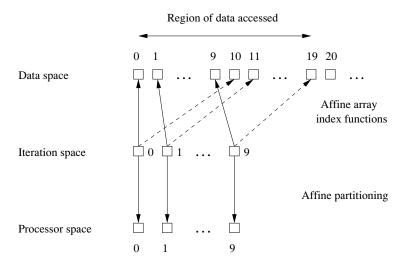

Figure 11 4 Iteration data and processor space for Example 11 4

- 1 Iteration Space The iteration space is the set of iterations whose ID s are given by the values held by the loop index variables A d deep loop nest i e d nested loops has d index variables and is thus modeled by a d dimensional space. The space of iterations is bounded by the lower and upper bounds of the loop indexes. The loop of this example de ness a one dimensional space of 10 iterations, labeled by the loop index values i 0 1 9
- 2 Data Space The data space is given directly by the array declarations. In this example elements in the array are indexed by a=0.1=99. Even though all arrays are linearized in a program's address space we treat n dimensional arrays as n dimensional spaces and assume that the individual indexes stay within their bounds. In this example, the array is one dimensional anyway.

11 1 BASIC CONCEPTS

- 4 A ne Array Index Function Each array access in the code speci es a mapping from an iteration in the iteration space to an array element in the data space. The access function is a neifit involves multiplying the loop index variables by constants and adding constants. Both the array index functions i 10 and i are a ne From the access function we can tell the dimension of the data accessed. In this case, since each index function has one loop variable, the space of accessed array elements is one dimensional.
- 5 A ne Partitioning We parallelize a loop by using an a ne function to assign iterations in an iteration space to processors in the processor space. In our example we simply assign iteration i to processor i. We can also specify a new execution order with a ne functions. If we wish to execute the loop above sequentially but in reverse, we can specify the ordering function succinctly with an anne expression 10 i. Thus, iteration 9 is the 1st iteration to execute and so on
- 6 Region of Data Accessed To nd the best a ne partitioning it useful to know the region of data accessed by an iteration. We can get the region of data accessed by combining the iteration space information with the array index function. In this case, the array access Zi=10 touches the region $\{a \mid 10 = a = 20\}$ and the access Zi touches the region $\{a \mid 0 = a = 10\}$
- 7 Data Dependence To determine if the loop is parallelizable we ask if there is a data dependence that crosses the boundary of each iteration. For this example we rst consider the dependences of the write accesses in the loop. Since the access function Zi-10 maps different iterations to different array locations there are no dependences regarding the order in which the various iterations write values to the array. Is there a dependence be tween the read and write accesses. Since only Z10-Z11-Z19 are written by the access Zi-10- and only Z0-Z1-Z19- are read by the access Zi- there can be no dependencies regarding the relative order of a read and a write. Therefore, this loop is parallelizable.

is each iteration of the loop is independent of all other iterations and we can execute the iterations in parallel or in any order we choose Notice however that if we made a small change say by increasing the upper limit on loop index i to 10 or more then there would be dependencies as some elements of array Z would be written on one iteration and then read 10 iterations later. In that case the loop could not be parallelized completely and we would have to think carefully about how iterations were partitioned among processors and how we ordered iterations

Formulating the problem in terms of multidimensional spaces and a ne mappings between these spaces lets us use standard mathematical techniques to solve the parallelization and locality optimization problem generally. For example, the region of data accessed can be found by the elimination of variables using the Fourier Motzkin elimination algorithm. Data dependence is shown to be equivalent to the problem of integer linear programming. Finally, inding the anneal negative problem of solving a set of linear constraints. Don't worry if you are not familiar with these concepts as they will be explained starting in Section 11.3

11 2 Matrix Multiply An In Depth Example

We shall introduce many of the techniques used by parallel compilers in an ex tended example. In this section we explore the familiar matrix multiplication algorithm to show that it is nontrivial to optimize even a simple and easily parallelizable program. We shall see how rewriting the code can improve data locality that is processors are able to do their work with far less communication with global memory or with other processors depending on the architecture than if the straightforward program is chosen. We shall also discuss how cognizance of the existence of cache lines that hold several consecutive data elements can improve the running time of programs such as matrix multiplication

11 2 1 The Matrix Multiplication Algorithm

In Fig 11 5 we see a typical matrix multiplication program 2 It takes two n-n matrices X and Y and produces their product in a third n-n matrix Z. Recall that Z_{ij} —the element of matrix Z in row i and column j—must become $\sum_{k=1}^{n} X_{ik} Y_{kj}$

The code of Fig. 11.5 generates n^2 results each of which is an inner product between one row and one column of the two matrix operands. Clearly the

 $^{^2}$ In programs of this chapter we shall generally use C syntax but to make multidimensional array accesses the central issue for most of the chapter easier to read we shall use Fortran style array references that is Z i j instead of Z i j

11 2 MATRIX MULTIPLY AN IN DEPTH EXAMPLE

```
for i 0 i n i
for j 0 j n j
Z i j 0 0
for k 0 k n k
Z i j Z i j X i k Y k j
```

Figure 11 5 The basic matrix multiplication algorithm

calculations of each of the elements of Z are independent and can be executed in parallel

The larger n is the more times the algorithm touches each element. That is there are $3n^2$ locations among the three matrices but the algorithm performs n^3 operations each of which multiplies an element of X by an element of Y and adds the product to an element of Z. Thus, the algorithm is computation intensive and memory accesses should not in principle constitute a bottleneck

Serial Execution of the Matrix Multiplication

Let us rst consider how this program behaves when run sequentially on a uniprocessor. The innermost loop reads and writes the same element of Z and uses a row of X and a column of Y Z i j can easily be stored in a register and requires no memory accesses. Assume without loss of generality that the matrix is laid out in row major order, and that c is the number of array elements in a cache line

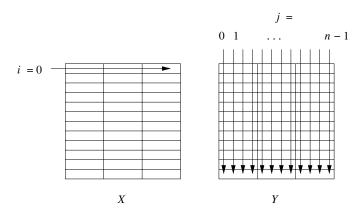

Figure 11 6 The data access pattern in matrix multiply

Figure 11 6 suggests the access pattern as we execute one iteration of the outer loop of Fig. 11.5. In particular, the picture shows the i rst iteration with i 0. Each time we move from one element of the i rst row of i to the next

CHAPTER 11 OPTIMIZING FOR PARALLELISM AND LOCALITY

we visit each element in a single column of Y. We see in Fig. 11.6 the assumed organization of the matrices into cache lines. That is each small rectangle represents a cache line holding four array elements i.e. c 4 and n 12 in the picture

Accessing X puts little burden on the cache. One row of X is spread among only n c cache lines. Assuming these all t in the cache only n c cache misses occur for a t xed value of index t and the total number of misses for all of t is t t the minimum possible we assume t is divisible by t for convenience

However while using one row of X the matrix multiplication algorithm accesses all the elements of Y column by column. That is when j=0 the inner loop brings to the cache the entire—rst column of Y. Notice that the elements of that column are stored among n di—erent cache lines. If the cache is big enough or n small enough to hold n cache lines and no other uses of the cache force some of these cache lines to be expelled—then the column for j=0 will still be in the cache when we need the second column of Y. In that case there will not be another n cache misses reading Y until j=c at which time we need to bring into the cache an entirely di—erent set of cache lines for Y. Thus to complete the—rst iteration of the outer loop—with i=0—requires between n^2 —c and n^2 cache misses—depending on whether columns of cache lines can survive from one iteration of the second loop to the next

Moreover as we complete the outer loop for i-1-2 and so on we may have many additional cache misses as we read Y or none at all. If the cache is big enough that all n^2-c cache lines holding Y can reside together in the cache then we need no more cache misses. The total number of cache misses is thus $2n^2-c$ half for X and half for Y. However, if the cache can hold one column of Y but not all of Y, then we need to bring all of Y into cache again each time we perform an iteration of the outer loop. That is, the number of cache misses is n^2-c-n^3-c the rest term is for X and the second is for Y. Worst, if we cannot even hold one column of Y in the cache, then we have n^2 cache misses per iteration of the outer loop and a total of n^2-c-n^3 cache misses

Row by Row Parallelization

Now let us consider how we could use some number of processors say p proces sors to speed up the execution of Fig. 11.5. An obvious approach to parallelizing matrix multiplication is to assign different rows of Z to different processors. A processor is responsible for n p consecutive rows, we assume n is divisible by p for convenience. With this division of labor, each processor needs to access n p rows of matrices X and Z but the entire Y matrix. One processor will compute n^2 p elements of Z performing n^3 p multiply and add operations to do so

While the computation time thus decreases in proportion to p the communication cost actually rises in proportion to p. That is each of p processors has to read n^2 p elements of X but all n^2 elements of Y. The total number of cache lines that must be delivered to the caches of the p processors is at least

11.2 MATRIX MULTIPLY AN IN DEPTH EXAMPLE

 n^2 c pn^2 c the two terms are for delivering X and copies of Y respectively. As p approaches n the computation time becomes O n^2 while the communication cost is O n^3 . That is the bus on which data is moved between memory and the processors caches becomes the bottleneck. Thus with the proposed data layout using a large number of processors to share the computation can actually slow down the computation rather than speed it up

11 2 2 Optimizations

The matrix multiplication algorithm of Fig 11 5 shows that even though an algorithm may reuse the same data it may have poor data locality. A reuse of data results in a cache hit only if the reuse happens soon enough before the data is displaced from the cache. In this case n^2 multiply add operations separate the reuse of the same data element in matrix Y so locality is poor. In fact, n operations separate the reuse of the same cache line in Y. In addition on a multiprocessor reuse may result in a cache hit only if the data is reused by the same processor. When we considered a parallel implementation in Section 11 2.1 we saw that elements of Y had to be used by every processor. Thus the reuse of Y is not turned into locality.

Changing Data Layout

One way to improve the locality of a program is to change the layout of its data structures. For example, storing Y in column major order would have improved the reuse of cache lines for matrix Y. The applicability of this approach is limited because the same matrix normally is used in different operations. If Y played the role of X in another matrix multiplication, then it would sufer from being stored in column major order since the rest matrix in a multiplication is better stored in row major order.

Blocking

It is sometimes possible to change the execution order of the instructions to improve data locality. The technique of interchanging loops however does not improve the matrix multiplication routine. Suppose the routine were written to generate a column of matrix Z at a time instead of a row at a time. That is make the j loop the outer loop and the i loop the second loop. Assuming matrices are still stored in row major order. matrix Y enjoys better spatial and temporal locality but only at the expense of matrix X

Blocking is another way of reordering iterations in a loop that can greatly improve the locality of a program Instead of computing the result a row or a column at a time we divide the matrix up into submatrices or blocks as suggested by Fig 11 7 and we order operations so an entire block is used over a short period of time Typically the blocks are squares with a side of length B If B evenly divides n then all the blocks are square. If B does not evenly

CHAPTER 11 OPTIMIZING FOR PARALLELISM AND LOCALITY

divide n then the blocks on the lower and right edges will have one or both sides of length less than B

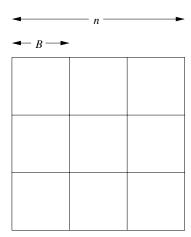

Figure 11 7 A matrix divided into blocks of side B

Figure 11 8 shows a version of the basic matrix multiplication algorithm where all three matrices have been blocked into squares of side B. As in Fig. 11.5 Z is assumed to have been initialized to all 0 s. We assume that B divides n if not then we need to modify line 4 so the upper limit is min ii B n and similarly for lines 5 and 6

```

Figure 11 8 Matrix multiplication with blocking

The outer three loops lines 1 through 3 use indexes $ii\ jj$ and kk which are always incremented by B and therefore always mark the left or upper edge of some blocks. With xed values of $ii\ jj$ and kk lines 4 through 7 enable the blocks with upper left corners $X\ ii\ kk$ and $Y\ kk\ jj$ to make all possible contributions to the block with upper left corner $Z\ ii\ jj$

If we pick B properly we can signi cantly decrease the number of cache misses compared with the basic algorithm when all of X Y or Z cannot t in the cache. Choose B such that it is possible to t one block from each of the matrices in the cache. Because of the order of the loops we actually need each

Another View of Block Based Matrix Multiplication

We can imagine that the matrices X Y and Z of Fig. 11.8 are not n matrices of oating point numbers but rather n B n B matrices whose elements are themselves B B matrices of oating point numbers. Lines 1 through 3 of Fig. 11.8 are then like the three loops of the basic algorithm in Fig. 11.5 but with n B as the size of the matrices rather than n We can then think of lines 4 through 7 of Fig. 11.8 as implementing a single multiply and add operation of Fig. 11.5 Notice that in this operation the single multiply step is a matrix multiply step and it uses the basic algorithm of Fig. 11.5 on the oating point numbers that are elements of the two matrices involved. The matrix addition is element wise addition of oating point numbers

block of Z in cache only once so as in the analysis of the basic algorithm in Section 11 2 1 we shall not count the cache misses due to Z

To bring a block of X or Y to the cache takes B^2 c cache misses recall c is the number of elements in a cache line. However with xed blocks from X and Y we perform B^3 multiply and add operations in lines. 4 through 7 of Fig. 11.8 Since the entire matrix multiplication requires n^3 multiply and add operations the number of times we need to bring a pair of blocks to the cache is n^3 B^3 . As we require $2B^2$ c cache misses each time we do the total number of cache misses is $2n^3$ Bc

It is interesting to compare this—gure $2n^3$ Bc with the estimates given in Section 11 2.1 There we said that if entire matrices can—t in the cache—then O n^2 c—cache misses su—ce—However—in that case—we can pick B—n—i e—make each matrix be a single block—We again get O n^2 —c—as our estimate of cache misses—On the other hand—we observed that if entire matrices will not—t in cache—we require O n^3 —c—cache misses—or even O n^3 —cache misses—In that case—assuming that we can still pick a signi—cantly large B—e g—B—could be 200—and we could still—t three blocks of 8 byte numbers in a one megabyte cache—there is a great advantage to using blocking in matrix multiplication

The blocking technique can be reapplied for each level of the memory hi erarchy. For example, we may wish to optimize register usage by holding the operands of a 2—2 matrix multiplication in registers. We choose successively bigger block sizes for the di-erent levels of caches and physical memory.

Similarly we can distribute blocks between processors to minimize data traf c Experiments showed that such optimizations can improve the performance of a uniprocessor by a factor of 3 and the speed up on a multiprocessor is close to linear with respect to the number of processors used

11 2 3 Cache Interference

Unfortunately there is somewhat more to the story of cache utilization Most caches are not fully associative see Section 7.4.2 In a direct mapped cache if n is a multiple of the cache size then all the elements in the same row of an n array will be competing for the same cache location. In that case bringing in the second element of a column will throw away the cache line of the rst even though the cache has the capacity to keep both of these lines at the same time. This situation is referred to as cache interference

There are various solutions to this problem. The rst is to rearrange the data once and for all so that the data accessed is laid out in consecutive data locations. The second is to embed the n- n array in a larger m- n array where m is chosen to minimize the interference problem. Third in some cases we can choose a block size that is guaranteed to avoid interference

11 2 4 Exercises for Section 11 2

Exercise 11 2 1 The block based matrix multiplication algorithm of Fig 11 8 does not have the initialization of the matrix Z to zero as the code of Fig 11 5 does Add the steps that initialize Z to all zeros in Fig 11 8

11 3 Iteration Spaces

The motivation for this study is to exploit the techniques that in simple settings like matrix multiplication as in Section 11 2 were quite straightforward. In the more general setting the same techniques apply but they are far less intuitive. But by applying some linear algebra, we can make everything work in the general setting.

As discussed in Section 11 1 5 there are three kinds of spaces in our trans formation model iteration space data space and processor space. Here we start with the iteration space. The iteration space of a loop nest is defined to be all the combinations of loop index values in the nest.

Often the iteration space is rectangular as in the matrix multiplication example of Fig 11.5. There each of the nested loops had a lower bound of 0 and an upper bound of n-1. However in more complicated but still quite realistic loop nests the upper and or lower bounds on one loop index can depend on the values of the indexes of the outer loops. We shall see an example shortly

11 3 1 Constructing Iteration Spaces from Loop Nests

To begin let us describe the sort of loop nests that can be handled by the techniques to be developed. Each loop has a single loop index which we assume is incremented by 1 at each iteration. That assumption is without loss of generality since if the incrementation is by integer c-1 we can always replace

11 3 ITERATION SPACES

uses of the index i by uses of ci a for some positive or negative constant a and then increment i by 1 in the loop. The bounds of the loop should be written as a ne expressions of outer loop indices

Example 11 5 Consider the loop

which increments i by 3 each time around the loop. The e ect is to set to 0 each of the elements Z 2 Z 5 Z 8. Z 98. We can get the same e ect with

That is we substitute 3j-2 for i. The lower limit i-2 becomes j-0 just solve 3j-2-2 for j and the upper limit i-100 becomes j-32 simplify 3j-2-100 to get j-32 67 and round down because j has to be an integer

Typically we shall use for loops in loop nests A while loop or repeat loop can be replaced by a for loop if there is an index and upper and lower bounds for the index as would be the case in something like the loop of Fig 11 9 a A for loop like for i 0 i 100 i serves exactly the same purpose

However some while or repeat loops have no obvious limit. For example Fig 11.9 b may or may not terminate but there is no way to tell what condition on i in the unseen body of the loop causes the loop to break. Figure 11.9 c is another problem case. Variable n might be a parameter of a function for example. We know the loop iterates n times but we don't know what n is at compile time, and in fact we may expect that different executions of the loop will execute different numbers of times. In cases like be and compute we must treat the upper limit on i as in nity

A d deep loop nest can be modeled by a d dimensional space. The dimensions are ordered with the kth dimension representing the kth nested loop counting from the outermost loop inward. A point x_1 x_2 x_d in this space represents values for all the loop indexes the outermost loop index has value x_1 the second loop index has value x_2 and so on. The innermost loop index has value x_d

But not all points in this space represent combinations of indexes that ac tually occur during execution of the loop nest. As an a ne function of outer loop indices each lower and upper loop bound de nes an inequality dividing the iteration space into two half spaces those that are iterations in the loop the *positive* half space and those that are not the *negative* half space. The conjunction logical AND of all the linear equalities represents the intersection of the positive half spaces which de nes a convex polyhedron which we call the *iteration space* for the loop nest. A *convex polyhedron* has the property that if

```
0
while i 100
     some statements not involving i
       i 1
              a A while loop with obvious limits
i
    0
while 1
     some statements
       i 1
    i
        b It is unclear when or if this loop terminates
i
   0
while in
     some statements not involving i or n
        i 1
         c We don't know the value of n so we don't
```

Figure 11 9 Some while loops

know when this loop terminates

two points are in the polyhedron all points on the line between them are also in the polyhedron. All the iterations in the loop are represented by the points with integer coordinates found within the polyhedron described by the loop bound inequalities. And conversely all integer points within the polyhedron represent iterations of the loop nest at some time

Figure 11 10 A 2 dimensional loop nest

Example 11 6 Consider the 2 dimensional loop nest in Fig 11 10 We can model this two deep loop nest by the 2 dimensional polyhedron shown in Fig 11 11 The two axes represent the values of the loop indexes i and j Index i can take on any integral value between 0 and 5 index j can take on any integral value such that i j 7 \square

11 3 ITERATION SPACES

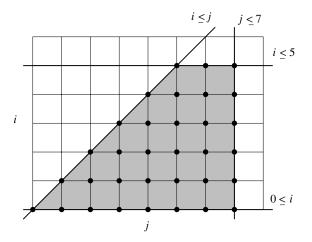

Figure 11 11 The iteration space of Example 11 6

Iteration Spaces and Array Accesses

In the code of Fig. 11.10, the iteration space is also the portion of the array A that the code accesses. That sort of access where the array indexes are also loop indexes in some order is very common. However, we should not confuse the space of iterations whose dimensions are loop indexes, with the data space. If we had used in Fig. 11.10 an array access like Z 2 i i j instead of Z j i, the difference would have been apparent

11 3 2 Execution Order for Loop Nests

A sequential execution of a loop nest sweeps through iterations in its iteration space in an ascending lexicographic order. A vector \mathbf{i} i_0 i_1 i_n is lexi $cographically less than another vector <math>\mathbf{i}'$ i'_0 i'_1 i'_n written \mathbf{i} \mathbf{i}' if and only if there exists an m min n n' such that i_0 i_1 i_m i'_0 i'_1 i'_m and i_{m-1} i'_{m-1} Note that m 0 is possible and in fact common

Example 11 7 With i as the outer loop the iterations in the loop nest in Example 11 6 are executed in the order shown in Fig. 11 12 \Box

11 3 3 Matrix Formulation of Inequalities

The iterations in a d deep loop can be represented mathematically as

$$\{\mathbf{i} \text{ in } Z^d \mid \mathbf{Bi} \quad \mathbf{b} \quad \mathbf{0}\}$$

```
0 \ 0
       0.1
              0.2
                      0.3
                                     0.5
                                             0.6
                                                    0.7
              1 2
       1 1
                      1 3
                              1 4
                                     1 5
                                             1 6
                                                    1 7
              2 2
                      2 3
                             2 4
                                     2 5
                                             2 6
                                                    2 7
                      3 3
                              3 4
                                     3 5
                                             3 6
                                                    3 7

Figure 11 12 Iteration order for loop nest of Fig 11 10

Here

- $1\ Z$ as is conventional in mathematics represents the set of integers positive negative and zero
- 2 **B** is a d d integer matrix
- 3 **b** is an integer vector of length d and
- 4 **0** is a vector of d 0 s

Example 11 8 We can write the inequalities of Example 11 6 as in Fig. 11 13 That is the range of i is described by i 0 and i 5 the range of j is described by j i and j 7 We need to put each of these inequalities in the form ui vj w 0 Then u v becomes a row of the matrix \mathbf{B} in the inequality 11 1 and w becomes the corresponding component of the vector \mathbf{b} For instance i 0 is of this form with u 1 v 0 and w 0 This inequality is represented by the first row of \mathbf{B} and top element of \mathbf{b} in Fig. 11 13

$$\left[\begin{array}{ccc} 1 & 0 \\ 1 & 0 \\ 1 & 1 \\ 0 & 1 \end{array}\right] \quad i \\ j \quad \left[\begin{array}{c} 0 \\ 5 \\ 0 \\ 7 \end{array}\right] \quad \left[\begin{array}{c} 0 \\ 0 \\ 0 \\ 0 \end{array}\right]$$

Figure 11 13 Matrix vector multiplication and a vector inequality represents the inequalities de ning an iteration space

As another example the inequality i 5 is equivalent to 1 i 0 j 5 0 and is represented by the second row of **B** and **b** in Fig 11 13 Also j i becomes 1 i 1 j 0 0 and is represented by the third row Finally j 7 becomes 0 i 1 j 7 0 and is the last row of the matrix and vector

Manipulating Inequalities

To convert inequalities as in Example 11 8 we can perform transformations much as we do for equalities e.g. adding or subtracting from both sides or multiplying both sides by a constant. The only special rule we must remember is that when we multiply both sides by a negative number we have to reverse the direction of the inequality. Thus i=5 multiplied by 1 becomes i=5 Adding 5 to both sides gives i=5 0 which is essentially the second row of Fig. 11 13

11 3 4 Incorporating Symbolic Constants

Sometimes we need to optimize a loop nest that involves certain variables that are loop invariant for all the loops in the nest. We call such variables symbolic constants but to describe the boundaries of an iteration space we need to treat them as variables and create an entry for them in the vector of loop indexes i.e. the vector \mathbf{i} in the general formulation of inequalities 11.1

Example 11 9 Consider the simple loop

This loop de nes a one dimensional iteration space with index i bounded by i 0 and i n Since n is a symbolic constant we need to include it as a variable giving us a vector of loop indexes i n In matrix vector form this iteration space is defined by

$$i \text{ in } Z \qquad \begin{array}{ccc} 1 & 1 & i & & 0 \\ 1 & 0 & & n & & 0 \end{array}$$

Notice that although the vector of array indexes has two dimensions only the rst of these representing i is part of the output—the set of points lying with the iteration space—

11 3 5 Controlling the Order of Execution

The linear inequalities extracted from the lower and upper bounds of a loop body de ne a set of iterations over a convex polyhedron. As such the represen tation assumes no execution ordering between iterations within the iteration space. The original program imposes one sequential order on the iterations which is the lexicographic order with respect to the loop index variables ordered from the outermost to the innermost. However, the iterations in the space can be executed in any order as long as their data dependences are honored. i.e. the order in which writes and reads of any array element are performed by the various assignment statements inside the loop nest do not change

The problem of how we choose an ordering that honors the data dependences and optimizes for data locality and parallelism is hard and is dealt with later starting from Section 11 7 Here we assume that a legal and desirable ordering is given and show how to generate code that enforce the ordering Let us start by showing an alternative ordering for Example 11 6

Example 11 10 There are no dependences between iterations in the program in Example 11 6 We can therefore execute the iterations in arbitrary order sequentially or concurrently. Since iteration i j accesses element Z j i in the code the original program visits the array in the order of Fig. 11 14 a. To improve spatial locality, we prefer to visit contiguous words in the array consecutively as in Fig. 11 14 b.

This access pattern is obtained if we execute the iterations in the order shown in Fig. 11 14 c. That is instead of sweeping the iteration space in Fig. 11 11 horizontally we sweep the iteration space vertically so j becomes the index of the outer loop. The code that executes the iterations in the above order is

Given a convex polyhedron and an ordering of the index variables how do we generate the loop bounds that sweep through the space in lexicographic order of the variables. In the example above, the constraint i-j shows up as a lower bound for index j in the inner loop in the original program but as an upper bound for index i again in the inner loop in the transformed program

The bounds of the outermost loop expressed as linear combinations of symbolic constants and constants de ne the range of all the possible values it can take on The bounds for inner loop variables are expressed as linear combinations of outer loop index variables symbolic constants and constants They de ne the range the variable can take on for each combination of values in outer loop variables

Projection

Geometrically speaking we can not the loop bounds of the outer loop index in a two deep loop nest by projecting the convex polyhedron representing the iteration space onto the outer dimension of the space. The projection of a polyhedron on a lower dimensional space is intuitively the shadow cast by the object onto that space. The projection of the two dimensional iteration space in Fig. 11.11 onto the i axis is the vertical line from 0 to 5, and the projection onto

c Preferred order of iterations

Figure 11 14 Reordering the accesses and iterations for a loop nest

the j axis is the horizontal line from 0 to 7. When we project a 3 dimensional object along the z axis onto a 2 dimensional x and y plane, we eliminate variable z losing the height of the individual points and simply record the 2 dimensional footprint of the object in the x y plane.

Loop bound generation is only one of the many uses of projection Projection can be de ned formally as follows. Let S be an n dimensional polyhedron. The projection of S onto the rst m of its dimensions is the set of points $x_1 \ x_2 \ x_m$ such that for some $x_{m-1} \ x_{m-2} \ x_n$ vector $x_1 \ x_2 \ x_n$ is in S. We can compute projection using Fourier Motzkin elimination as follows

Algorithm 11 11 Fourier Motzkin elimination

INPUT A polyhedron S with variables x_1 x_2 x_n That is S is a set of linear constraints involving the variables x_i One given variable x_m is specified to be the variable to be eliminated

OUTPUT A polyhedron S' with variables x_1 x_{m-1} x_{m-1} x_n i.e. all the variables of S except for x_m that is the projection of S onto dimensions other than the mth

METHOD Let C be all the constraints in S involving x_m Do the following

1 For every pair of a lower bound and an upper bound on x_m in C such as

$$\begin{array}{ccc}
L & c_1 x_m \\
c_2 x_m & U
\end{array}$$

create the new constraint

$$c_2L$$
 c_1U

Note that c_1 and c_2 are integers but L and U may be expressions with variables other than x_m

- 2 If integers c_1 and c_2 have a common factor divide both sides by that factor
- 3 If the new constraint is not satis able then there is no solution to S i e the polyhedra S and S' are both empty spaces
- 4 S' is the set of constraints S-C plus all the constraints generated in step 2

Note incidentally that if x_m has u lower bounds and v upper bounds eliminating x_m produces up to uv inequalities but no more \Box

The constraints added in step 1 of Algorithm 11 11 correspond to the implications of constraints C on the remaining variables in the system. Therefore there is a solution in S' if and only if there exists at least one corresponding

11 3 ITERATION SPACES

solution in S Given a solution in S' the range of the corresponding x_m can be found by replacing all variables but x_m in the constraints C by their actual values

Example 11 12 Consider the inequalities defining the iteration space in Fig 11 11 Suppose we wish to use Fourier Motzkin elimination to project the two dimensional space away from the i dimension and onto the j dimension. There is one lower bound on i 0 i and two upper bounds i j and i 5. This generates two constraints 0 j and 0 5. The latter is trivially true and can be ignored. The former gives the lower bound on j and the original upper bound j 7 gives the upper bound \square

Loop Bounds Generation

Now that we have de ned Fourier Motzkin elimination the algorithm to gen erate the loop bounds to iterate over a convex polyhedron. Algorithm 11 13 is straightforward. We compute the loop bounds in order from the innermost to the outer loops. All the inequalities involving the innermost loop index variables are written as the variables lower or upper bounds. We then project away the dimension representing the innermost loop and obtain a polyhedron with one fewer dimension. We repeat until the bounds for all the loop index variables are found.

Algorithm 11 13 Computing bounds for a given order of variables

INPUT A convex polyhedron S over variables v_1 v_n

OUTPUT A set of lower bounds L_i and upper bounds U_i for each v_i expressed only in terms of the v_j s for j-i

METHOD The algorithm is described in Fig. 11.15 \Box

Example 11 14 We apply Algorithm 11 13 to generate the loop bounds that sweep the the iteration space of Fig. 11 11 vertically. The variables are ordered j i. The algorithm generates these bounds

$$\begin{array}{ccc}
L_i & 0 \\
U_i & 5 j \\
L_j & 0 \\
U_j & 7
\end{array}$$

We need to satisfy all the constraints thus the bound on i is min 5 j There are no redundancies in this example \Box

Figure 11 16 Diagonalwise ordering of the iteration space of Fig. 11 11

11 3 6 Changing Axes

Note that sweeping the iteration space horizontally and vertically as discussed above are just two of the most common ways of visiting the iteration space. There are many other possibilities for example we can sweep the iteration space in Example 11 6 diagonal by diagonal as discussed below in Example 11 15

Example 11 15 We can sweep the iteration space shown in Fig 11 11 diag onally using the order shown in Fig 11 16 The di erence between the coordinates j and i in each diagonal is a constant starting with 0 and ending with 7 Thus we de ne a new variable k j i and sweep through the iteration space in lexicographic order with respect to k and j Substituting i j k in the inequalities we get

11 3 ITERATION SPACES

To create the loop bounds for the order described above we can apply Algo rithm 11 13 to the above set of inequalities with variable ordering $k \ j$

$$\begin{array}{cccc}
L_j & k \\
U_j & 5 & k & 7 \\
L_k & 0 \\
U_k & 7
\end{array}$$

From these inequalities we generate the following code replacing i by j-k in array accesses

In general we can change the axes of a polyhedron by creating new loop index variables that represent a ne combinations of the original variables and de ning an ordering on those variables. The hard problem lies in choosing the right axes to satisfy the data dependences while achieving the parallelism and locality objectives. We discuss this problem starting with Section 11.7 What we have established here is that once the axes are chosen it is straightforward to generate the desired code as shown in Example 11.15

There are many other iteration traversal orders not handled by this tech nique For example we may wish to visit all the odd rows in an iteration space before we visit the even rows Or we may want to start with the iterations in the middle of the iteration space and progress to the fringes For applications that have a ne access functions however the techniques described here cover most of the desirable iteration orderings

11 3 7 Exercises for Section 11 3

Exercise 11 3 1 Convert each of the following loops to a form where the loop indexes are each incremented by 1

```
a for i 10 i 50 i i 7 X i i 1 0
b for i 3 i 10 i i 2 X i X i 1
c for i 50 i 10 i X i 0
```

Exercise 11 3 2 Draw or describe the iteration spaces for each of the following loop nests

- a The loop nest of Fig 11 17 a
- b The loop nest of Fig 11 17 b

```
1 i
for i
             30 i
                  40 i j
   for j i 2 j
      Хij
           a Loop nest for Exercise 11 3 2 a
for i
       10 i
             1000 i
   for j i j i 10 j
      Хіj
           b Loop nest for Exercise 11 3 2 b
for i 0 i
             100 i
   for j 0 j 100 i j
      for k ij k 100 ij k
          Xijk 0
           c Loop nest for Exercise 11 3 2 c
```

Figure 11 17 Loop nests for Exercise 11 3 2

c The loop nest of Fig 11 17 c

Exercise 11 3 3 Write the constraints implied by each of the loop nests of Fig 11 17 in the form of 11 1 That is give the values of the vectors \mathbf{i} and \mathbf{b} and the matrix \mathbf{B}

Exercise 11 3 4 Reverse each of the loop nesting orders for the nests of Fig 11 17

Exercise 11 3 5 Use the Fourier Motzkin elimination algorithm to eliminate i from each of the sets of constraints obtained in Exercise 11 3 3

Exercise 11 3 6 Use the Fourier Motzkin elimination algorithm to eliminate j from each of the sets of constraints obtained in Exercise 11 3 3

Exercise 11 3 7 For each of the loop nests in Fig 11 17 rewrite the code so the axis i is replaced by the major diagonal i.e. the direction of the axis is characterized by i j The new axis should correspond to the outermost loop

Exercise 11 3 8 Repeat Exercise 11 3 7 for the following changes of axes

- a Replace i by i j i.e. the direction of the axis is the lines for which i j is a constant. The new axis corresponds to the outermost loop
- b Replace j by i 2j The new axis corresponds to the outermost loop

11 4 AFFINE ARRAY INDEXES

Exercise 11 3 9 Let A B and C be integer constants in the following loop with C 1 and B A

Rewrite the loop so the incrementation of the loop variable is 1 and the initial ization is to 0 that is to be of the form

for integers D E and F Express D E and F in terms of A B and C

Exercise 11 3 10 For a generic two loop nest

with A through E integer constants write the constraints that de ne the loop nest s iteration space in matrix vector form i.e. in the form \mathbf{Bi} b $\mathbf{0}$

Exercise 11 3 11 Repeat Exercise 11 3 10 for a generic two loop nest with symbolic integer constants m and n as in

As before A B and C stand for special cointeger constants. Only i j m and n should be mentioned in the vector of unknowns. Also remember that only i and j are output variables for the expression

11 4 A ne Array Indexes

The focus of this chapter is on the class of a ne array accesses where each array index is expressed as a ne expressions of loop indexes and symbolic constants A ne functions provide a succinct mapping from the iteration space to the data space making it easy to determine which iterations map to the same data or same cache line

Just as the a ne upper and lower bounds of a loop can be represented as a matrix vector calculation we can do the same for a ne access functions. Once placed in the matrix vector form, we can apply standard linear algebra to nd pertinent information such as the dimensions of the data accessed, and which iterations refer to the same data.

1141 A ne Accesses

We say that an array access in a loop is a ne if

- 1 The bounds of the loop are expressed as a ne expressions of the sur rounding loop variables and symbolic constants and
- 2 The index for each dimension of the array is also an anne expression of surrounding loop variables and symbolic constants

Example 11 16 Suppose i and j are loop index variables bounded by a ne expressions Some examples of a ne array accesses are Z i Z i j 1 Z 0 Z i i and Z 2 i 1 3 j 10 If n is a symbolic constant for a loop nest then Z 3 n n j is another example of an a ne array access. However Z i j and Z n j are not a ne accesses. \square

Each a ne array access can be described by two matrices and two vectors. The rst matrix vector pair is the ${\bf B}$ and ${\bf b}$ that describe the iteration space for the access as in the inequality of Equation 11.1. The second pair which we usually refer to as ${\bf F}$ and ${\bf f}$ represent the function s of the loop index variables that produce the array index esc used in the various dimensions of the array access

Formally we represent an array access in a loop nest that uses a vector of index variables \mathbf{i} by the four tuple \mathcal{F} $\langle \mathbf{F} \ \mathbf{f} \ \mathbf{B} \ \mathbf{b} \rangle$ it maps a vector \mathbf{i} within the bounds

Bi b 0

to the array element location

Fi f

Example 11 17 In Fig 11 18 are some common array accesses expressed in matrix notation. The two loop indexes are i and j and these form the vector i Also X Y and Z are arrays with 1 2 and 3 dimensions respectively

The rst access X i 1 is represented by a 1 2 matrix \mathbf{F} and a vector \mathbf{f} of length 1 Notice that when we perform the matrix vector multiplication and add in the vector \mathbf{f} we are left with a single function i 1 which is exactly the formula for the access to the one dimensional array X Also notice the third access Y j j 1 which after matrix vector multiplication and addition yields a pair of functions j j 1 These are the indexes of the two dimensions of the array access

Finally let us observe the fourth access Y 1 2 This access is a constant and unsurprisingly the matrix \mathbf{F} is all 0 s. Thus the vector of loop indexes \mathbf{i} does not appear in the access function \square

Figure 11 18 Some array accesses and their matrix vector representations

11 4 2 A ne and Nona ne Accesses in Practice

There are certain common data access patterns found in numerical programs that fail to be a ne Programs involving sparse matrices are one important example. One popular representation for sparse matrices is to store only the nonzero elements in a vector and auxiliary index arrays are used to mark where a row starts and which columns contain nonzeros. Indirect array accesses are used in accessing such data. An access of this type—such as $X \ Y \ i$ —is a nona—ne access to the array X—If the sparsity is regular—as in banded matrices having nonzeros only around the diagonal—then dense arrays can be used to represent the subregions with nonzero elements. In that case accesses may be a—ne

Another common example of nona ne accesses is linearized arrays Programmers sometimes use a linear array to store a logically multidimensional object. One reason why this is the case is that the dimensions of the array may not be known at compile time. An access that would normally look like $Z \ i \ j$ would be expressed as $Z \ i \ n \ j$ which is a quadratic function. We can convert the linear access into a multidimensional access if every access can

be decomposed into separate dimensions with the guarantee that none of the components exceeds its bound. Finally, we note that induction variable analy sees can be used to convert some nonan ne accesses into a ne ones as shown in Example 11.18

Example 11 18 We can rewrite the code

as

to make the access to matrix Z a ne \Box

b Y \ i j j k k i
c Z \ 3 \ 2 j k 2 i 1
```

11 5 Data Reuse

From array access functions we derive two kinds of information useful for locality optimization and parallelization

- 1 Data reuse for locality optimization we wish to identify sets of iterations that access the same data or the same cache line
- 2 Data dependence for correctness of parallelization and locality loop trans formations we wish to identify all the data dependences in the code Re call that two not necessarily distinct accesses have a data dependence if instances of the accesses may refer to the same memory location and at least one of them is a write

11 5 DATA REUSE

In many cases whenever we identify iterations that reuse the same data there are data dependences between them

Whenever there is a data dependence obviously the same data is reused For example in matrix multiplication the same element in the output array is written O n times. The write operations must be executed in the original execution order 3 we can exploit the reuse by allocating a register to hold one element of the output array while it is being computed

However not all reuse can be exploited in locality optimizations here is an example illustrating this issue

Example 11 19 Consider the following loop

We observe that the loop writes to a different location at each iteration so there are no reuses or dependences on the different write operations. The loop how ever reads locations 5 8 11 14 17 and writes locations 3 10 17 24. The read and write iterations access the same elements 17 38 and 59 and so on. That is the integers of the form 17 21j for j 0 1 2 are all those integers that can be written both as $7i_1$ 3 and as $3i_2$ 5 for some integers i_1 and i_2 . However, this reuse occurs rarely and cannot be exploited easily if at all. \Box

Data dependence is di-erent from reuse analysis in that one of the accesses sharing a data dependence must be a write access. More importantly data dependence needs to be both correct and precise. It needs to indial dependences for correctness and it should not indispurious dependences because they can cause unnecessary serialization.

With data reuse we only need to $\,$ nd where most of the exploitable reuses are $\,$ This problem is much simpler so we take up this topic here in this section and tackle data dependences in the next. We simplify reuse analysis by ignoring loop bounds because they seldom change the shape of the reuse. Much of the reuse exploitable by a ne partitioning resides among instances of the same array accesses and accesses that share the same $\,$ coe $\,$ cient $\,$ matrix $\,$ what we have typically called $\,$ F in the $\,$ a ne index function. As shown above access patterns like $\,$ 7i $\,$ 3 and $\,$ 3i $\,$ 5 have no reuse of interest

11 5 1 Types of Reuse

We rst start with Example 11 20 to illustrate the dierent kinds of data reuses. In the following we need to distinguish between the access as an instruction in

³There is a subtle point here Because of the commutativity of addition we would get the same answer to the sum regardless of the order in which we performed the sum However this case is very special In general it is far too complex for the compiler to determine what computation is being performed by a sequence of arithmetic steps followed by writes and we cannot rely on there being any algebraic rules that will help us reorder the steps safely

a program e g x Z i j from the execution of this instruction many times as we execute the loop nest For emphasis we may refer to the statement itself as a $static\ access$ while the various iterations of the statement as we execute its loop nest are called $dynamic\ accesses$

Reuses can be classi ed as self versus group If iterations reusing the same data come from the same static access we refer to the reuse as self reuse if they come from di erent accesses we refer to it as group reuse. The reuse is temporal if the same exact location is referenced it is spatial if the same cache line is referenced.

Example 11 20 Consider the following loop nest

Accesses Z j Z j l and Z j l each have self spatial reuse because consecutive iterations of the same access refer to contiguous array elements. Presumably contiguous elements are very likely to reside on the same cache line. In addition, they all have self temporal reuse since the exact elements are used over and over again in each iteration in the outer loop. In addition, they all have the same coes cient matrix, and thus have group reuse. There is group reuse both temporal and spatial between the different accesses. Although there are $4n^2$ accesses in this code if the reuse can be exploited, we only need to bring in about n c cache lines into the cache, where c is the number of words in a cache line. We drop a factor of n due to self spatial reuse, a factor of c to due to spatial locality, and nally a factor of 4 due to group reuse.

In the following we show how we can use linear algebra to extract the reuse information from a ne array accesses. We are interested in not just inding how much potential savings there are but also which iterations are reusing the data so that we can try to move them close together to exploit the reuse

11 5 2 Self Reuse

There can be substantial savings in memory accesses by exploiting self reuse. If the data referenced by a static access has k dimensions and the access is nested in a loop d deep for some d-k then the same data can be reused n^{d-k} times where n is the number of iterations in each loop. For example, if a 3 deep loop nest accesses one column of an array then there is a potential savings factor of n^2 accesses. It turns out that the dimensionality of an access corresponds to the concept of the rank of the coe-cient matrix in the access and we can not which iterations refer to the same location by unding the null space of the matrix as explained below

11 5 DATA REUSE

Rank of a Matrix

The rank of a matrix \mathbf{F} is the largest number of columns or equivalently rows of \mathbf{F} that are linearly independent. A set of vectors is *linearly independent* if none of the vectors can be written as a linear combination of nitely many other vectors in the set

Example 11 21 Consider the matrix

$$\left[\begin{array}{ccc} 1 & 2 & 3 \\ 5 & 7 & 9 \\ 4 & 5 & 6 \\ 2 & 1 & 0 \end{array}\right]$$

Notice that the second row is the sum of the rst and third rows while the fourth row is the third row minus twice the rst row. However the rst and third rows are linearly independent neither is a multiple of the other. Thus the rank of the matrix is 2

We could also draw this conclusion by examining the columns The third column is twice the second column minus the rst column On the other hand any two columns are linearly independent. Again, we conclude that the rank is 2

Example 11 22 Let us look at the array accesses in Fig 11 18 The rst access Xi 1 has dimension 1 because the rank of the matrix 1 0 is 1 That is the one row is linearly independent as is the rst column

The second access Y i j has dimension 2. The reason is that the matrix

$$\begin{array}{cc} 1 & 0 \\ 0 & 1 \end{array}$$

has two independent rows and therefore two independent columns of course The third access Y j j = 1 is of dimension 1 because the matrix

$$\begin{bmatrix} 0 & 1 \\ 0 & 1 \end{bmatrix}$$

has rank 1 Note that the two rows are identical so only one is linearly in dependent. Equivalently the rst column is 0 times the second column so the columns are not independent. Intuitively in a large square array Y the only elements accessed lie along a one dimensional line just above the main diagonal

The fourth access Y 1 2 has dimension 0 because a matrix of all 0 s has rank 0 Note that for such a matrix we cannot $\$ nd a linear sum of even one row that is nonzero $\$ Finally the last access $\ Z$ i i j has dimension 2 Note that in the matrix for this access

$$\left[\begin{array}{cc}0&0\\1&0\\2&1\end{array}\right]$$

the last two rows are linearly independent neither is a multiple of the other However the rst row is a linear sum of the other two rows with both coe cients 0 \Box

Null Space of a Matrix

A reference in a d deep loop nest with rank r accesses O n^r data elements in O n^d iterations so on average O n^d r iterations must refer to the same array element. Which iterations access the same data. Suppose an access in this loop nest is represented by matrix vector combination \mathbf{F} and \mathbf{f} Let \mathbf{i} and \mathbf{i}' be two iterations that refer to the same array element. Then \mathbf{Fi} \mathbf{f} \mathbf{Fi}' \mathbf{f} Rearranging terms we get

$$\mathbf{F} \mathbf{i} \mathbf{i}' \mathbf{0}$$

There is a well known concept from linear algebra that characterizes when i and i' satisfy the above equation. The set of all solutions to the equation $\mathbf{F}\mathbf{v} = \mathbf{0}$ is called the *null space* of \mathbf{F} . Thus, two iterations refer to the same array element if the difference of their loop index vectors belongs to the null space of matrix \mathbf{F} .

It is easy to see that the null vector \mathbf{v} $\mathbf{0}$ always satis es $\mathbf{F}\mathbf{v}$ $\mathbf{0}$ That is two iterations surely refer to the same array element if their difference is $\mathbf{0}$ in other words if they are really the same iteration. Also the null space is truly a vector space. That is if $\mathbf{F}\mathbf{v}_1$ $\mathbf{0}$ and $\mathbf{F}\mathbf{v}_2$ $\mathbf{0}$ then \mathbf{F} \mathbf{v}_1 \mathbf{v}_2 $\mathbf{0}$ and \mathbf{F} $\mathbf{c}\mathbf{v}_1$ $\mathbf{0}$

If the matrix \mathbf{F} is fully ranked that is its rank is d then the null space of \mathbf{F} consists of only the null vector. In that case iterations in a loop nest all refer to different data. In general, the dimension of the null space also known as the nullity is d-r. If d-r then for each element, there is a d-r dimensional space of iterations that access that element

The null space can be represented by its basis vectors A k dimensional null space is represented by k independent vectors any vector that can be expressed as a linear combination of the basis vectors belongs to the null space

Example 11 23 Let us reconsider the matrix of Example 11 21

$$\left[\begin{array}{ccc}
1 & 2 & 3 \\
5 & 7 & 9 \\
4 & 5 & 6 \\
2 & 1 & 0
\end{array}\right]$$

We determined in that example that the rank of the matrix is 2 thus the nullity is 3 2 1 To nd a basis for the null space which in this case must be a single nonzero vector of length 3 we may suppose a vector in the null space to

be x y z and try to solve the equation

$$\begin{bmatrix}
 1 & 2 & 3 \\
 5 & 7 & 9 \\
 4 & 5 & 6 \\
 2 & 1 & 0
 \end{bmatrix}
 \begin{bmatrix}
 x \\
 y \\
 z
 \end{bmatrix}
 \begin{bmatrix}
 0 \\
 0 \\
 0
 \end{bmatrix}$$

If we multiply the rst two rows by the vector of unknowns we get the two equations

$$\begin{array}{cccc}
x & 2y & 3z & 0 \\
5x & 7y & 9z & 0
\end{array}$$

We could write the equations that come from the third and fourth rows as well but because there are no three linearly independent rows we know that the additional equations add no new constraints on x y and z. For instance the equation we get from the third row 4x 5y 6z 0 can be obtained by subtracting the rst equation from the second

We must eliminate as many variables as we can from the above equations Start by using the first equation to solve for x that is x=2y=3z. Then substitute for x in the second equation to get 3y=6z or y=2z. Since x=2y=3z and y=2z it follows that x=z. Thus the vector x=y=z is really z=2z=z. We may pick any nonzero value of z to form the one and only basis vector for the null space. For example, we may choose z=1 and use z=1 as the basis of the null space.

Example 11 24 The rank nullity and null space for each of the references in Example 11 17 are shown in Fig. 11 19. Observe that the sum of the rank and nullity in all the cases is the depth of the loop nest. 2. Since the accesses Y i j and Z 1 i 2 i j have a rank of 2 all iterations refer to different locations

Accesses X i 1 and Y j j 1 both have rank 1 matrices so O n iterations refer to the same location. In the former case entire rows in the iteration space refer to the same location. In other words, iterations that dier only in the j dimension share the same location, which is succinctly represented by the basis of the null space 0.1. For Y j j 1 entire columns in the iteration space refer to the same location, and this fact is succinctly represented by the basis of the null space 1.0

Finally the access Y 1 2 refers to the same location in all the iterations. The null space corresponding has 2 basis vectors 0 1 1 0 meaning that all pairs of iterations in the loop nest refer to exactly the same location \Box

11 5 3 Self Spatial Reuse

The analysis of spatial reuse depends on the data layout of the matrix C matrices are laid out in row major order and Fortran matrices are laid out in column major order. In other words array elements $X \ i \ j$ and $X \ i \ j$ 1 are

CHAPTER 11 OPTIMIZING FOR PARALLELISM AND LOCALITY

ACCESS	Affine Expression		RANK	NULL ITY	BASIS OF NULL SPACE
X i 1	$egin{bmatrix} 1 & 0 & i \ j & \end{matrix}$	1	1	1	0 1
Yij	$ \begin{array}{cccccccccccccccccccccccccccccccccccc$	0	2	0	
Үјј1	$egin{pmatrix} 0 & 1 & i \ 0 & 1 & j \end{pmatrix}$	0 1	1	1	1 0

Z 1 i 2 i j	$\left[\begin{array}{cc}0&0\\1&0\\2&1\end{array}\right] \stackrel{i}{j}$	$\left[\begin{array}{c}1\\0\\0\end{array}\right]$	2	0	

Figure 11 19 Rank and nullity of a ne accesses

contiguous in C and X i j and X i 1 j are contiguous in Fortran Without loss of generality in the rest of the chapter we shall adopt the C row major array layout

As a rst approximation we consider two array elements to share the same cache line if and only if they share the same row in a two dimensional array More generally in an array of d dimensions we take array elements to share a cache line if they di er only in the last dimension. Since for a typical array and cache many array elements can t in one cache line there is significant speedup to be had by accessing an entire row in order even though strictly speaking we occasionally have to wait to load a new cache line

The trick to discovering and taking advantage of self spatial reuse is to drop the last row from the coe-cient matrix ${\bf F}$ If the resulting truncated matrix has rank that is less than the depth of the loop nest then we can assure spatial locality by making sure that the innermost loop varies only the last coordinate of the array

Example 11 25 Consider the last access Z 1 i 2 i j in Fig 11 19 If we

11 5 DATA REUSE

delete the last row we are left with the truncated matrix

 $\begin{array}{cc} 0 & 0 \\ 1 & 0 \end{array}$

The rank of this matrix is evidently 1 and since the loop nest has depth 2 there is the opportunity for spatial reuse. In this case since j is the inner loop index the inner loop visits contiguous elements of the array Z stored in row major order. Making i the inner loop index will not yield spatial locality since as i changes both the second and third dimensions change. \Box

The general rule for determining whether there is self spatial reuse is as follows. As always we assume that the loop indexes correspond to columns of the coe-cient matrix in order with the outermost loop rst and the innermost loop last. Then in order for there to be spatial reuse the vector $0 \ 0 \ 1$ must be in the null space of the truncated matrix. The reason is that if this vector is in the null space then when we is all loop indexes but the innermost one we know that all dynamic accesses during one run through the inner loop vary in only the last array index. If the array is stored in row major order then these elements are all near one another perhaps in the same cache line

Example 11 26 Note that 0.1 transposed as a column vector is in the null space of the truncated matrix of Example 11 25. Thus as mentioned there we expect that with j as the inner loop index, there will be spatial locality. On the other hand, if we reverse the order of the loops so i is the inner loop, then the coefficient matrix becomes

 $\begin{array}{cc} 0 & 0 \\ 0 & 1 \end{array}$

Now 0.1 is not in the null space of this matrix. Rather the null space is generated by the basis vector 1.0. Thus as we suggested in Example 11.25 we do not expect spatial locality if i is the inner loop

We should observe however that the test for 0.0 0 1 being in the null space is not quite su-cient to assure spatial locality. For instance, suppose the access were not Z 1 i 2 i j but Z 1 i 2 i 50 j. Then only every ftieth element of Z would be accessed during one run of the inner loop, and we would not reuse a cache line unless it were long enough to hold more than 50 elements.

1154 Group Reuse

We compute group reuse only among accesses in a loop sharing the same coef cient matrix. Given two dynamic accesses \mathbf{Fi}_1 \mathbf{f}_1 and \mathbf{Fi}_2 \mathbf{f}_2 reuse of the same data requires that

 $\mathbf{Fi}_1 \quad \mathbf{f}_1 \quad \mathbf{Fi}_2 \quad \mathbf{f}_2$

or

$$\mathbf{F} \ \mathbf{i}_1 \quad \mathbf{i}_2 \qquad \mathbf{f}_2 \quad \mathbf{f}_1$$

Suppose \mathbf{v} is one solution to this equation. Then if \mathbf{w} is any vector in the null space of \mathbf{F} \mathbf{w} \mathbf{v} is also a solution and in fact those are all the solutions to the equation

Example 11 27 The following 2 deep loop nest

has two array accesses Z i j and Z i 1 j Observe that these two accesses are both characterized by the coe-cient matrix

$$\begin{array}{cc} 1 & 0 \\ 0 & 1 \end{array}$$

like the second access Yij in Fig. 11.19. This matrix has rank 2 so there is no self temporal reuse

However each access exhibits self spatial reuse. As described in Section 11.5.3 when we delete the bottom row of the matrix, we are left with only the top row. 1.0 which has rank 1. Since 0.1 is in the null space of this truncated matrix, we expect spatial reuse. As each incrementation of inner loop index j increases the second array index by one, we in fact do access adjacent array elements, and will make maximum use of each cache line.

Although there is no self temporal reuse for either access observe that the two references $Z \ i \ j$ and $Z \ i \ 1 \ j$ access almost the same set of array elements. That is there is group temporal reuse because the data read by access $Z \ i \ 1 \ j$ is the same as the data written by access $Z \ i \ j$ except for the case $i \ 1$. This simple pattern applies to the entire iteration space and can be exploited to improve data locality in the code. Formally, discounting the loop bounds, the two accesses $Z \ i \ j$ and $Z \ i \ 1 \ j$ refer to the same location in iterations $i_1 \ j_1$ and $i_2 \ j_2$ respectively provided

Rewriting the terms we get

That is j_1 j_2 and i_2 i_1 1

Notice that the reuse occurs along the i axis of the iteration space. That is the iteration i_2 j_2 occurs n iterations of the inner loop after the iteration

11 5 DATA REUSE

 i_1 j_1 Thus many iterations are executed before the data written is reused. This data may or may not still be in the cache. If the cache manages to hold two consecutive rows of matrix Z then access Z i 1 j does not miss in the cache, and the total number of cache misses for the entire loop nest is n^2 c where c is the number of elements per cache line. Otherwise, there will be twice as many misses since both static accesses require a new cache line for each c dynamic accesses. \Box

Example 11 28 Suppose there are two accesses

$$A i j i \quad j \text{ and } A i \quad 1 \quad j \quad 1 \quad i \quad j$$

in a 3 deep loop nest with indexes i j and k from the outer to the inner loop. Then two accesses \mathbf{i}_1 i_1 j_1 k_1 and \mathbf{i}_2 i_2 j_2 k_2 reuse the same element whenever

$$\left[\begin{array}{ccc} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 1 & 1 & 0 \end{array} \right] \left[\begin{array}{c} i_1 \\ j_1 \\ k_1 \end{array} \right] \quad \left[\begin{array}{ccc} 0 \\ 0 \\ 0 \end{array} \right] \quad \left[\begin{array}{ccc} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 1 & 1 & 0 \end{array} \right] \left[\begin{array}{c} i_2 \\ j_2 \\ k_2 \end{array} \right] \quad \left[\begin{array}{c} 1 \\ 1 \\ 0 \end{array} \right]$$

One solution to this equation for a vector \mathbf{v} i_1 i_2 j_1 j_2 k_1 k_2 is \mathbf{v} 1 1 0 that is i_1 i_2 1 j_1 j_2 1 and k_1 k_2 4 However the null space of the matrix

$$\mathbf{F} = \left[\begin{array}{ccc} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 1 & 1 & 0 \end{array} \right]$$

is generated by the basis vector 0 0 1 that is the third loop index k can be arbitrary Thus \mathbf{v} the solution to the above equation is any vector 1 1 m for some m Put another way a dynamic access to $A\ i\ j\ i$ j in a loop nest with indexes $i\ j$ and k is reused not only by other dynamic accesses $A\ i\ j\ i$ j with the same values of i and j and a di erent value of k but also by dynamic accesses $A\ i\ 1\ j$ 1 i j with loop index values i 1 j 1 and any value of k

Although we shall not do so here we can reason about group spatial reuse analogously As per the discussion of self spatial reuse we simply drop the last dimension from consideration

The extent of reuse is di erent for the di erent categories of reuse. Self temporal reuse gives the most bene to a reference with a k dimensional null space reuses the same data O n^k times. The extent of self-spatial reuse is limited by the length of the cache line. Finally, the extent of group reuse is limited by the number of references in a group sharing the reuse.

 $^{^4}$ It is interesting to observe that although there is a solution in this case there would be no solution if we changed one of the third components from i-j to i-j-1. That is in the example as given both accesses touch those array elements that lie in the 2 dimensional subspace S de ned by the third component is the sum of the rst two components. If we changed i-j to i-j-1 none of the elements touched by the second access would lie in S and there would be no reuse at all

11 5 5 Exercises for Section 11 5

Exercise 11 5 1 Compute the ranks of each of the matrices in Fig 11 20 Give both a maximal set of linearly independent columns and a maximal set of linearly independent rows

$$\begin{bmatrix} 0 & 1 & 5 \\ 1 & 2 & 6 \\ 2 & 3 & 7 \\ 3 & 4 & 8 \end{bmatrix} \quad \begin{bmatrix} 1 & 2 & 3 & 4 \\ 5 & 6 & 7 & 8 \\ 9 & 10 & 12 & 15 \\ 3 & 2 & 2 & 3 \end{bmatrix} \quad \begin{bmatrix} 0 & 0 & 1 \\ 0 & 1 & 1 \\ 1 & 1 & 1 \\ 5 & 6 & 3 \end{bmatrix}$$
a
b
c

Figure 11 20 Compute the ranks and null spaces of these matrices

Exercise 11 5 2 Find a basis for the null space of each matrix in Fig 11 20

Exercise 11 5 3 Assume that the iteration space has dimensions variables $i \ j$ and k For each of the accesses below describe the subspaces that refer to the following single elements of the array

Exercise 11 5 4 Suppose array A is stored in row major order and accessed inside the following loop nest

Indicate for each of the following accesses whether it is possible to rewrite the loops so that the access to A exhibits self spatial reuse that is entire cache lines are used consecutively. Show how to rewrite the loops if so. Note the rewriting of the loops may involve both reordering and introduction of new loop indexes. However, you may not change the layout of the array e.g. by changing it to column major order. Also note in general reordering of loop indexes may be legal or illegal depending on criteria we develop in the next section. However, in this case where the elect of each access is simply to set an array element to 0 you do not have to worry about the elect of reordering loops as far as the semantics of the program is concerned.

11 6 ARRAY DATA DEPENDENCE ANALYSIS

```
    a A i 1 i k j 0
    b A j k i i 0
    c A i j k i j k 0
    d A i j k i j i k 0
```

Exercise 11 5 5 In Section 11 5 3 we commented that we get spatial locality if the innermost loop varies only as the last coordinate of an array access However that assertion depended on our assumption that the array was stored in row major order What condition would assure spatial locality if the array were stored in column major order

Exercise 11 5 6 In Example 11 28 we observed that the existence of reuse between two similar accesses depended heavily on the particular expressions for the coordinates of the array Generalize our observation there to determine for which functions f i j there is reuse between the accesses A i j i and A i 1 j 1 f i j

Exercise 11 5 7 In Example 11 27 we suggested that there will be more cache misses than necessary if rows of the matrix Z are so long that they do not t in the cache. If that is the case how could you rewrite the loop nest in order to guarantee group spatial reuse

11 6 Array Data Dependence Analysis

Parallelization or locality optimizations frequently reorder the operations ex ecuted in the original program. As with all optimizations operations can be reordered only if the reordering does not change the program soutput. Since we cannot in general understand deeply what a program does code optimization generally adopts a simpler conservative test for when we can be sure that the program output is not a ected we check that the operations on any memory location are done in the same order in the original and modi ed programs. In the present study we focus on array accesses so the array elements are the memory locations of concern

Two accesses whether read or write are clearly independent can be re ordered if they refer to two di erent locations. In addition read operations do not change the memory state and therefore are also independent. Following Section 11.5 we say that two accesses are data dependent if they refer to the same memory location and at least one of them is a write operation. To be sure that the modi ed program does the same as the original the relative execution ordering between every pair of data dependent operations in the original program must be preserved in the new program.

Recall from Section 10 2 1 that there are three avors of data dependence

1 True dependence where a write is followed by a read of the same location

- 2 Antidependence where a read is followed by a write to the same location
- 3 Output dependence which is two writes to the same location

In the discussion above data dependence is de ned for dynamic accesses. We say that a static access in a program depends on another as long as there exists a dynamic instance of the $\,$ rst access that depends on some instance of the second 5

It is easy to see how data dependence can be used in parallelization. For example, if no data dependences are found in the accesses of a loop, we can easily assign each iteration to a different processor. Section 11.7 discusses how we use this information systematically in parallelization.

11 6 1 De nition of Data Dependence of Array Accesses

Let us consider two static accesses to the same array in possibly different loops. The first is represented by access function and bounds \mathcal{F} $\langle \mathbf{F} \ \mathbf{f} \ \mathbf{B} \ \mathbf{b} \rangle$ and is in a d deep loop nest the second is represented by \mathcal{F}' $\langle \mathbf{F}' \ \mathbf{f}' \ \mathbf{B}' \ \mathbf{b}' \rangle$ and is in a d' deep loop nest. These accesses are data dependent if

- 1 At least one of them is a write reference and
- 2 There exist vectors **i** in Z^d and **i**' in $Z^{d'}$ such that

Since a static access normally embodies many dynamic accesses it is also meaningful to ask if its dynamic accesses may refer to the same memory loca tion. To search for dependencies between instances of the same static access, we assume \mathcal{F} — \mathcal{F}' and augment the definition above with the additional constraint that \mathbf{i} / \mathbf{i}' to rule out the trivial solution

Example 11 29 Consider the following 1 deep loop nest

This loop has two accesses Zi-1 and Zi the rst is a read reference and the second a write. To ind all the data dependences in this program, we need to check if the write reference shares a dependence with itself and with the read reference.

 $^{^5}$ Recall the di erence between static and dynamic accesses. A static access is an array reference at a particular location in a program while a dynamic access is one execution of that reference

11 6 ARRAY DATA DEPENDENCE ANALYSIS

1 Data dependence between Z i 1 and Z i Except for the rst iteration each iteration reads the value written in the previous iteration Mathe matically we know that there is a dependence because there exist integers i and i' such that

```
1 i 10 1 i' 10 and i 1 i'
```

There are nine solutions to the above system of constraints i 2 i' 1 i 3 i' 2 and so forth

2 Data dependence between Z i and itself It is easy to see that di erent iterations in the loop write to di erent locations that is there are no data dependencies among the instances of the write reference Z i Math ematically we know that there does not exist a dependence because there do not exist integers i and i' satisfying

1
$$i$$
 10 1 i' 10 i i' and i / i'

Notice that the third condition i i' comes from the requirement that Z i and Z i' are the same memory location. The contradictory fourth condition i / i' comes from the requirement that the dependence be nontrivial between di erent dynamic accesses

It is not necessary to consider data dependences between the read reference $Z\,i-1$ and itself because any two read accesses are independent $\ \square$

11 6 2 Integer Linear Programming

Data dependence requires $\,$ nding whether there exist integers that satisfy a system consisting of equalities and inequalities. The equalities are derived from the matrices and vectors representing the accesses the inequalities are derived from the loop bounds. Equalities can be expressed as inequalities an equality x-y can be replaced by two inequalities x-y and y-x

Thus data dependence may be phrased as a search for integer solutions that satisfy a set of linear inequalities which is precisely the well known problem of integer linear programming. Integer linear programming is an NP complete problem. While no polynomial algorithm is known heuristics have been developed to solve linear programs involving many variables and they can be quite fast in many cases. Unfortunately such standard heuristics are inappropriate for data dependence analysis where the challenge is to solve many small and simple integer linear programs rather than large complicated integer linear programs.

The data dependence analysis algorithm consists of three parts

- 1 Apply the GCD Greatest Common Divisor test which checks if there is an integer solution to the equalities using the theory of linear Diophan tine equations If there are no integer solutions then there are no data dependences Otherwise we use the equalities to substitute for some of the variables thereby obtaining simpler inequalities
- 2 Use a set of simple heuristics to handle the large numbers of typical in equalities
- 3 In the rare case where the heuristics do not work we use a linear integer programming solver that uses a branch and bound approach based on Fourier Motzkin elimination

11 6 3 The GCD Test

The rst subproblem is to check for the existence of integer solutions to the equalities Equations with the stipulation that solutions must be integers are known as *Diophantine equations* The following example shows how the issue of integer solutions arises it also demonstrates that even though many of our examples involve a single loop nest at a time the data dependence formulation applies to accesses in possibly di erent loops

Example 11 30 Consider the following code fragment

The access Z 2 i only touches even elements of Z while access Z 2 j 1 touches only odd elements. Clearly these two accesses share no data dependence regardless of the loop bounds. We can execute iterations in the second loop before the rst or interleave the iterations. This example is not as contrived as it may look. An example where even and odd numbers are treated dierently is an array of complex numbers, where the real and imaginary components are laid out side by side.

To prove the absence of data dependences in this example we reason as follows Suppose there were integers i and j such that Z 2 i and Z 2 j 1 are the same array element. We get the Diophantine equation

$$2i$$
 $2j$ 1

There are no integers i and j that can satisfy the above equation. The proof is that if i is an integer, then 2i is even. If j is an integer, then 2j is even so 2j-1 is odd. No even number is also an odd number. Therefore, the equation

11 6 ARRAY DATA DEPENDENCE ANALYSIS

has no integer solutions and thus there is no dependence between the read and write accesses \Box

To describe when there is a solution to a linear Diophantine equation we need the concept of the *greatest common divisor* GCD of two or more integers. The GCD of integers a_1 a_2 a_n denoted gcd a_1 a_2 a_n is the largest integer that evenly divides all these integers GCD s can be computed esciently by the well known Euclidean algorithm, see the box on the subject

Example 11 31 gcd 24 36 54 6 because 24 6 36 6 and 54 6 each have remainder 0 yet any integer larger than 6 must leave a nonzero remainder when dividing at least one of 24 36 and 54 For instance 12 divides 24 and 36 evenly but not 54

The importance of the GCD is in the following theorem

Theorem 11 32 The linear Diophantine equation

$$a_1x_1 \quad a_2x_2 \quad a_nx_n \quad c$$

has an integer solution for x_1 x_2 x_n if and only if gcd a_1 a_2 a_n divides c

Example 11 33 We observed in Example 11 30 that the linear Diophantine equation 2i + 2j + 1 has no solution. We can write this equation as

$$2i$$
 $2j$ 1

Now gcd 2 2 2 and 2 does not divide 1 evenly. Thus there is no solution For another example consider the equation

$$24x \quad 36y \quad 54z \quad 30$$

Since gcd 24 36 54 6 and 30 6 5 there is a solution in integers for x y and z One solution is x 1 y 0 and z 1 but there are an in nity of other solutions \Box

The rst step to the data dependence problem is to use a standard method such as Gaussian elimination to solve the given equalities. Every time a linear equation is constructed apply Theorem 11 32 to rule out if possible the existence of an integer solution. If we can rule out such solutions then answer no. Otherwise we use the solution of the equations to reduce the number of variables in the inequalities.

Example 11 34 Consider the two equalities

$$\begin{array}{cccc} x & 2y & z & & 0 \\ 3x & 2y & z & & 5 \end{array}$$

The Euclidean Algorithm

The Euclidean algorithm for a nding a decompositive integers and a decompositive numbers or the GCD of a negative and a positive number is the same as the GCD of their absolute values so we can assume all integers are positive

If a b then $\gcd a$ b a If a b let c be the remainder of a b If c 0 then b evenly divides a so $\gcd a$ b b Otherwise compute $\gcd b$ c this result will also be $\gcd a$ b

To compute gcd a_1 a_2 a_n for n 2 use the Euclidean algorithm to compute gcd a_1 a_2 c Then recursively compute gcd c a_3 a_4 a_n

Looking at each equality by itself it appears there might be a solution For the rst equality gcd 1 2 1 1 divides 0 and for the second equality gcd 3 2 1 1 divides 5 However if we use the rst equality to solve for z=2y=x and substitute for z in the second equality we get 2x=4y=5 This Diophantine equation has no solution since gcd 2 4 2 does not divide 5 evenly \square

11 6 4 Heuristics for Solving Integer Linear Programs

The data dependence problem requires many simple integer linear programs be solved. We now discuss several techniques to handle simple inequalities and a technique to take advantage of the similarity found in data dependence analysis

Independent Variables Test

Many of the integer linear programs from data dependence consist of inequalities that involve only one unknown The programs can be solved simply by testing if there are integers between the constant upper bounds and constant lower bounds independently

Example 11 35 Consider the nested loop

11 6 ARRAY DATA DEPENDENCE ANALYSIS

To nd if there is a data dependence between Zij and Zj 10 i 11 we ask if there exist integers ij i' and j' such that

The GCD test applied to the two equalities above will determine that there may be an integer solution The integer solutions to the equalities are expressed by

$$i$$
 t_1 j t_2 i' t_2 11 j' t_1 10

for any integers t_1 and t_2 Substituting the variables t_1 and t_2 into the linear inequalities we get

$$\begin{array}{cccccc} 0 & & t_1 & & 10 \\ 0 & & t_2 & & 10 \\ 0 & & t_2 & 11 & & 10 \\ 0 & & t_1 & 10 & & 10 \end{array}$$

Thus combining the lower bounds from the last two inequalities with the upper bounds from the rst two we deduce

$$\begin{array}{cccc}
10 & t_1 & 10 \\
11 & t_2 & 10
\end{array}$$

Since the lower bound on t_2 is greater than its upper bound there is no integer solution and hence no data dependence. This example shows that even if there are equalities involving several variables, the GCD test may still create linear inequalities that involve one variable at a time.

Acyclic Test

Another simple heuristic is to $\,$ nd if there exists a variable that is bounded below or above by a constant. In certain circumstances we can safely replace the variable by the constant the simplified inequalities have a solution if and only if the original inequalities have a solution. Specifically suppose every lower bound on v_i is of the form

$$c_0 c_i v_i ext{ for some } c_i 0$$

while the upper bounds on v_i are all of the form

$$c_i v_i - c_0 - c_1 v_1 - c_{i-1} v_{i-1} - c_{i-1} v_{i-1} - c_n v_n$$

where c_i is nonnegative. Then we can replace variable v_i by its smallest possible integer value. If there is no such lower bound, we simply replace v_i with ∞

Similarly if every constraint involving v_i can be expressed in the two forms above but with the directions of the inequalities reversed then we can replace variable v_i with the largest possible integer value or by ∞ if there is no constant upper bound. This step can be repeated to simplify the inequalities and in some cases determine if there is a solution

Example 11 36 Consider the following inequalities

Variable v_1 is bounded from below by v_2 and from above by v_3 4 However v_2 is bounded from below only by the constant 1 and v_3 is bounded from above only by the constant 4 Thus replacing v_2 by 1 and v_3 by 4 in the inequalities we obtain

which can now be solved easily with the independent variables test \Box

The Loop Residue Test

Let us now consider the case where every variable is bounded from below and above by other variables. It is commonly the case in data dependence analysis that constraints have the form v_i v_j c which can be solved using a simplified version of the loop residue test due to Shostak. A set of these constraints can be represented by a directed graph whose nodes are labeled with variables. There is an edge from v_i to v_j labeled c whenever there is a constraint v_i v_j c

We de ne the weight of a path to be the sum of the labels of all the edges along the path. Each path in the graph represents a combination of the constraints in the system. That is we can infer that v-v'-c whenever there exists a path from v to v' with weight c. A cycle in the graph with weight c represents the constraint v-v-c for each node v on the cycle. If we can not a negatively weighted cycle in the graph, then we can infer v-v which is impossible. In this case, we can conclude that there is no solution and thus no dependence

We can also incorporate into the loop residue test constraints of the form c-v and v-c for variable v and constant c. We introduce into the system of inequalities a new dummy variable v_0 —which is added to each constant upper and lower bound. Of course v_0 must have value 0 but since the loop residue test only looks for cycles—the actual values of the variables never becomes significant. To handle constant bounds—we replace

11 6 ARRAY DATA DEPENDENCE ANALYSIS

Example 11 37 Consider the inequalities

$$\begin{array}{cccc} 1 & & v_1 & v_2 & & 10 \\ 0 & & v_3 & & 4 \\ v_2 & & v_1 & & \\ & & & 2v_1 & & 2v_3 & 7 \end{array}$$

The constant upper and lower bounds on v_1 become v_0 v_1 1 and v_1 v_0 10 the constant bounds on v_2 and v_3 are handled similarly. Then converting the last constraint to v_1 v_3 4 we can create the graph shown in Fig. 11 21. The cycle v_1 v_3 v_0 v_1 has weight 1 so there is no solution to this set of inequalities. \square

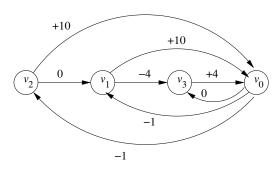

Figure 11 21 Graph for the constraints of Example 11 37

Memoization

Often similar data dependence problems are solved repeatedly because simple access patterns are repeated throughout the program. One important technique to speed up data dependence processing is to use *memoization*. Memoization tabulates the results to the problems as they are generated. The table of stored solutions is consulted as each problem is presented, the problem needs to be solved only if the result to the problem cannot be found in the table

11 6 5 Solving General Integer Linear Programs

We now describe a general approach to solving the integer linear programming problem. The problem is NP complete our algorithm uses a branch and bound approach that can take an exponential amount of time in the worst case. How ever it is rare that the heuristics of Section 11 6 4 cannot resolve the problem and even if we do need to apply the algorithm of this section, it seldom needs to perform the branch and bound step.

The approach is to structured for the existence of rational solutions to the inequalities. This problem is the classical linear programming problem. If there is no rational solution to the inequalities then the regions of data touched by the accesses in question do not overlap and there surely is no data dependence. If there is a rational solution, we set try to prove that there is an integer solution which is commonly the case. Failing that, we then split the polyhedron bounded by the inequalities into two smaller problems and recurse.

Example 11 38 Consider the following simple loop

The elements touched by access Z i are Z 1 Z 9 while the elements touched by Z i 10 are Z 11 Z 19 The ranges do not overlap and therefore there are no data dependences. More formally, we need to show that there are no two dynamic accesses i and i' with 1 i 9 1 i' 9 and i i' 10 If there were such integers i and i' then we could substitute i' 10 for i and get the four constraints on i' 1 i' 9 and 1 i' 10 9 However i' 10 9 implies i' 1 which contradicts 1 i' Thus no such integers i and i' exist \square

Algorithm 11 39 describes how to determine if an integer solution can be found for a set of linear inequalities based on the Fourier Motzkin elimination algorithm

Algorithm 11 39 Branch and bound solution to integer linear programming problems

INPUT A convex polyhedron S_n over variables v_1 v_n OUTPUT yes if S_n has an integer solution no otherwise

METHOD The algorithm is shown in Fig. 11 22 \Box

Lines 1 through 3 attempt to nd a rational solution to the inequalities If there is no rational solution there is no integer solution. If a rational solution is found this means that the inequalities de ne a nonempty polyhedron. It is relatively rare for such a polyhedron not to include any integer solutions—for that to happen the polyhedron must be relatively thin along some dimension and—t between integer points

Thus lines 4 through 9 try to check quickly if there is an integer solution Each step of the Fourier Motzkin elimination algorithm produces a polyhedron with one fewer dimension than the previous one We consider the polyhedra in reverse order. We start with the polyhedron with one variable and assign to that variable an integer solution roughly in the middle of the range of possible values if possible. We then substitute the value for the variable in all other polyhedra decreasing their unknown variables by one. We repeat the same process until

Figure 11 22 Finding an integer solution in inequalities

we have processed all the polyhedra in which case an integer solution is found or we have found a variable for which there is no integer solution

If we cannot $\$ nd an integer value for even the $\$ rst variable there is no integer solution line 10. Otherwise all we know is that there is no integer solution including the combination of special content integers we have picked so far and the result is inconclusive. Lines $\$ 11 through $\$ 13 represent the branch and bound step. If variable $\ v_i$ is found to have a rational but not integer solution we split the polyhedron into two with the $\$ rst requiring that $\ v_i$ must be an integer smaller than the rational solution found and the second requiring that $\ v_i$ must be an integer greater than the rational solution found. If neither has a solution then there is no dependence

1166 Summary

We have shown that essential pieces of information that a compiler can glean from array references are equivalent to certain standard mathematical concepts Given an access function \mathcal{F} $\langle \mathbf{F} \ \mathbf{f} \ \mathbf{B} \ \mathbf{b} \rangle$

1 The dimension of the data region accessed is given by the rank of the matrix **F** The dimension of the space of accesses to the same location is given by the nullity of **F** Iterations whose di erences belong to the null space of **F** refer to the same array elements

- 2 Iterations that share self temporal reuse of an access are separated by vectors in the null space of \mathbf{F} Self spatial reuse can be computed similarly by asking when two iterations use the same row rather than the same element. Two accesses \mathbf{Fi}_1 \mathbf{f}_1 and \mathbf{Fi}_2 \mathbf{f}_2 share easily exploitable locality along the \mathbf{d} direction if \mathbf{d} is the particular solution to the equation \mathbf{Fd} \mathbf{f}_1 \mathbf{f}_2 In particular if \mathbf{d} is the direction corresponding to the innermost loop i.e. the vector 0 0 0 1 then there is spatial locality if the array is stored in row major form
- 3 The data dependence problem whether two references can refer to the same location is equivalent to integer linear programming. Two access functions share a data dependence if there are integer valued vectors \mathbf{i} and \mathbf{i}' such that $\mathbf{Bi} \quad \mathbf{0} \quad \mathbf{B'i'} \quad \mathbf{0} \quad \mathbf{and} \quad \mathbf{Fi} \quad \mathbf{f} \quad \mathbf{F'i'} \quad \mathbf{f'}$

11 7 Finding Synchronization Free Parallelism

Having developed the theory of a ne array accesses their reuse of data and the dependences among them we shall now begin to apply this theory to paral lelization and optimization of real programs. As discussed in Section 11 1 4 it is important that we nd parallelism while minimizing communication among processors. Let us start by studying the problem of parallelizing an application without allowing any communication or synchronization between processors at all. This constraint may appear to be a purely academic exercise how often can we nd programs and routines that have such a form of parallelism. In fact, many such programs exist in real life, and the algorithm for solving this problem is useful in its own right. In addition, the concepts used to solve this problem can be extended to handle synchronization and communication.

1171 An Introductory Example

Shown in Fig 11 23 is an excerpt of a C translation with Fortran style array accesses retained for clarity from a 5000 line Fortran multigrid algorithm to solve three dimensional Euler equations. The program spends most its time in a small number of routines like the one shown in the gure. It is typical of many numerical programs. These often consist of numerous for loops with di erent nesting levels and they have many array accesses all of which are a ne expressions of surrounding loop indexes. To keep the example short, we have elided lines from the original program with similar characteristics.

The code of Fig. 11.23 operates on the scalar variable T and a number of di erent arrays with di erent dimensions. Let us rst examine the use of variable T. Because each iteration in the loop uses the same variable T we cannot execute the iterations in parallel. However, T is used only as a way to hold a common subexpression used twice in the same iteration. In the rst two of the three loop nests in Fig. 11.23 each iteration of the innermost loop writes a value into T and uses the value immediately after twice in the same iteration. We can eliminate the dependences by replacing each use of T by the right hand side expression in the previous assignment of T without changing the semantics of the program. Or we can replace the scalar T by an array. We then have each iteration j i use its own array element T j i

With this modi cation the computation of an array element in each as signment statement depends only on other array elements with the same values for the last two components j and i respectively. We can thus group all

```
for j 2 j
                jl j
  for i 2 i
     AP j i
     Τ
                   1 0 1 0
                            AP j i
                   T AP j i

        DW 1 k j i
```

Figure 11 23 Code excerpt of a multigrid algorithm

operations that operate on the j i th element of all arrays into one computation unit and execute them in the original sequential order. This modification produces jl l il l units of computation that are all independent of one another. Notice that second and third nests in the source program involve a third loop with index k. However, because there is no dependence between dynamic accesses with the same values for j and i we can safely perform the loops on k inside the loops on j and i that is within a computation unit

Knowing that these computation units are independent enables a number of legal transforms on this code. For example, instead of executing the code as originally written a uniprocessor can perform the same computation by executing the units of independent operation one unit at a time. The resulting code shown in Fig. 11 24 has improved temporal locality because results produced are consumed immediately.

The independent units of computation can also be assigned to di erent processors and executed in parallel without requiring any synchronization or communication. Since there are $\ j1\ 1$ il 1 independent units of computation we can utilize at most $\ j1\ 1$ il 1 processors. By organizing the processors as if they were in a 2 dimensional array with ID s $\ j\ i$ where 2 $\ j$ $\ j1$ and 2 $\ i$ il the SPMD program to be executed by each processor is simply the body in the inner loop in Fig. 11 24

```

Figure 11 24 Code of Fig 11 23 transformed to carry outermost parallel loops

The above example illustrates the basic approach to nding synchronization free parallelism. We are rst split the computation into as many independent units as possible. This partitioning exposes the scheduling choices available. We then assign computation units to the processors depending on the number of processors we have. Finally, we generate an SPMD program that is executed on each processor.

1172 A ne Space Partitions

A loop nest is said to have k degrees of parallelism if it has within the nest k parallelizable loops—that is loops such that there are no data dependencies between di erent iterations of the loops—For example—the code in Fig. 11 24 has 2 degrees of parallelism—It is convenient to assign the operations in a computation with k degrees of parallelism to a processor array with k dimensions

We shall assume initially that each dimension of the processor array has as many processors as there are iterations of the corresponding loop. After all the independent computation units have been found we shall map these virtual processors to the actual processors. In practice, each processor should be responsible for a fairly large number of iterations because otherwise there is not enough work to amortize away the overhead of parallelization.

We break down the program to be parallelized into elementary statements such as 3 address statements. For each statement we ind an a ne space partition that maps each dynamic instance of the statement as identified by its loop indexes to a processor ID

Example 11 40 As discussed above the code of Fig. 11 24 has two degrees of parallelism. We view the processor array as a 2 dimensional space. Let p_1 p_2 be the ID of a processor in the array. The parallelization scheme discussed in Section 11 71 can be described by simple an expansion partition. All the statements in the rst loop nest have this same an expansion.

All the statements in the second and third loop nests have the following same a ne partition

The algorithm to nd synchronization free parallelism consists of three steps

- 1 Find for each statement in the program an a ne partition that maxi mizes the degree of parallelism. Note that we generally treat the state ment rather than the single access as the unit of computation. The same a ne partition must apply to each access in the statement. This grouping of accesses makes sense since there is almost always dependence among accesses of the same statement anyway.
- 2 Assign the resulting independent computation units among the processors and choose an interleaving of the steps on each processor. This assignment is driven by locality considerations
- 3 Generate an SPMD program to be executed on each processor

We shall discuss next how to nd the a ne partition functions how to generate a sequential program that executes the partitions serially and how to generate an SPMD program that executes each partition on a di erent processor. After we discuss how parallelism with synchronizations is handled in Sections 11.8 through 11.9.9 we return to Step 2 above in Section 11.10 and discuss the optimization of locality for uniprocessors and multiprocessors.

11 7 3 Space Partition Constraints

To require no communication each pair of operations that share a data dependence must be assigned to the same processor. We refer to these constraints as space partition constraints. Any mapping that satisfies these constraints are ates partitions that are independent of one another. Note that such constraints can be satisfied by putting all the operations in a single partition. Unfortunately, that solution does not yield any parallelism. Our goal is to create

as many independent partitions as possible while satisfying the space partition constraints that is operations are not placed on the same processor unless it is necessary

When we restrict ourselves to a ne partitions then instead of maximizing the number of independent units we may maximize the degree number of dimensions of parallelism. It is sometimes possible to create more independent units if we can use *piecewise* a ne partitions. A piecewise a ne partition divides instances of a single access into di erent sets and allows a di erent a ne partition for each set. However, we shall not consider such an option here

Formally an a ne partition of a program is synchronization free if and only if for every two not necessarily distinct accesses sharing a dependence \mathcal{F}_1 $\langle \mathbf{F}_1 \ \mathbf{f}_1 \ \mathbf{B}_1 \ \mathbf{b}_1 \rangle$ in statement s_1 nested in d_1 loops and $\mathcal{F}_2 \ \langle \mathbf{F}_2 \ \mathbf{f}_2 \ \mathbf{B}_2 \ \mathbf{b}_2 \rangle$ in statement s_2 nested in d_2 loops the partitions $\langle \mathbf{C}_1 \ \mathbf{c}_1 \rangle$ and $\langle \mathbf{C}_2 \ \mathbf{c}_2 \rangle$ for state ments s_1 and s_2 respectively satisfy the following space partition constraints

For all \mathbf{i}_1 in Z^{d_1} and \mathbf{i}_2 in Z^{d_2} such that

it is the case that C_1i_1 c_1 C_2i_2 c_2

The goal of the parallelization algorithm is to nd for each statement the partition with the highest rank that satis es these constraints

Shown in Fig 11 25 is a diagram illustrating the essence of the space partition constraints. Suppose there are two static accesses in two loop nests with index vectors \mathbf{i}_1 and \mathbf{i}_2 . These accesses are dependent in the sense that they access at least one array element in common and at least one of them is a write. The gure shows particular dynamic accesses in the two loops that hap pen to access the same array element according to the anneaccess functions $\mathbf{F}_1\mathbf{i}_1$ and $\mathbf{F}_2\mathbf{i}_2$ Synchronization is necessary unless the annear partitions for the two static accesses $\mathbf{C}_1\mathbf{i}_1$ and $\mathbf{C}_2\mathbf{i}_2$ assign the dynamic accesses to the same processor

If we choose an a ne partition whose rank is the maximum of the ranks of all statements we get the maximum possible parallelism. However under this partitioning some processors may be idle at times while other processors are executing statements whose a ne partitions have a smaller rank. This situation may be acceptable if the time taken to execute those statements is relatively short. Otherwise, we can choose an a ne partition whose rank is smaller than the maximum possible as long as that rank is greater than 0.

We show in Example 11 41 a small program designed to illustrate the power of the technique Real applications are usually much simpler than this but may have boundary conditions resembling some of the issues shown here We shall use this example throughout this chapter to illustrate that programs with

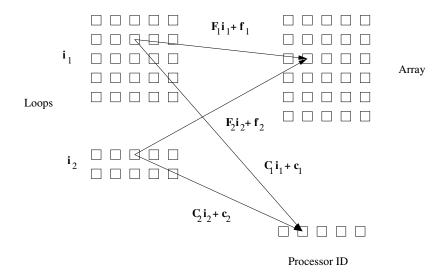

Figure 11 25 Space partition constraints

a ne accesses have relatively simple space partition constraints that these constraints can be solved using standard linear algebra techniques and that the desired SPMD program can be generated mechanically from the an e partitions

Example 11 41 This example shows how we formulate the space partition constraints for the program consisting of the small loop nest with two state ments s_1 and s_2 shown in Figure 11 26

Figure 11 26 A loop nest exhibiting long chains of dependent operations

We show the data dependences in the program in Figure 11 27. That is each black dot represents an instance of statement s_1 and each white dot represents an instance of statement s_2 . The dot located at coordinates i j represents the instance of the statement that is executed for those values of the loop indexes. Note however that the instance of s_2 is located just below the instance of s_1 for the same i j pair so the vertical scale of j is greater than the horizontal scale of i

Notice that $X \ i \ j$ is written by $s_1 \ i \ j$ that is by the instance of statement s_1 with index values i and j It is later read by $s_2 \ i \ j$ 1 so $s_1 \ i \ j$ must

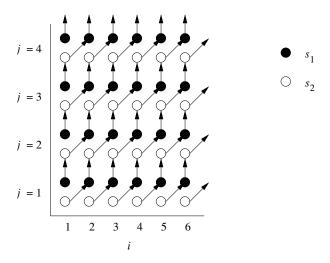

Figure 11 27 Dependences of the code in Example 11 41

precede s_2 i j 1 This observation explains the vertical arrows from black dots to white dots Similarly Y i j is written by s_2 i j and later read by s_1 i 1 j Thus s_2 i j must precede s_1 i 1 j which explains the arrows from white dots to black

It is easy to see from this diagram that this code can be parallelized without synchronization by assigning each chain of dependent operations to the same processor. However, it is not easy to write the SPMD program that implements this mapping scheme. While the loops in the original program have 100 iterations each there are 200 chains with half originating and ending with statement s_1 and the other half originating and ending with s_2 . The lengths of the chains vary from 1 to 100 iterations

Since there are two statements we are seeking two a ne partitions one for each statement. We only need to express the space partition constraints for one dimensional a ne partitions. These constraints will be used later by the solution method that tries to and all the independent one dimensional a ne partitions and combine them to get multidimensional a ne partitions. We can thus represent the anne partition for each statement by a 1-2 matrix and a 1-1 vector to translate the vector of indexes i j into a single processor number. Let $\langle C_{11}C_{12} \ c_1 \rangle \langle C_{21}C_{22} \ c_2 \rangle$ be the one dimensional anne partitions for the statements s_1 and s_2 respectively

We apply six data dependence tests

- 1 Write access X i j and itself in statement s_1
- 2 Write access X i j with read access X i j in statement s_1
- 3 Write access X i j in statement s_1 with read access X i j 1 in state ment s_2

- 4 Write access Y i j and itself in statement s_2
- 5 Write access $Y \ i \ j$ with read access $Y \ i \ j$ in statement s_2
- 6 Write access $Y \ i \ j$ in statement s_2 with read access $Y \ i \ 1 \ j$ in statement s_1

We see that the dependence tests are all simple and highly repetitive. The only dependences present in this code occur in case 3 between instances of accesses $X \ i \ j$ and $X \ i \ j$ 1 and in case 6 between $Y \ i \ j$ and $Y \ i$ 1 j

The space partition constraints imposed by the data dependence between $X \ i \ j$ in statement s_1 and $X \ i \ j$ 1 in statement s_2 can be expressed in the following terms

For all $i \ j$ and $i' \ j'$ such that

we have

That is the rst four conditions say that $i\ j$ and $i'\ j'$ lie within the iteration space of the loop nest and the last two conditions say that the dynamic accesses $X\ i\ j$ and $X\ i\ j$ 1 touch the same array element. We can derive the space partition constraint for accesses $Y\ i$ 1 j in statement s_2 and $Y\ i\ j$ in statement s_1 in a similar manner. \square

11 7 4 Solving Space Partition Constraints

Once the space partition constraints have been extracted standard linear algebra techniques can be used to not the an expartitions satisfying the constraints. Let us not show how we not the solution to Example 11 41

Example 11 42 We can disthesia the anti-example 11 41 with the following steps

- 1 Create the space partition constraints shown in Example 11 41 We use the loop bounds in determining the data dependences but they are not used in the rest of the algorithm otherwise
- 2 The unknown variables in the equalities are i i' j j' C_{11} C_{12} c_1 C_{21} C_{22} and c_2 Reduce the number of unknowns by using the equalities due to the access functions i i' and j j' 1 We do so using Gaussian elimination which reduces the four variables to two say t_1 i i' and t_2 j j' 1 The equality for the partition becomes

3 The equation above holds for all combinations of t_1 and t_2 Thus it must be that

$$\begin{array}{ccc} C_{11} & C_{21} & & 0 \\ C_{12} & C_{22} & & 0 \\ c_1 & c_2 & C_{22} & & 0 \end{array}$$

If we perform the same steps on the constraint between the accesses $Y \ i - 1 \ j$ and $Y \ i \ j$ we get

$$\begin{array}{ccc} C_{11} & C_{21} & & 0 \\ C_{12} & C_{22} & & 0 \\ c_1 & c_2 & C_{21} & & 0 \end{array}$$

Simplifying all the constraints together we obtain the following relation ships

$$C_{11}$$
 C_{21} C_{22} C_{12} c_2 c_1

- 4 Find all the independent solutions to the equations involving only un knowns in the coe cient matrix ignoring the unknowns in the constant vectors in this step. There is only one independent choice in the coef cient matrix so the anne partitions we seek can have at most a rank of one. We keep the partition as simple as possible by setting $C_{11} = 1$. We cannot assign 0 to C_{11} because that will create a rank 0 coeficient matrix which maps all iterations to the same processor. It then follows that $C_{21} = 1$, $C_{22} = 1$, $C_{12} = 1$.
- 5 Find the constant terms We know that the difference between the constant terms c_2 c_1 must be 1 We get to pick the actual values however To keep the partitions simple we pick c_2 0 thus c_1 1

Let p be the ID of the processor executing iteration $i\ j$ In terms of p the a ne partition is

That is the i j th iteration of s_1 is assigned to the processor p i j 1 and the i j th iteration of s_2 is assigned to processor p i j \square

Algorithm 11 43 Finding a highest ranked synchronization free a ne par tition for a program

INPUT A program with a nearray accesses

OUTPUT A partition

METHOD Do the following

1 Find all data dependent pairs of accesses in a program for each pair of data dependent accesses \mathcal{F}_1 $\langle \mathbf{F}_1 \ \mathbf{f}_1 \ \mathbf{B}_1 \ \mathbf{b}_1 \rangle$ in statement s_1 nested in d_1 loops and \mathcal{F}_2 $\langle \mathbf{F}_2 \ \mathbf{f}_2 \ \mathbf{B}_2 \ \mathbf{b}_2 \rangle$ in statement s_2 nested in d_2 loops Let $\langle \mathbf{C}_1 \ \mathbf{c}_1 \rangle$ and $\langle \mathbf{C}_2 \ \mathbf{c}_2 \rangle$ represent the currently unknown partitions of statements s_1 and s_2 respectively. The space partition constraints state that if

$$\mathbf{F}_1\mathbf{i}_1 \quad \mathbf{f}_1 \quad \mathbf{F}_2\mathbf{i}_2 \quad \mathbf{f}_2$$

then

$$\mathbf{C}_1\mathbf{i}_1 \quad \mathbf{c}_1 \quad \mathbf{C}_2\mathbf{i}_2 \quad \mathbf{c}_2$$

for all \mathbf{i}_1 and \mathbf{i}_2 within their respective loop bounds. We shall generalize the domain of iterations to include all \mathbf{i}_1 in Z^{d_1} and \mathbf{i}_2 in Z^{d_2} that is the bounds are all assumed to be minus in nity to in nity. This assumption makes sense since an anne partition cannot make use of the fact that an index variable can take on only a limited set of integer values

- 2 For each pair of dependent accesses we reduce the number of unknowns in the index vectors
 - a Note that **Fi f** is the same vector as

$$\mathbf{F} \quad \mathbf{f} \quad \begin{array}{c} \mathbf{i} \\ 1 \end{array}$$

That is by adding an extra component 1 at the bottom of column vector \mathbf{i} we can make the column vector \mathbf{f} be an additional last column of the matrix \mathbf{F} We may thus rewrite the equality of the access functions $\mathbf{F}_1\mathbf{i}_1$ \mathbf{f}_1 $\mathbf{F}_2\mathbf{i}_2$ \mathbf{f}_2 as

$$\mathbf{F}_1 \qquad \mathbf{F}_2 \qquad \mathbf{f}_1 \qquad \mathbf{f}_2 \qquad \left[egin{array}{c} \mathbf{i}_1 \\ \mathbf{i}_2 \\ 1 \end{array}
ight] = 0$$

b The above equations will in general have more than one solution However we may still use Gaussian elimination to solve the equations for the components of \mathbf{i}_1 and \mathbf{i}_2 as best we can That is eliminate as many variables as possible until we are left with only variables that cannot be eliminated The resulting solution for \mathbf{i}_1 and \mathbf{i}_2 will have the form

$$\begin{bmatrix} \mathbf{i}_1 \\ \mathbf{i}_2 \\ 1 \end{bmatrix} \quad \mathbf{U} \quad \mathbf{t}$$

where \mathbf{U} is an upper triangular matrix and \mathbf{t} is a vector of free variables ranging over all integers

c We may use the same trick as in Step 2a to rewrite the equality of the partitions Substituting the vector \mathbf{i}_1 \mathbf{i}_2 1 with the result from Step 2b we can write the constraints on the partitions as

$$\mathbf{C}_1 \quad \mathbf{C}_2 \quad \mathbf{c}_1 \quad \mathbf{c}_2 \quad \mathbf{U} \quad \frac{\mathbf{t}}{1} \quad 0$$

3 Drop the nonpartition variables The equations above hold for all combinations of ${\bf t}$ if

$$\mathbf{C}_1$$
 \mathbf{C}_2 \mathbf{c}_1 \mathbf{c}_2 \mathbf{U} $\mathbf{0}$

Rewrite these equations in the form $\mathbf{A}\mathbf{x} = \mathbf{0}$ where \mathbf{x} is a vector of all the unknown coeficients of the anne partitions

- 4 Find the rank of the a ne partition and solve for the coe cient matrices Since the rank of an a ne partition is independent of the value of the constant terms in the partition we eliminate all the unknowns that come from the constant vectors like \mathbf{c}_1 or \mathbf{c}_2 thus replacing $\mathbf{A}\mathbf{x} = \mathbf{0}$ by sim pli ed constraints $\mathbf{A}'\mathbf{x}' = \mathbf{0}$ Find the solutions to $\mathbf{A}'\mathbf{x}' = \mathbf{0}$ expressing them as \mathbf{B} a set of basis vectors spanning the null space of \mathbf{A}'
- 5 Find the constant terms Derive one row of the desired a ne partition from each basis vector in \mathbf{B} and derive the constant terms using $\mathbf{A}\mathbf{x} = \mathbf{0}$

Note that Step 3 ignores the constraints imposed by the loop bounds on variables ${\bf t}$ The constraints are only stricter as a result and the algorithm must therefore be safe. That is we place constraints on the ${\bf C}$ s and ${\bf c}$ s assuming ${\bf t}$ is arbitrary. Conceivably there would be other solutions for the ${\bf C}$ s and ${\bf c}$ s that are valid only because some values of ${\bf t}$ are impossible. Not searching for these other solutions may cause us to miss an optimization but cannot cause the program to be changed to a program that does something different from what the original program does

11 7 5 A Simple Code Generation Algorithm

Algorithm 11 43 generates a ne partitions that split computations into inde pendent partitions. Partitions can be assigned arbitrarily to different processors since they are independent of one another. A processor may be assigned more than one partition and can interleave the execution of its partitions as long as operations within each partition, which normally have data dependences are executed sequentially.

It is relatively easy to generate a correct program given an a ne partition We rst introduce Algorithm 11 45 a simple approach to generating code for a single processor that executes each of the independent partitions sequentially Such code optimizes temporal locality since array accesses that have several uses are very close in time. Moreover, the code easily can be turned into an SPMD program that executes each partition on a different processor. The code generated is unfortunately inedicine we shall next discuss optimizations to make the code execute excited.

The essential idea is as follows. We are given bounds for the index variables of a loop nest and we have determined in Algorithm 11 43 a partition for the accesses of a particular statement s. Suppose we wish to generate sequential code that performs the action of each processor sequentially. We create an outermost loop that iterates through the processor IDs. That is each iteration of this loop performs the operations assigned to a particular processor ID. The original program is inserted as the loop body of this loop in addition a test is added to guard each operation in the code to ensure that each processor only executes the operations assigned to it. In this way we guarantee that the processor executes all the instructions assigned to it and does so in the original sequential order.

Example 11 44 Let us generate code that executes the independent partitions in Example 11 41 sequentially. The original sequential program is from Fig. 11 26 is repeated here as Fig. 11 28

```
for i 1 i 100 i
for j 1 j 100 j
X i j X i j Y i 1 j s1
Y i j Y i j X i j 1 s2
```

Figure 11 28 Repeat of Fig 11 26

In Example 11 42 the a ne partitioning algorithm found one degree of parallelism. Thus the processor space can be represented by a single variable p. Recall also from that example that we selected an an example that for all values of index variables i and j with 1 i 100 and 1 j 100 assigned

- 1 Instance i j of statement s_1 to processor p i j 1 and
- 2 Instance $i \ j$ of statement s_2 to processor p = i j

We can generate the code in three steps

- a 100 p 98 if we use the function p i j 1 that we get for statement s_1 and
- b 99 p 99 if we use p i j from statement s_2
- 2 Find all the processor IDs participating in any of the statements When we take the union of these ranges we get 100 p 99 these bounds are su cient to cover all instances of both statements s_1 and s_2
- 3 Generate the code to iterate through the computations in each partition sequentially. The code shown in Fig. 11-29 has an outer loop that iterates through all the partition IDs participating in the computation line. 1 Each partition goes through the motion of generating the indexes of all the iterations in the original sequential program in lines. 2 and 3 so that it can pick out the iterations the processor p is supposed to execute. The tests of lines 4 and 6 make sure that statements s_1 and s_2 are executed only when the processor p would execute them

The generated code while correct is extremely ine cient. First even though each processor executes computation from at most 99 iterations it gen erates loop indexes for 100-100 iterations an order of magnitude more than necessary. Second each addition in the innermost loop is guarded by a test creating another constant factor of overhead. These two kinds of ine ciencies are dealt with in Sections 11-76 and 11-77 respectively.

```
99 p
1
     for p
               100 p
2
         for i
                  1 i
                          100 i
3
                              100 j
             for
                      1 j
4
                 if
                     р
                          i j 1
                              X i j
5
                     Xij
                                                      s1
6
                         iј
                              X i j 1
7
                     Yij
                                                      s2
8
```

Figure 11 29 A simple rewriting of Fig 11 28 that iterates over processor space

Although the code of Fig. 11 29 appears designed to execute on a uniprocessor we could take the inner loops lines 2 through 8 and execute them on 200 different processors each of which had a different value for p from 100 to 99. Or we could partition the responsibility for the inner loops among any number of processors less than 200 as long as we arranged that each processor knew what values of p it was responsible for and executed lines 2 through 8 for just those values of p

Algorithm 11 45 Generating code that executes partitions of a program sequentially

INPUT A program P with a ne array accesses Each statement s in the program has associated bounds of the form $\mathbf{B}_s\mathbf{i}$ \mathbf{b}_s $\mathbf{0}$ where \mathbf{i} is the vector of loop indexes for the loop nest in which statement s appears. Also associated with statement s is a partition $\mathbf{C}_s\mathbf{i}$ \mathbf{c}_s \mathbf{p} where \mathbf{p} is an m dimensional vector of variables representing a processor ID m is the maximum over all statements in program P of the rank of the partition for that statement

OUTPUT A program equivalent to P but iterating over the processor space rather than over loop indexes

METHOD Do the following

- 1 For each statement use Fourier Motzkin elimination to project out all the loop index variables from the bounds
- 2 Use Algorithm 11 13 to determine bounds on the partition ID s
- 3 Generate loops one for each of the m dimensions of processor space Let $\mathbf{p} = p_1 \ p_2 = p_m$ be the vector of variables for these loops that is there is one variable for each dimension of the processor space Each loop variable p_i ranges over the union of the partition spaces for all statements in the program P

Note that the union of the partition spaces is not necessarily convex. To keep the algorithm simple instead of enumerating only those partitions that have a nonempty computation to perform set the lower bound of each p_i to the minimum of all the lower bounds imposed by all statements and the upper bound of each p_i to the maximum of all the upper bounds imposed by all statements. Some values of \mathbf{p} may thereby have no operations

The code to be executed by each partition is the original sequential program. However every statement is guarded by a predicate so that only those operations belonging to the partition are executed. \Box

An example of Algorithm 11 45 will follow shortly Bear in mind however that we are still far from the optimal code for typical examples

11 7 6 Eliminating Empty Iterations

We now discuss the rst of the two transformations necessary to generate ef cient SPMD code. The code executed by each processor cycles through all the iterations in the original program and picks out the operations that it is supposed to execute. If the code has k degrees of parallelism, the e ect is that each processor performs k orders of magnitude more work. The purpose of the rst transformation is to tighten the bounds of the loops to eliminate all the empty iterations

We begin by considering the statements in the program one at a time A statement s iteration space to be executed by each partition is the original iteration space plus the constraint imposed by the a nepartition We can generate

tight bounds for each statement by applying Algorithm 11 13 to the new iter ation space the new index vector is like the original sequential index vector with processor ID s added as outermost indexes Recall that the algorithm will generate tight bounds for each index in terms of surrounding loop indexes

After nding the iteration spaces of the di erent statements we combine them loop by loop making the bounds the union of those for each statement Some loops end up having a single iteration as illustrated by Example 11 46 below and we can simply eliminate the loop and simply set the loop index to the value for that iteration

Example 11 46 For the loop of Fig 11 30 a Algorithm 11 43 will create the a nepartition

$$\begin{array}{cccc}
s_1 & p & i \\
s_2 & p & j
\end{array}$$

Algorithm 11 45 will create the code of Fig 11 30 b Applying Algorithm 11 13 to statement s_1 produces the bound p i p or simply i p Similarly the algorithm determines j p for statement s_2 Thus we get the code of Fig 11 30 c Copy propagation of variables i and j will eliminate the unnec essary test and produce the code of Fig 11 30 d

We now return to Example 11 44 and illustrate the step to merge multiple iteration spaces from di erent statements together

Example 11 47 Let us now tighten the loop bounds of the code in Exam ple 11 44 The iteration space executed by partition p for statement s_1 is defined by the following equalities and inequalities

Applying Algorithm 11 13 to the above creates the constraints shown in Fig 11 31 a Algorithm 11 13 generates the constraint p=2 i 100 p=1 from i=p-1 j and 1=j 100 and tightens the upper bound of p to 98 Likewise the bounds for each of the variables for statement s_2 are shown in Fig 11 31 b

The iteration spaces for s_1 and s_2 in Fig 11 31 are similar but as expected from Fig 11 27 certain limits di er by 1 between the two. The code in Fig 11 32 executes over this union of iteration spaces. For example, for i use max 1 p 1 as the lower bound and min 100 101 p as the upper bound. Note that the innermost loop has 2 iterations except that it has only one the rst and last time it is executed. The overhead in generating loop indexes is thus reduced by an order of magnitude. Since the iteration space executed is larger than either that of s_1 and s_2 conditionals are still necessary to select when these statements are executed.

a Initial code

```
for p 1 p N p
  for i 1 i N i
      if p i
            Y i Z i s1
  for j 1 j N j
      if p j
            X j Y j s2
```

b Result of applying Algorithm 11 45

```
for p 1 p N p
i p
if p i
Y i Z i s1
j p
if p j
X j Y j s2
```

11 7 7 Eliminating Tests from Innermost Loops

The second transformation is to remove conditional tests from the inner loops As seen from the examples above conditional tests remain if the iteration spaces of statements in the loop intersect but not completely. To avoid the need for conditional tests, we split the iteration space into subspaces, each of which executes the same set of statements. This optimization requires code to be duplicated and should only be used to remove conditionals in the inner loops.

To split an iteration space to reduce tests in inner loops we apply the following steps repeatedly until we remove all the tests in the inner loops

- 1 Select a loop that consists of statements with di erent bounds
- 2 Split the loop using a condition such that some statement is excluded from at least one of its components. We choose the condition from among the boundaries of the overlapping dierent polyhedra. If some statement has all its iterations in only one of the half planes of the condition then such a condition is useful.
- 3 Generate code for each of these iteration spaces separately

Example 11 48 Let us remove the conditionals from the code of Fig. 11 32 Statements s_1 and s_2 are mapped to the same set of partition ID's except for

```
for p
          100 p
                    99
             \mathtt{max}\ 1\ \mathtt{p}\ 1
                              min 100 101 p
        i
    for
                         i
        for j
                max 1 i p 1 j
                                    min 100 i p
            if p i j 1
                Хіj
                         Хіj
                                                  s1
            if p i j
                         X i j 1
                Yij
                                    Yij
                                                  s2
```

Figure 11 32 Code of Fig 11 29 improved by tighter loop bounds

the boundary partitions at either end. Thus we separate the partition space into three subspaces

The code for each subspace can then be specialized for the value s of p contained Figure 11 33 shows the resulting code for each of the three iteration spaces

Notice that the rst and third spaces do not need loops on i or j because for the particular value of p that de nes each space these loops are degenerate they have only one iteration. For example, in space 1, substituting p=100 in the loop bounds restricts i to 1, and subsequently j to 100. The assignments to p in spaces 1, and 3, are evidently dead code and can be eliminated

Next we split the loop with index i in space 2 Again the rst and last iterations of loop index i are di erent. Thus we split the loop into three subspaces

```
a \max 1 \ p 1 i p 2 where only s_2 is executed b \max 1 \ p 2 i \min 100 \ 100 p where both s_1 and s_2 are executed and c 101 p i \min 101 p 100 where only s_1 is executed
```

The loop nest for space 2 in Fig 11 33 can thus be written as in Fig 11 34 a Figure 11 34 b shows the optimized program. We have substituted Fig 11 34 a for the loop nest in Fig 11 33. We also propagated out assignments to p i and j into the array accesses. When optimizing at the intermediate code level some of these assignments will be identified as common subexpressions and re-extracted from the array access code. \Box

11 7 8 Source Code Transforms

We have seen how we can derive from simple a ne partitions for each statement programs that are signi cantly di erent from the original source. It is not apparent from the examples seen so far how a ne partitions correlate with changes at the source level. This section shows that we can reason about source code changes relatively easily by breaking down a ne partitions into a series of primitive transforms.

Seven Primitive A ne Transforms

Every a ne partition can be expressed as a series of primitive a ne transforms each of which corresponds to a simple change at the source level. There are seven kinds of primitive transforms, the rst four primitives are illustrated in Fig. 11 35, the last three also known as unimodular transforms are illustrated in Fig. 11 36.

The gure shows one example for each primitive a source an a ne partition and the resulting code. We also draw the data dependences for the code before and after the transforms. From the data dependence diagrams, we see that each primitive corresponds to a simple geometric transform and induces a relatively simple code transform. The seven primitives are

Unimodular Transforms

A unimodular transform is represented by just a unimodular coe cient matrix and no constant vector A $unimodular \ matrix$ is a square matrix whose determinant is 1. The significance of a unimodular transform is that it maps an n dimensional iteration space to another n dimensional polyhedron where there is a one to one correspondence between iterations of the two spaces

- 1 Fusion The fusion transform is characterized by mapping multiple loop indexes in the original program to the same loop index. The new loop fuses statements from di erent loops
- 2 Fission Fission is the inverse of fusion It maps the same loop index for di erent statements to di erent loop indexes in the transformed code This splits the original loop into multiple loops
- 3 Re indexing Re indexing shifts the dynamic executions of a statement by a constant number of iterations The a ne transform has a constant term
- 4 Scaling Consecutive iterations in the source program are spaced apart by a constant factor. The anne transform has a positive nonunit coefficient
- 5 Reversal Execute iterations in a loop in reverse order Reversal is char acterized by having 1 as a coe cient
- 6 Permutation Permute the inner and outer loops The a ne transform consists of permuted rows of the identity matrix
- 7 Skewing Iterate through the iteration space in the loops at an angle The a ne transform is a unimodular matrix with 1 s on the diagonal

A Geometric Interpretation of Parallelization

The a ne transforms shown in all but the ssion example are derived by apply ing the synchronization free a ne partition algorithm to the respective source codes. We shall discuss how ssion can parallelize code with synchronization in the next section. In each of the examples, the generated code has an outer most parallelizable loop whose iterations can be assigned to different processors and no synchronization is necessary.

These examples illustrate that there is a simple geometric interpretation of how parallelization works Dependence edges always point from an earlier instance to a later instance. So dependences between separate statements not nested in any common loop follows the lexical order dependences between

statements nested in the same loop follow the lexicographic order. Geometrically dependences of a two dimensional loop nest always point within the range meaning that the angle of the dependence must be below 180 but no less than 0

The a ne transforms change the ordering of iterations such that all the dependences are found only between operations nested within the same iteration of the outermost loop. In other words, there are no dependence edges at the boundaries of iterations in the outermost loop. We can parallelize simple source codes by drawing their dependences and inding such transforms geometrically

11 7 9 Exercises for Section 11 7

Exercise 11 7 1 For the following loop

- a What is the largest number of processors that can be used e ectively to execute this loop
- b Rewrite the code with processor p as a parameter
- c Set up and nd one solution to the space partition constraints for this loop
- d What is the a ne partition of highest rank for this loop

Exercise 11 7 2 Repeat Exercise 11 7 1 for the loop nests in Fig 11 37

Exercise 11 7 3 Rewrite the following code

so it consists of a single loop. Rewrite the loop in terms of a processor number p so the code can be partitioned among 100 processors. with iteration p executed by processor p

                            Aijk1
                                      Bijk
                      \mathbf{c}
```

Figure 11 37 Code for Exercise 11 7 2

the only constraints are that the statement s that forms the body of the loop nest must execute iterations s i 1 j and s i j 1 before executing iteration s i j Verify that these are the only necessary constraints. Then rewrite the code so that the outer loop has index variable p and on the pth iteration of the outer loop all instances of s i j such that i j p are executed

Exercise 11 7 5 Repeat Exercise 11 7 4 but arrange that on the pth iteration of the outer loop instances of s such that i j p are executed

 $\begin{array}{ccc} 2 & 1 \\ 1 & 1 \end{array}$

is unimodular Describe the transformation it performs on a two dimensional loop nest

Exercise 11 7 8 Repeat Exercise 11 7 7 on the matrix

 $\begin{array}{cc} 1 & 3 \\ 2 & 5 \end{array}$

11 8 Synchronization Between Parallel Loops

Most programs have no parallelism if we do not allow processors to perform any synchronizations. But adding even a small constant number of synchronization operations to a program can expose more parallelism. We shall rst discuss parallelism made possible by a constant number of synchronizations in this section and the general case where we embed synchronization operations in loops in the next

11 8 1 A Constant Number of Synchronizations

Programs with no synchronization free parallelism may contain a sequence of loops some of which are parallelizable if they are considered independently. We can parallelize such loops by introducing synchronization barriers before and after their execution. Example 11 49 illustrates the point

Figure 11 38 Two sequential loop nests

Example 11 49 In Fig 11 38 is a program representative of an ADI Alter nating Direction Implicit integration algorithm. There is no synchronization free parallelism. Dependences in the rst loop nest require that each processor works on a column of array X however dependences in the second loop nest require that each processor works on a row of array X. For there to be no communication, the entire array has to reside on the same processor, hence there

is no parallelism. We observe however that both loops are independently parallelizable

One way to parallelize the code is to have di erent processors work on di erent columns of the array in the $\,$ rst loop synchronize and wait for all processors to $\,$ nish and then operate on the individual rows. In this way all the computation in the algorithm can be parallelized with the introduction of just one synchronization operation. However, we note that while only one synchronization is performed this parallelization requires almost all the data in matrix X to be transferred between processors. It is possible to reduce the amount of communication by introducing more synchronizations, which we shall discuss in Section 11.9.9. \Box

It may appear that this approach is applicable only to programs consisting of a sequence of loop nests. However, we can create additional opportunities for the optimization through code transforms. We can apply loop, ssion to decompose loops in the original program into several smaller loops, which can then be parallelized individually by separating them with barriers. We illustrate this technique with Example 11 50.

Example 11 50 Consider the following loop

Without knowledge of the values in array A we must assume that the access in statement s_2 may write to any of the elements of W. Thus the instances of s_2 must be executed sequentially in the order they are executed in the original program

There is no synchronization free parallelism and Algorithm 11 43 will simply assign all the computation to the same processor. However, at the least instances of statement s_1 can be executed in parallel. We can parallelize part of this code by having different processors perform difference instances of state ment s_1 . Then in a separate sequential loop one processor say numbered 0 executes s_2 as in the SPMD code shown in Fig. 11 39.

11 8 2 Program Dependence Graphs

To nd all the parallelism made possible by a constant number of synchroniza tions we can apply ssion to the original program greedily Break up loops into as many separate loops as possible and then parallelize each loop indepen dently

To expose all the opportunities for loop—ssion—we use the abstraction of a program dependence graph—PDG—A program dependence graph of a program

11.8 SYNCHRONIZATION BETWEEN PARALLEL LOOPS

```
X p Y p Z p s1
  synchronization barrier
if p 0
  for i 1 i n i
  W A i X i s2
```

Figure 11 39 SPMD code for the loop in Example 11 50 with p being a variable holding the processor ID

is a graph whose nodes are the assignment statements of the program and whose edges capture the data dependences and the directions of the data dependence between statements. An edge from statement s_1 to statement s_2 exists whenever some dynamic instance of s_1 shares a data dependence with a *later* dynamic instance of s_2

To construct the PDG for a program we rst nd the data dependences between every pair of not necessarily distinct static accesses in every pair of not necessarily distinct statements. Suppose we determine that there is a dependence between access \mathcal{F}_1 in statement s_1 and access \mathcal{F}_2 in statement s_2 . Recall that an instance of a statement is specified by an index vector \mathbf{i} is the loop index of the kth outermost loop in which the statement is embedded

- 1 If there exists a data dependent pair of instances i_1 of s_1 and i_2 of s_2 and i_1 is executed before i_2 in the original program written i_1 s_1s_2 i_2 then there is an edge from s_1 to s_2
- 2 Similarly if there exists a data dependent pair of instances i_1 of s_1 and i_2 of s_2 and i_2 s_1s_2 i_1 then there is an edge from s_2 to s_1

Note that it is possible for a data dependence between two statements s_1 and s_2 to generate both an edge from s_1 to s_2 and an edge from s_2 back to s_1

In the special case where statements s_1 and s_2 are not distinct $\mathbf{i_1}$ s_1s_2 $\mathbf{i_2}$ if and only if $\mathbf{i_1}$ $\mathbf{i_2}$ $\mathbf{i_1}$ is lexicographically less than $\mathbf{i_2}$ In the general case s_1 and s_2 may be different statements possibly belonging to different loop nests

Example 11 51 For the program of Example 11 50 there are no dependences among the instances of statement s_1 However the *i*th instance of statement s_2 must follow the *i*th instance of statement s_1 Worse since the reference W A i may write any element of array W the *i*th instance of s_2 depends on all previous instances of s_2 That is statement s_2 depends on itself. The PDG for the program of Example 11 50 is shown in Fig. 11 40. Note that there is one cycle in the graph containing s_2 only.

The program dependence graph makes it easy to determine if we can split statements in a loop—Statements connected in a cycle in a PDG cannot be

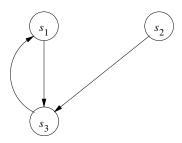

Figure 11 40 Program dependence graph for the program of Example 11 50

split If s_1 s_2 is a dependence between two statements in a cycle then some instance of s_1 must execute before some instance of s_2 and vice versa Note that this mutual dependence occurs only if s_1 and s_2 are embedded in some common loop Because of the mutual dependence we cannot execute all instances of one statement before the other and therefore loop ssion is not allowed. On the other hand if the dependence s_1 s_2 is unidirectional we can split up the loop and execute all the instances of s_1 rst then those of s_2

b Its dependence graph

Figure 11 41 Program and dependence graph for Example 11 52

Example 11 52 Figure 11 41 b shows the program dependence graph for the program of Fig 11 41 a Statements s_1 and s_3 belong to a cycle in the graph and therefore cannot be placed in separate loops. We can however split statement s_2 out and execute all its instances before executing the rest of the computation as in Fig 11 42. The rst loop is parallelizable but the second is not. We can parallelize the rst loop by placing barriers before and after its parallel execution.

11 8 3 Hierarchical Time

While the relation s_1s_2 can be very hard to compute in general there is a family of programs to which the optimizations of this section are commonly applied and for which there is a straightforward way to compute dependencies Assume that the program is block structured consisting of loops and simple arithmetic operations and no other control constructs. A statement in the program is either an assignment statement a sequence of statements or a loop construct whose body is a statement. The control structure thus represents a hierarchy. At the top of the hierarchy is the node representing the statement of the whole program. An assignment statement is a leaf node. If a statement is a sequence then its children are the statements within the sequence laid out from left to right according to their lexical order. If a statement is a loop, then its children are the components of the loop body which is typically a sequence of one or more statements.

Figure 11 43 A hierarchically structured program

Example 11 53 The hierarchical structure of the program in Fig 11 43 is shown in Fig 11 44 The hierarchical nature of the execution sequence is high

lighted in Fig. 11.45. The single instance of s_0 precedes all other operations because it is the rst statement executed. Next we execute all instructions from the rst iteration of the outer loop before those in the second iteration and so forth. For all dynamic instances whose loop index i has value 0, the statements s_1 L_2 L_3 and s_5 are executed in lexical order. We can repeat the same argument to generate the rest of the execution order.

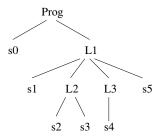

Figure 11 44 Hierarchical structure of the program in Example 11 53

1	s_0						
2	L_1	i	0	s_1			
3				L_2	j	0	s_2
4							s_3
5					j	1	s_2
6							s_3
7							
8				L_3	k	0	s_4
9					k	1	s_4
10							
11				s_5			
12		i	1	s_1			
13							

Figure 11 45 Execution order of the program in Example 11 53

We can resolve the ordering of two instances from two di erent statements in a hierarchical manner. If the statements share common loops we compare the values of their common loop indexes starting with the outermost loop. As soon as we indicate a di erence between their index values, the di erence determines the ordering. Only if the index values for the outer loops are the same do we need to compare the indexes of the next inner loop. This process is analogous to how we would compare time expressed in terms of hours minutes and seconds. To compare two times, we instrument the hours and only if they refer to

11 8 SYNCHRONIZATION BETWEEN PARALLEL LOOPS

the same hour would we compare the minutes and so forth If the index values are the same for all common loops then we resolve the order based on their relative lexical placement. Thus, the execution order for the simple nested loop programs we have been discussing is often referred to as hierarchical time.

Let s_1 be a statement nested in a d_1 deep loop and s_2 in a d_2 deep loop sharing d common outer loops note d d_1 and d d_2 certainly Suppose \mathbf{i} i_1 i_2 i_{d_1} is an instance of s_1 and \mathbf{j} j_1 j_2 j_{d_2} is an instance of s_2

 $\mathbf{i} \quad s_1 s_2 \mathbf{j}$ if and only if either

- $1 \quad i_1 \ i_2 \qquad i_d \qquad j_1 \ j_2 \qquad j_d \quad \text{or} \quad$
- $2 \quad i_1 \ i_2 \qquad i_d \quad j_1 \ j_2 \qquad j_d \ \ \text{and} \ s_1 \ \text{appears lexically before} \ s_2$

The predicate i_1 i_2 i_d j_1 j_2 j_d can be written as a disjunction of linear inequalities

$$i_1 \quad j_1 \quad i_1 \quad j_1 \quad i_2 \quad j_2 \qquad \qquad i_1 \quad j_1 \qquad \qquad i_{d-1} \quad j_{d-1} \quad i_d \quad j_d$$

A PDG edge from s_1 to s_2 exists as long as the data dependence condition and one of the disjunctive clauses can be made true simultaneously. Thus we may need to solve up to d or d-1 linear integer programs depending on whether s_1 appears lexically before s_2 to determine the existence of one edge

11 8 4 The Parallelization Algorithm

We now present a simple algorithm that rst splits up the computation into as many di erent loops as possible then parallelizes them independently

Algorithm 11 54 Maximize the degree of parallelism allowed by O 1 synchronizations

INPUT A program with array accesses

OUTPUT SPMD code with a constant number of synchronization barriers

METHOD

- 1 Construct the program dependence graph and partition the statements into strongly connected components SCCs Recall from Section 10 5 8 that a strongly connected component is a maximal subgraph of the original whose every node in the subgraph can reach every other node
- $2\,$ Transform the code to execute SCC s in a topological order by applying ssion if necessary
- 3 Apply Algorithm 11 43 to each SCC to nd all of its synchronization free parallelism Barriers are inserted before and after each parallelized SCC

While Algorithm 11 54 $\,$ nds all degrees of parallelism with O 1 $\,$ synchronizations it has a number of weaknesses. First it may introduce unnecessary synchronizations. As a matter of fact, if we apply this algorithm to a program that can be parallelized without synchronization, the algorithm will parallelize each statement independently and introduce a synchronization barrier between the parallel loops executing each statement. Second, while there may only be a constant number of synchronizations, the parallelization scheme may transfer a lot of data among processors with each synchronization. In some cases, the cost of communication makes the parallelism too expensive, and we may even be better of executing the program sequentially on a uniprocessor. In the following sections, we shall next take up ways to increase data locality, and thus reduce the amount of communication

119 Pipelining

In pipelining a task is decomposed into a number of stages to be performed on di erent processors. For example, a task computed using a loop of n iterations can be structured as a pipeline of n stages. Each stage is assigned to a different processor, when one processor is nished with its stage, the results are passed as input to the next processor in the pipeline.

In the following we start by explaining the concept of pipelining in more detail. We then show a real life numerical algorithm known as successive over relaxation to illustrate the conditions under which pipelining can be applied in Section 11.9.2. We then formally deniente constraints that need to be solved in Section 11.9.6 and describe an algorithm for solving them in Section 11.9.7. Programs that have multiple independent solutions to the time partition constraints are known as having outermost fully permutable loops such loops can be pipelined easily as discussed in Section 11.9.8.

11 9 1 What is Pipelining

Our initial attempts to parallelize loops partitioned the iterations of a loop nest so that two iterations that shared data were assigned to the same processor Pipelining allows processors to share data but generally does so only in a local way with data passed from one processor to another that is adjacent in the processor space. Here is a simple example

Example 11 55 Consider the loop

```
for i 1 i mi
for j 1 j n j
Xi Xi Yij
```

This code sums up the ith row of Y and adds it to the ith element of X. The inner loop—corresponding to the summation—must be performed sequentially

Time	Processors					
	1		2		3	
1	<i>X</i> 1	Y 1 1				
2	X 2	Y 2 1	X 1	Y 1 2		
3	X 3	$Y \ 3 \ 1$	X 2	Y 2 2	X 1	Y 1 3
4	X 4	Y 4 1	X 3	$Y \ 3 \ 2$	X 2	Y 2 3
5			X 4	Y 4 2	X 3	$Y \ 3 \ 3$
6					X 4	Y 43

Figure 11 49 Pipelined execution of Example 11 55 with m=4 and n=3

because of the data dependence 6 however the di erent summation tasks are independent. We can parallelize this code by having each processor perform a separate summation. Processor i accesses row i of Y and updates the ith element of X

Alternatively we can structure the processors to execute the summation in a pipeline and derive parallelism by overlapping the execution of the summations as shown in Fig 11 49. More speci cally each iteration of the inner loop can be treated as a stage of a pipeline stage j takes an element of X generated in the previous stage adds to it an element of Y and passes the result to the next stage. Notice that in this case each processor accesses a column instead of a row of Y. If Y is stored in column major form, there is a gain in locality by partitioning according to columns rather than by rows

We can initiate a new task as soon as the rst processor is done with the rst stage of the previous task. At the beginning the pipeline is empty and only the rst processor is executing the rst stage. After it completes the results are passed to the second processor while the rst processor starts on the second task and so on. In this way the pipeline gradually lls until all the processors are busy. When the rst processor nishes with the last task the pipeline starts to drain with more and more processors becoming idle until the last processor nishes the last task. In the steady state n tasks can be executed concurrently in a pipeline of n processors. \square

It is interesting to contrast pipelining with simple parallelism where di er ent processors execute di erent tasks

Pipelining can only be applied to nests of depth at least two We can treat each iteration of the outer loop as a task and the iterations in the inner loop as stages of that task

Tasks executed on a pipeline may share dependences Information per taining to the same stage of each task is held on the same processor thus results generated by the *i*th stage of a task can be used by the *i*th stage

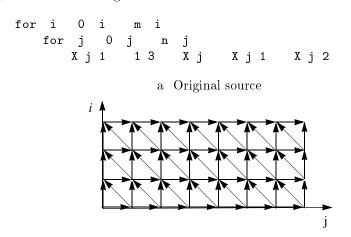

⁶Remember that we do not take advantage of the assumed commutativity and associativity of addition

of subsequent tasks with no communication cost Similarly each input data element used by a single stage of di erent tasks needs to reside only on one processor as illustrated by Example 11 55

If the tasks are independent then simple parallelization has better proces sor utilization because processors can execute all at once without having to pay for the overhead of lling and draining the pipeline However as shown in Example 11 55 the pattern of data accesses in a pipelined scheme is different from that of simple parallelization Pipelining may be preferable if it reduces communication

11 9 2 Successive Over Relaxation SOR An Example

Successive over relaxation SOR is a technique for accelerating the conver gence of relaxation methods for solving sets of simultaneous linear equations A relatively simple template illustrating its data access pattern is shown in Fig 11 50 a. Here the new value of an element in the array depends on the values of elements in its neighborhood. Such an operation is performed repeat edly until some convergence criterion is met

b Data dependences in the code

Figure 11 50 An example of successive over relaxation SOR

Shown in Fig 11 50 b is a picture of the key data dependences. We do not show dependences that can be inferred by the dependences already included in the gure For example iteration i j depends on iterations i j 1 i j 2 and so on. It is clear from the dependences that there is no synchronization free parallelism. Since the longest chain of dependences consists of O m n edges by introducing synchronization we should be able to and one degree of parallelism and execute the O mn operations in O m n unit time

In particular we observe that iterations that lie along the 150 diagonals⁷ in Fig 11 50 b do not share any dependences. They only depend on the iterations that lie along diagonals closer to the origin. Therefore we can parallelize this code by executing iterations on each diagonal in order starting at the origin and proceeding outwards. We refer to the iterations along each diagonal as a wavefront and such a parallelization scheme as wavefronting.

11 9 3 Fully Permutable Loops

We rst introduce the notion of full permutability a concept useful for pipelining and other optimizations. Loops are fully permutable if they can be permuted arbitrarily without changing the semantics of the original program. Once loops are put in a fully permutable form, we can easily pipeline the code and apply transformations such as blocking to improve data locality.

The SOR code as it written in Fig 11 50 a is not fully permutable. As shown in Section 11 7 8 permuting two loops means that iterations in the original iteration space are executed column by column instead of row by row. For instance, the original computation in iteration 2.3 would execute before that of 1.4 violating the dependences shown in Fig 11 50 b.

We can however transform the code to make it fully permutable $\mbox{Applying}$ the a \mbox{ne} transform

 $\begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix}$

to the code yields the code shown in Fig 11 51 a. This transformed code is fully permutable and its permuted version is shown in Fig 11 51 c. We also show the iteration space and data dependences of these two programs in Fig 11 51 b and d respectively. From the gure we can easily see that this ordering preserves the relative ordering between every data dependent pair of accesses

When we permute loops we change the set of operations executed in each iteration of the outermost loop drastically. The fact that we have this degree of freedom in scheduling means that there is a lot of slack in the ordering of operations in the program. Slack in scheduling means opportunities for parallelization. We show later in this section that if a nest has k outermost fully permutable loops by introducing just O n synchronizations we can get O k 1 degrees of parallelism n is the number of iterations in a loop

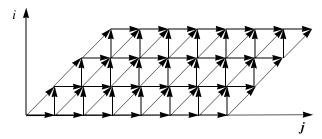

11 9 4 Pipelining Fully Permutable Loops

A loop with k outermost fully permutable loops can be structured as a pipeline with O(k-1) dimensions. In the SOR example k-2 so we can structure the processors as a linear pipeline

⁷I e the sequences of points formed by repeatedly moving down 1 and right 2

b Data dependences of the code in a

c A permutation of the loops in a

d Data dependences of the code in b

Figure 11 51 $\,$ Fully permutable version of the code Fig. 11 50 $\,$

We can pipeline the SOR code in two different ways shown in Fig. 11.52 a and Fig. 11.52 b corresponding to the two possible permutations shown in Fig. 11.51 a and c respectively. In each case every column of the iteration space constitutes a task and every row constitutes a stage. We assign stage i to processor i thus each processor executes the inner loop of the code. Ignoring boundary conditions a processor can execute iteration i only after processor p. 1 has executed iteration i.

```
0 p m
for j p j p n j
   if p 0 wait p 1
   X j p 1  1 3   X j p  X j p 1  X j p 2
   if p min m j signal p 1
```

a Processors assigned to rows

```
0
          m n
for i
      max 0 p
                i
                    min m p
  if p
         max 0 i
                 wait p 1
           1 3
  Xpi1
                 Хрі
                         Xpi1
                                  Xpi2
                р
                  i signal p 1
         m n
```

b Processors assigned to columns

Figure 11 52 Two pipelining implementations of the code from Fig. 11 51

Suppose every processor takes exactly the same amount of time to execute an iteration and synchronization happens instantaneously. Both these pipelined schemes would execute the same iterations in parallel the only difference is that they have different processor assignments. All the iterations executed in parallel lie along the 135 diagonals in the iteration space in Fig. 11.51 b which corresponds to the 150 diagonals in the iteration space of the original code see Fig. 11.50 b

However in practice processors with caches do not always execute the same code in the same amount of time and the time for synchronization also varies Unlike the use of synchronization barriers which forces all processors to operate in lockstep pipelining requires processors to synchronize and communicate with at most two other processors. Thus pipelining has relaxed wavefronts allowing some processors to surge ahead while others lag momentarily. This exibility reduces the time processors spend waiting for other processors and improves parallel performance.

The two pipelining schemes shown above are but two of the many ways in which the computation can be pipelined As we said once a loop is fully

permutable we have a lot of freedom in how we wish to parallelize the code The rst pipeline scheme maps iteration i j to processor i the second maps iteration i j to processor j We can create alternative pipelines by mapping iteration i j to processor c_0i c_1j provided c_0 and c_1 are positive constants Such a scheme would create pipelines with relaxed wavefronts between 90 and 180 both exclusive

1195 General Theory

The example just completed illustrates the following general theory underlying pipelining if we can come up with at least two di erent outermost loops for a loop nest and satisfy all the dependences then we can pipeline the computation A loop with k outermost fully permutable loops has k-1 degrees of pipelined parallelism

Loops that cannot be pipelined do not have alternative outermost loops Example 11 56 shows one such instance. To honor all the dependences each iteration in the outermost loop must execute precisely the computation found in the original code. However, such code may still contain parallelism in the inner loops which can be exploited by introducing at least n synchronizations where n is the number of iterations in the outermost loop.

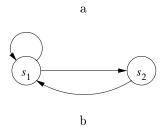

Figure 11 53 A sequential outer loop a and its PDG b

Example 11 56 Figure 11 53 is a more complex version of the problem we saw in Example 11 50 As shown in the program dependence graph in Fig 11 53 b statements s_1 and s_2 belong to the same strongly connected component Be cause we do not know the contents of matrix A we must assume that the access in statement s_2 may read from any of the elements of X. There is a true dependence from statement s_1 to statement s_2 and an antidependence from

statement s_2 to statement s_1 There is no opportunity for pipelining either because all operations belonging to iteration i in the outer loop must precede those in iteration i 1 To $\,$ nd more parallelism we repeat the parallelization process on the inner loop. The iterations in the second loop can be parallelized without synchronization. Thus 200 barriers are needed with one before and one after each execution of the inner loop.

11 9 6 Time Partition Constraints

We now focus on the problem of nding pipelined parallelism. Our goal is to turn a computation into a set of pipelinable tasks. To and pipelined parallelism we do not solve directly for what is to be executed on each processor like we did with loop parallelization. Instead we ask the following fundamental question. What are all the possible execution sequences that honor the original data dependences in the loop. Obviously the original execution sequence satistics estall the data dependences. The question is if there are an entransformations that can create an alternative schedule where iterations of the outermost loop execute a different set of operations from the original and yet all the dependences are satisted. If we cannot such transforms we can pipeline the loop. The key point is that if there is freedom in scheduling operations there is parallelism details of how we derive pipelined parallelism from such transforms will be explained later.

To nd acceptable reorderings of the outer loop we wish to nd one dimensional a ne transforms one for each statement that map the original loop index values to an iteration number in the outermost loop. The transforms are legal if the assignment can satisfy all the data dependences in the program. The time partition constraints shown below simply say that if one operation is dependent upon the other then the rst must be assigned an iteration in the outermost loop no earlier than that of the second. If they are assigned in the same iteration then it is understood that the rst will be executed after than the second within the iteration.

An a ne partition mapping of a program is a *legal time partition* if and only if for every two not necessarily distinct accesses sharing a dependence say

$$\mathcal{F}_1 \quad \langle \mathbf{F}_1 \ \mathbf{f}_1 \ \mathbf{B}_1 \ \mathbf{b}_1 \rangle$$

in statement s_1 which is nested in d_1 loops and

$$\mathcal{F}_2 = \langle \mathbf{F}_2 \ \mathbf{f}_2 \ \mathbf{B}_2 \ \mathbf{b}_2 \rangle$$

in statement s_2 nested in d_2 loops the one dimensional partition mappings $\langle \mathbf{C}_1 \ \mathbf{c}_1 \rangle$ and $\langle \mathbf{C}_2 \ \mathbf{c}_2 \rangle$ for statements s_1 and s_2 respectively satisfy the *time* partition constraints

For all \mathbf{i}_1 in Z^{d_1} and \mathbf{i}_2 in Z^{d_2} such that

a
$$\mathbf{i}_1$$
 s_1s_2 \mathbf{i}_2

This constraint illustrated in Fig 11 54 looks remarkably similar to the space partition constraints. It is a relaxation of the space partition constraints in that if two iterations refer to the same location, they do not necessarily have to be mapped to the same partition, we only require that the original relative execution order between the two iterations is preserved. That is, the constraints here have a where the space partition constraints have

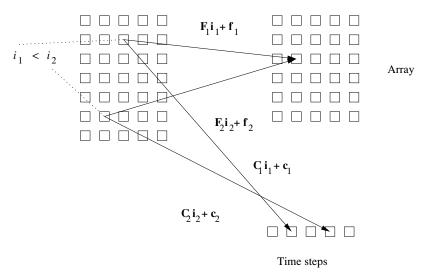

Figure 11 54 Time Partition Constraints

We know that there exists at least one solution to the time partition constraints. We can map operations in each iteration of the outermost loop back to the same iteration and all the data dependences will be satisfied. This solution is the only solution to the time partition constraints for programs that cannot be pipelined. On the other hand, if we can and several independent solutions to time partition constraints the program can be pipelined. Each independent solution corresponds to a loop in the outermost fully permutable nest. For instance, there is only one independent solution to the timing constraints extracted from the program in Example 11.56, where there is no pipelined par allelism. As another instance, there are two independent solutions to the SOR code example of Section 11.9.2

Example 11 57 Let us consider Example 11 56 and in particular the data dependences of references to array X in statements s_1 and s_2 Because the

access is not a ne in statement s_2 we approximate the access by modeling matrix X simply as a scalar variable in dependence analysis involving statement s_2 Let i j be the index value of a dynamic instance of s_1 and let i' be the index value of a dynamic instance of s_2 Let the computation mappings of statements s_1 and s_2 be $\langle C_{11} \ C_{12} \ c_1 \rangle$ and $\langle C_{21} \ c_2 \rangle$ respectively

Let us rst consider the time partition constraints imposed by dependences from statement s_1 to s_2 . Thus i if the transformed i j th iteration of s_1 must be no later than the transformed ith iteration of s_2 that is

$$C_{11}$$
 C_{12} $\stackrel{i}{j}$ c_1 $C_{21}i'$ c_2

Expanding we get

$$C_{11}i$$
 $C_{12}j$ c_1 $C_{21}i'$ c_2

Since j can be arbitrarily large independent of i and i' it must be that $C_{12} = 0$. Thus one possible solution to the constraints is

$$C_{11}$$
 C_{21} 1 and C_{12} c_1 c_2 0

Similar arguments about the data dependence from s_2 to s_1 and s_2 back to itself will yield a similar answer. In this particular solution, the ith iteration of the outer loop which consists of the instance i of s_2 and all instances i j of s_1 are all assigned to timestep i. Other legal choices of C_{11} , C_{21} , c_1 , and c_2 yield similar assignments although there might be timesteps at which nothing happens. That is all ways to schedule the outer loop require the iterations to execute in the same order as in the original code. This statement holds whether all 100 iterations are executed on the same processor on 100 different processors or anything in between.

Example 11 58 In the SOR code shown in Fig 11 50 a the write reference X j 1 shares a dependence with itself and with the three read references in the code. We are seeking computation mapping $\langle C_1 \ C_2 \ c \rangle$ for the assignment statement such that

if there is a dependence from i j to i' j' By de nition i j i' j' that is either i i' or i i' j j'

Let us consider three of the pairs of data dependences

1 True dependence from write access $X \ j$ 1 to read access $X \ j$ 2 Since the instances must access the same location j 1 j' 2 or j j' 1 Substituting j j' 1 into the timing constraints we get

$$C_1 i' i C_2 0$$

Since j j' 1 j j' the precedence constraints reduce to i i' Therefore

$$C_1$$
 C_2 0

2 Antidependence from read access X j 2 to write access X j 1 Here j 2 j' 1 or j j' 1 Substituting j j' 1 into the timing constraints we get

$$C_1 i' i C_2 0$$

When i = i' we get

$$C_2 = 0$$

When $i \quad i' \text{ since } C_2 \quad 0 \text{ we get}$

$$C_1 = 0$$

3 Output dependence from write access X j 1 back to itself. Here j j'. The timing constraints reduce to

$$C_1 i' i 0$$

Since only i = i' is relevant we again get

$$C_1 = 0$$

The rest of the dependences do not yield any new constraints In total there are three constraints

$$\begin{array}{ccc} C_1 & 0 \\ C_2 & 0 \\ C_1 & C_2 & 0 \end{array}$$

Here are two independent solutions to these constraints

$$\begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix}$$

The rst solution preserves the execution order of the iterations in the outer most loop. Both the original SOR code in Fig. 11 50 a and the transformed code shown in Fig. 11 51 a are examples of such an arrangement. The second solution places iterations lying along the 135 diagonals in the same outer loop. The code shown in Fig. 11 51 b is an example of a code with that outermost loop composition.

Notice that there are many other possible pairs of independent solutions For example

$$\begin{array}{ccc} 1 & 2 \\ 1 & 1 \end{array}$$

would also be independent solutions to the same constraints. We choose the simplest vectors to simplify code transformation \Box

11 9 7 Solving Time Partition Constraints by Farkas Lemma

Since time partition constraints are similar to space partition constraints can we use a similar algorithm to solve them Unfortunately the slight difference between the two problems translates into a big technical difference between the two solution methods Algorithm 11 43 simply solves for \mathbf{C}_1 \mathbf{c}_1 \mathbf{C}_2 and \mathbf{c}_2 such that for all \mathbf{i}_1 in Z^{d_1} and \mathbf{i}_2 in Z^{d_2} if

$$\mathbf{F}_1 \mathbf{i}_1 \quad \mathbf{f}_1 \quad \mathbf{F}_2 \mathbf{i}_2 \quad \mathbf{f}_2$$

then

$$\mathbf{C}_1 \mathbf{i}_1 \quad \mathbf{c}_1 \quad \mathbf{C}_2 \mathbf{i}_2 \quad \mathbf{c}_2$$

The linear inequalities due to the loop bounds are only used in determining if two references share a data dependence and are not used otherwise

To nd solutions to the time partition constraints we cannot ignore the linear inequalities \mathbf{i} i' ignoring them often would allow only the trivial so lution of placing all iterations in the same partition. Thus the algorithm to nd solutions to the time partition constraints must handle both equalities and inequalities

The general problem we wish to solve is given a matrix A and a vector c such that for all vectors x such that Ax 0 it is the case that c^Tx 0 In other words we are seeking c such that the inner product of c and any coordinates in the polyhedron de ned by the inequalities Ax 0 always yields a nonnegative answer

This problem is addressed by Farkas Lemma Let **A** be an m n matrix of reals and let **c** be a real nonzero n vector Farkas lemma says that either the primal system of inequalities

$$\mathbf{A}\mathbf{x} = \mathbf{0} \mathbf{c}^{\mathrm{T}}\mathbf{x} = \mathbf{0}$$

has a real valued solution \mathbf{x} or the dual system

$$\mathbf{A}^{\mathrm{T}}\mathbf{y}$$
 \mathbf{c} \mathbf{y} $\mathbf{0}$

has a real valued solution y but never both

The dual system can be handled by using Fourier Motzkin elimination to project away the variables of y. For each c that has a solution in the dual system the lemma guarantees that there are no solutions to the primal system. Put another way we can prove the negation of the primal system i.e. we can prove that $c^Tx = 0$ for all x such that Ax = 0 by inding a solution y to the dual system $A^Ty = c$ and y = 0

Algorithm 11 59 Finding a set of legal maximally independent a ne time partition mappings for an outer sequential loop

About Farkas Lemma

The proof of the lemma can be found in many standard texts on linear programming Farkas Lemma originally proved in 1901 is one of the theorems of the alternative These theorems are all equivalent but despite attempts over the years a simple intuitive proof for this lemma or any of its equivalents has not been found

INPUT A loop nest with array accesses

OUTPUT A maximal set of linearly independent time partition mappings

METHOD The following steps constitute the algorithm

- 1 Find all data dependent pairs of accesses in a program
- 2 For each pair of data dependent accesses \mathcal{F}_1 $\langle \mathbf{F}_1 \ \mathbf{f}_1 \ \mathbf{B}_1 \ \mathbf{b}_1 \rangle$ in state ment s_1 nested in d_1 loops and \mathcal{F}_2 $\langle \mathbf{F}_2 \ \mathbf{f}_2 \ \mathbf{B}_2 \ \mathbf{b}_2 \rangle$ in statement s_2 nested in d_2 loops let $\langle \mathbf{C}_1 \ c_1 \rangle$ and $\langle \mathbf{C}_2 \ c_2 \rangle$ be the unknown time partition mappings of statements s_1 and s_2 respectively Recall the time partition constraints state that

For all \mathbf{i}_1 in Z^{d_1} and \mathbf{i}_2 in Z^{d_2} such that

a
$$\mathbf{i}_1$$
 s_1s_2 \mathbf{i}_2

$$\mathbf{b} \quad \mathbf{B}_1 \mathbf{i}_1 \quad \mathbf{b}_1 \quad \mathbf{0}$$

c
$$\mathbf{B}_2 \mathbf{i}_2$$
 \mathbf{b}_2 $\mathbf{0}$ and

$$\mathbf{d} \quad \mathbf{F}_1 \mathbf{i}_1 \quad \mathbf{f}_1 \quad \mathbf{F}_2 \mathbf{i}_2 \quad \mathbf{f}_2$$

it is the case that $\mathbf{C}_1\mathbf{i}_1$ \mathbf{c}_1 $\mathbf{C}_2\mathbf{i}_2$ \mathbf{c}_2

Since $\mathbf{i}_1 \quad s_1 s_2 \quad \mathbf{i}_2$ is a disjunctive union of a number of clauses we can create a system of constraints for each clause and solve each of them separately as follows

a Similarly to step 2a in Algorithm 11 43 apply Gaussian elimination to the equations

$$\mathbf{F}_1 \mathbf{i}_1 \quad \mathbf{f}_1 \quad \mathbf{F}_2 \mathbf{i}_2 \quad \mathbf{f}_2$$

to reduce the vector

$$\left[egin{array}{c} \mathbf{i}_1 \ \mathbf{i}_2 \ 1 \end{array}
ight]$$

to some vector of unknowns \mathbf{x}

b Let c be all the unknowns in the partition mappings Express the linear inequality constraints due to the partition mappings as

$$\mathbf{c}^{\mathrm{T}}\mathbf{D}\mathbf{x} = \mathbf{0}$$

for some matrix **D**

c Express the precedence constraints on the loop index variables and the loop bounds as

$$\mathbf{A}\mathbf{x} = \mathbf{0}$$

for some matrix A

d Apply Farkas Lemma Finding \mathbf{x} to satisfy the two constraints above is equivalent to \mathbf{x} nding \mathbf{y} such that

$$\mathbf{A}^{\mathrm{T}}\mathbf{y} \quad \mathbf{D}^{\mathrm{T}}\mathbf{c} \text{ and } \mathbf{y} \quad \mathbf{0}$$

Note that $\mathbf{c}^T \mathbf{D}$ here is \mathbf{c}^T in the statement of Farkas Lemma and we are using the negated form of the lemma

- e In this form apply Fourier Motzkin elimination to project away the y variables and express the constraints on the coe cients c as Ec 0
- f Let $\mathbf{E}'\mathbf{c}'$ 0 be the system without the constant terms
- 3 Find a maximal set of linearly independent solutions to $\mathbf{E}'\mathbf{c}'$ 0 using Algorithm B 1 in Appendix B The approach of that complex algorithm is to keep track of the current set of solutions for each of the statements then incrementally look for more independent solutions by inserting constraints that force the solution to be linearly independent for at least one statement
- 4 From each solution of \mathbf{c}' found derive one a ne time partition mapping The constant terms are derived using $\mathbf{E}\mathbf{c} = \mathbf{0}$

Example 11 60 The constraints for Example 11 57 can be written as

$$C_{11}$$
 C_{12} C_{21} c_2 c_1 $\left[egin{array}{c} i \ j \ i' \ 1 \end{array}
ight]$ $oldsymbol{0}$

Farkas lemma says that these constraints are equivalent to

$$\begin{bmatrix} 1 \\ 0 \\ 1 \\ 0 \end{bmatrix} \quad z \quad \begin{bmatrix} C_{11} \\ C_{12} \\ C_{21} \\ c_2 & c_1 \end{bmatrix} \text{ and } z \quad 0$$

Solving this system we get

$$C_{11}$$
 C_{21} 0 and C_{12} c_2 c_1 0

Notice that these constraints are satis ed by the particular solution we obtained in Example 11 57 $\quad \Box$

11 9 8 Code Transformations

If there exist k independent solutions to the time partition constraints of a loop nest then it is possible to transform the loop nest to have k outermost fully permutable loops which can be transformed to create k-1 degrees of pipelining or to create k-1 inner parallelizable loops. Furthermore, we can apply blocking to fully permutable loops to improve data locality of uniprocessors as well as reducing synchronization among processors in a parallel execution

Exploiting Fully Permutable Loops

We can create a loop nest with k outermost fully permutable loops easily from k independent solutions to the time partition constraints. We can do so by simply making the kth solution the kth row of the new transform. Once the a netransform is created Algorithm 11 45 can be used to generate the code

Example 11 61 The solutions found in Example 11 58 for our SOR example were

$$\begin{array}{ccc} 1 & & 1 \\ 0 & & 1 \end{array}$$

Making the rst solution the rst row and the second solution the second row we get the transform

$$\begin{array}{cc} 1 & 0 \\ 1 & 1 \end{array}$$

which yields the code in Fig 11 51 a

Making the second solution the rst row instead we get the transform

$$\begin{array}{cc} 1 & 1 \\ 1 & 0 \end{array}$$

which yields the code in Fig. 11 51 c \Box

It is easy to see that such transforms produce a legal sequential program. The rst row partitions the entire iteration space according to the rst solution. The timing constraints guarantee that such a decomposition does not violate any data dependences. Then we partition the iterations in each of the outer most loop according to the second solution. Again this must be legal because we are dealing with just subsets of the original iteration space. The same goes for the rest of the rows in the matrix. Since we can order the solutions arbitrarily the loops are fully permutable.

Exploiting Pipelining

We can easily transform a loop with k outermost fully permutable loops into a code with k-1 degrees of pipeline parallelism

Example 11 62 Let us return to our SOR example. After the loops are transformed to be fully permutable, we know that iteration i_1 i_2 can be executed provided iterations i_1 i_2 1 and i_1 1 i_2 have been executed. We can guarantee this order in a pipeline as follows. We assign iteration i_1 to processor p_1 . Each processor executes iterations in the inner loop in the original sequential order thus guaranteeing that iteration i_1 i_2 executes after i_1 i_2 1. In addition, we require that processor p waits for the signal from processor p 1 that it has executed iteration p 1 i_2 before it executes iteration p i_2 . This technique generates the pipelined code Fig. 11.52 a and b from the fully permutable loops. Fig. 11.51 a and c respectively.

In general given k outermost fully permutable loops the iteration with index values i_1 i_k can be executed without violating data dependence constraints provided iterations

$$i_1 \quad 1 \quad i_2 \qquad i_k \quad i_1 \quad i_2 \quad 1 \quad i_3 \qquad i_k \qquad \qquad i_1 \qquad \quad i_{k-1} \quad i_k \quad 1$$

have been executed. We can thus assign the partitions of the rst k-1 dimensions of the iteration space to $O(n^{k-1})$ processors as follows. Each processor is responsible for one set of iterations whose indexes agree in the rst k-1 dimensions and vary over all values of the kth index. Each processor executes the iterations in the kth loop sequentially. The processor corresponding to values $p_1-p_2-p_{k-1}$ for the rst k-1 loop indexes can execute iteration i in the kth loop as long as it receives a signal from processors

$$p_1 \quad 1 \quad p_2 \qquad p_{k-1} \qquad p_1 \qquad p_{k-2} \quad p_{k-1} \quad 1$$

that they have executed their ith iteration in the kth loop

Wavefronting

It is also easy to generate k-1 inner parallelizable loops from a loop with k outermost fully permutable loops. Although pipelining is preferable, we include this information here for completeness

We partition the computation of a loop with k outermost fully permutable loops using a new index variable i' where i' is defined to be some combination of all the indices in the k permutable loop nest. For example i' i_1 i_k is one such combination

We create an outermost sequential loop that iterates through the i^\prime partitions in increasing order the computation nested within each partition is ordered as before. The rst k-1 loops within each partition are guaranteed to be parallelizable. Intuitively if given a two dimensional iteration space, this transform groups iterations along 135 diagonals as an execution of the outer most loop. This strategy guarantees that iterations within each iteration of the outermost loop have no data dependence

Blocking

A k deep fully permutable loop nest can be blocked in k dimensions. Instead of assigning the iterations to processors based on the value of the outer or inner loop indexes we can aggregate blocks of iterations into one unit. Blocking is useful for enhancing data locality as well as for minimizing the overhead of pipelining

Suppose we have a two dimensional fully permutable loop nest as in Fig 11 55 a and we wish to break the computation into b b blocks. The execution order of the blocked code is shown in Fig. 11 56 and the equivalent code is in Fig. 11 55 b

If we assign each block to one processor then all the passing of data from one iteration to another that is within a block requires no interprocessor communication. Alternatively, we can coarsen the granularity of pipelining by assigning a column of blocks to one processor. Notice that each processor synchronizes with its predecessors and successors only at block boundaries. Thus, another advantage of blocking is that programs only need to communicate data accessed at the boundaries of the block with their neighbor blocks. Values that are interior to a block are managed by only one processor.

Example 11 63 We now use a real numerical algorithm Cholesky decom position to illustrate how Algorithm 11 59 handles single loop nests with only pipelining parallelism. The code shown in Fig. 11 57 implements an O n^3 algorithm operating on a 2 dimensional data array. The executed iteration space is a triangular pyramid since j only iterates up to the value of the outer loop index i and k only iterates to the value of j. The loop has four statements all nested in different loops

Applying Algorithm 11 59 to this program —nds three legitimate time dimensions—It nests all the operations—some of which were originally nested in 1 and 2 deep loop nests into a 3 dimensional fully permutable loop nest—The code together with the mappings—is shown in Fig. 11 58

The code generation routine guards the execution of the operations with the original loop bounds to ensure that the new programs execute only operations

that are in the original code We can pipeline this code by mapping the 3 dimensional structure to a 2 dimensional processor space. Iterations $i2\ j2\ k2$ are assigned to the processor with ID $i2\ j2$. Each processor executes the innermost loop the loop with the index k2. Before it executes the kth iteration the processor waits for signals from the processors with ID s. i2 1 j2 and $i2\ j2$ 1. After it executes its iteration it signals processors i2 1 j2 and $i2\ j2$ 1. \Box

11 9 9 Parallelism With Minimum Synchronization

We have described three powerful parallelization algorithms in the last three sections. Algorithm 11 43 ands all parallelism requiring no synchronizations. Algorithm 11 54 ands all parallelism requiring only a constant number of synchronizations and Algorithm 11 59 ands all the pipelinable parallelism requiring O(n) synchronizations where n is the number of iterations in the outermost loop. As a rst approximation our goal is to parallelize as much of the computation as possible while introducing as little synchronization as necessary.

Algorithm 11 64 below nds all the degrees of parallelism in a program starting with the coarsest granularity of parallelism. In practice to parallelize a code for a multiprocessor we do not need to exploit all the levels of parallelism just the outermost possible ones until all the computation is parallelized and all the processors are fully utilized.

Algorithm 11 64 Find all the degrees of parallelism in a program with all the parallelism being as coarse grained as possible

INPUT A program to be parallelized

OUTPUT A parallelized version of the same program

METHOD Do the following

- 1 Find the maximum degree of parallelism requiring no synchronization Apply Algorithm 11 43 to the program
- 2 Find the maximum degree of parallelism that requires O 1 synchronizations Apply Algorithm 11 54 to each of the space partitions found in step 1 If no synchronization free parallelism is found the whole computation is left in one partition
- 3 Find the maximum degree of parallelism that requires O n synchronizations Apply Algorithm 11 59 to each of the partitions found in step 2 to nd pipelined parallelism. Then apply Algorithm 11 54 to each of the partitions assigned to each processor or the body of the sequential loop if no pipelining is found.
- 4 Find the maximum degree of parallelism with successively greater degrees of synchronizations Recursively apply Step 3 to computation belonging to each of the space partitions generated by the previous step

Example 11 65 Let us now return to Example 11 56 No parallelism is found by Steps 1 and 2 of Algorithm 11 64 that is we need more than a constant number of synchronizations to parallelize this code In Step 3 applying Algorithm 11 59 determines that there is only one legal outer loop which is the one in the original code of Fig 11 53 So the loop has no pipelined parallelism In the second part of Step 3 we apply Algorithm 11 54 to parallelize the inner loop. We treat the code within a partition like a whole program the only di erence being that the partition number is treated like a symbolic constant. In this case the inner loop is found to be parallelizable and therefore the code can be parallelized with n synchronization barriers.

Algorithm 11 64 nds all the parallelism in a program at each level of syn chronization. The algorithm prefers parallelization schemes that have less syn chronization but less synchronization does not mean that the communication is minimized. Here we discuss two extensions to the algorithm to address its weaknesses.

Considering Communication Cost

Step 2 of Algorithm 11 64 parallelizes each strongly connected component in dependently if no synchronization free parallelism is found. However, it may be possible to parallelize a number of the components without synchronization and communication. One solution is to greedily, and synchronization free parallelism among subsets of the program dependence graph that share the most data

If communication is necessary between strongly connected components we note that some communication is more expensive than others. For example the cost of transposing a matrix is significantly higher than just having to communicate between neighboring processors. Suppose s_1 and s_2 are statements in two separate strongly connected components accessing the same data in iterations \mathbf{i}_1 and \mathbf{i}_2 respectively. If we cannot and partition mappings $\langle \mathbf{C}_1 \ \mathbf{c}_1 \rangle$ and $\langle \mathbf{C}_2 \ \mathbf{c}_2 \rangle$ for statements s_1 and s_2 respectively such that

$$\mathbf{C}_1\mathbf{i}_1 \quad \mathbf{c}_1 \quad \mathbf{C}_2\mathbf{i}_2 \quad \mathbf{c}_2 \quad \mathbf{0}$$

we instead try to satisfy the constraint

$$\mathbf{C}_1\mathbf{i}_1 \quad \mathbf{c}_1 \quad \mathbf{C}_2\mathbf{i}_2 \quad \mathbf{c}_2$$

where is a small constant

Trading Communication for Synchronization

Sometimes we would rather perform more synchronizations to minimize communication Example 11 66 discusses one such example Thus if we cannot

parallelize a code with just neighborhood communication among strongly con nected components we should attempt to pipeline the computation instead of parallelizing each component independently. As shown in Example 11 66 pipelining can be applied to a sequence of loops

Example 11 66 For the ADI integration algorithm in Example 11 49 we have shown that optimizing the rst and second loop nests independently nds parallelism in each of the nests. However, such a scheme would require that the matrix be transposed between the loops incurring $O(n^2)$ data transposed between the loops incurring $O(n^2)$ data transposed between the loops incurring $O(n^2)$ data transposed between the loop and parallelism, we note that the entire program into a fully permutable loop nest as in Fig. 11 59. We then can apply blocking to reduce the communication overhead. This scheme would incur O(n) synchronizations but would require much less communication.

```
for j 0 j n j
  for i 1 i n 1 i
    if i n X i j f X i j X i 1 j
    if j 0 X i 1 j g X i 1 j X i 1 j 1
```

11 9 10 Exercises for Section 11 9

Exercise 11 9 1 In Section 11 9 4 we discussed the possibility of using di agonals other than the horizontal and vertical axes to pipeline the code of Fig 11 51 Write code analogous to the loops of Fig 11 52 for the diagonals a 135 b 120

Exercise 11 9 2 Figure 11 55 b can be simplified if b divides n evenly Rewrite the code under that assumption

Figure 11 60 Computing Pascal's triangle

Exercise 11 9 3 In Fig 11 60 is a program to compute the rst 100 rows of Pascal's triangle. That is $P \ i \ j$ will become the number of ways to choose j things out of i for $0 \ j \ i \ 100$

- a Rewrite the code as a single fully permutable loop nest
- b Use 100 processors in a pipeline to implement this code Write the code for each processor p in terms of p and indicate the synchronization necessary
- c Rewrite the code using square blocks of 10 iterations on a side Since the iterations form a triangle there will be only 1 2 10 55 blocks Show the code for a processor p_1 p_2 assigned to the p_1 th block in the i direction and the p_2 th block in the j direction in terms of p_1 and p_2

```
for i 0 i 100 1
   A i 0 0
              B1 i
                        s1
   A i 99 0
              B2 i
                        s2
for j 1 j 99
              j
   А ОјО
              ВЗ ј
                        s3
   A 99 j 0
              B4 j
for i 0 i 99 i
   for j 0 j 99 j
       for k 1 k 100
                     k
          Aijk
                     Aijk1
                                 Ai1jk1
              A i 1 j k 1
                           A i j 1 k 1
              A i j 1 k 1
                                 s5
```

Figure 11 61 Code for Exercise 11 9 4

Exercise 11 9 4 Repeat Exercise 11 9 2 for the code of Fig 11 61 However note that the iterations for this problem form a 3 dimensional cube of side 100 Thus the blocks for part c should be 10 10 10 and there are 1000 of them

Exercise 11 9 5 Let us apply Algorithm 11 59 to a simple example of the time partition constraints In what follows assume that the vector \mathbf{i}_1 is i_1 j_1 and vector \mathbf{i}_2 is i_2 j_2 technically both these vectors are transposed. The condition \mathbf{i}_1 s_1s_2 \mathbf{i}_2 consists of the following disjunction

```
i \quad i_1 \quad i_2 \text{ or} ii \quad i_1 \quad i_2 \text{ and } j_1 \quad j_2
```

The other equalities and inequalities are

Finally the time partition inequality with unknowns c_1 d_1 e_1 c_2 d_2 and e_2 is

$$c_1 i_1 \quad d_1 j_1 \quad e_1 \quad c_2 i_2 \quad d_2 j_2 \quad e_2$$

- a Solve the time partition constraints for case i that is where i_1 i_2 In particular eliminate as many of i_1 j_1 i_2 and j_2 as you can and set up the matrices D and A as in Algorithm 11 59 Then apply Farkas Lemma to the resulting matrix inequalities
- b Repeat part a for the case ii where i_1 i_2 and j_1 j_2

11 10 Locality Optimizations

The performance of a processor be it a part of a multiprocessor or not is highly sensitive to its cache behavior Misses in the cache can take tens of clock cycles so high cache miss rates can lead to poor processor performance. In the context of a multiprocessor with a common memory bus contention on the bus can further add to the penalty of poor data locality.

As we shall see even if we just wish to improve the locality of uniprocessors the a ne partitioning algorithm for parallelization is useful as a means of iden tifying opportunities for loop transformations. In this section we describe three techniques for improving data locality in uniprocessors and multiprocessors

- 1 We improve the temporal locality of computed results by trying to use the results as soon as they are generated. We do so by dividing a computation into independent partitions and executing all the dependent operations in each partition close together.
- 2 Array contraction reduces the dimensions of an array and reduces the number of memory locations accessed We can apply array contraction if only one location of the array is used at a given time
- 3 Besides improving temporal locality of computed results we also need to optimize for the spatial locality of computed results and for both the temporal and spatial locality of read only data Instead of executing each partition one after the other we interleave a number of the partitions so that reuses among partitions occur close together

11 10 1 Temporal Locality of Computed Data

The a ne partitioning algorithm pulls all the dependent operations together by executing these partitions serially we improve temporal locality of computed data. Let us return to the multigrid example discussed in Section 11.7.1. Applying Algorithm 11.43 to parallelize the code in Fig. 11.23 and two degrees of parallelism. The code in Fig. 11.24 contains two outer loops that iterate through the independent partitions serially. This transformed code has improved temporal locality since computed results are used immediately in the same iteration.

Thus even if our goal is to optimize for sequential execution it is protable to use parallelization to and these related operations and place them together. The algorithm we use here is similar to that of Algorithm 11 64 which and the granularities of parallelism starting with the outermost loop. As discussed in Section 11 9 9, the algorithm parallelizes strongly connected components in dividually if we cannot and synchronization free parallelism at each level. This parallelization tends to increase communication. Thus, we combine separately parallelized strongly connected components greedily if they share reuse.

11 10 2 Array Contraction

The optimization of array contraction provides another illustration of the trade o between storage and parallelism which was rst introduced in the context of instruction level parallelism in Section 10 2 3 Just as using more registers al lows for more instruction level parallelism using more memory allows for more loop level parallelism. As shown in the multigrid example in Section 11 7 1 expanding a temporary scalar variable into an array allows dierent iterations to keep dierent instances of the temporary variables and to execute at the same time. Conversely when we have a sequential execution that operates on one array element at a time serially we can contract the array replace it with a scalar and have each iteration use the same location.

In the transformed multigrid program shown in Fig. 11 24 each iteration of the inner loop produces and consumes a different element of AP AM T and a row of D. If these arrays are not used outside of the code excerpt, the iterations can serially reuse the same data storage instead of putting the values in different elements and rows respectively. Figure 11 62 shows the result of reducing the dimensionality of the arrays. This code runs faster than the original because it reads and writes less data. Especially in the case when an array is reduced to a scalar variable, we can allocate the variable to a register and eliminate the need to access memory altogether.

As less storage is used less parallelism is available. Iterations in the transformed code in Fig. 11.62 now share data dependences and no longer can be executed in parallel. To parallelize the code on P processors, we can expand each of the scalar variables by a factor of P and have each processor access its own private copy. Thus, the amount by which the storage is expanded is

```

Figure 11 62 Code of Fig 11 23 after partitioning Fig 11 24 and array contraction

directly correlated to the amount of parallelism exploited

There are three reasons it is common to $\,$ nd opportunities for array contraction

- 1 Higher level programming languages for scienti c applications such as Matlab and Fortran 90 support array level operations. Each subexpres sion of array operations produces a temporary array. Because the arrays can be large every array operation such as a multiply or add would require reading and writing many memory locations while requiring relatively few arithmetic operations. It is important that we reorder operations so that data is consumed as it is produced and that we contract these arrays into scalar variables.
- 2 Supercomputers built in the 80 s and 90 s are all vector machines so many scientic applications developed then have been optimized for such machines. Even though vectorizing compilers exist many programmers still write their code to operate on vectors at a time. The multigrid code example of this chapter is an example of this style.
- 3 Opportunities for contraction are also introduced by the compiler As illustrated by variable T in the multigrid example a compiler would ex pand arrays to improve parallelization. We have to contract them when the space expansion is not necessary

Example 11 67 The array expression Z = W = X = Y translates to

11 10 LOCALITY OPTIMIZATIONS

```
for i 0 in i Ti Wi Xi for i 0 in i Zi Ti Yi
```

Rewriting the code as

```
for i O i n i T W i X i Z i T Y i
```

can speed it up considerably. Of course at the level of C code, we would not even have to use the temporary T but could write the assignment to Z i as a single statement. However, here we are trying to model the intermediate code level at which a vector processor would deal with the operations.

Algorithm 11 68 Array contraction

INPUT A program transformed by Algorithm 11 64

OUTPUT An equivalent program with reduced array dimensions

METHOD A dimension of an array can be contracted to a single element if

- 1 Each independent partition uses only one element of the array
- 2 The value of the element upon entry to the partition is not used by the partition and
- 3 The value of the element is not live on exit from the partition

Identify the contractable dimensions — those that satisfy the three conditions above — and replace them with a single element — \Box

Algorithm 11 68 assumes that the program has rst been transformed by Al gorithm 11 64 to pull all the dependent operations into a partition and execute the partitions sequentially. It inds those array variables whose elements live ranges in different iterations are disjoint. If these variables are not live after the loop it contracts the array and has the processor operate on the same scalar location. After array contraction, it may be necessary to selectively expand arrays to accommodate for parallelism and other locality optimizations.

The liveness analysis required here is more complex than that described in Section 9 2 5 If the array is declared as a global variable or if it is a parameter interprocedural analysis is required to ensure that the value on exit is not used Furthermore we need to compute the liveness of individual array elements conservatively treating the array as a scalar would be too imprecise

11 10 3 Partition Interleaving

Di erent partitions in a loop often read the same data or read and write the same cache lines In this and the next two sections we discuss how to optimize for locality when reuse is found across partitions

Reuse in Innermost Blocks

We adopt the simple model that data can be found in the cache if it is reused within a small number of iterations. If the innermost loop has a large or un known bound only reuse across iterations of the innermost loop translates into a locality bene to Blocking creates inner loops with small known bounds allowing reuse within and across entire blocks of computation to be exploited. Thus, blocking has the elect of capitalizing on more dimensions of reuse

Example 11 69 Consider the matrix multiply code shown in Fig. 11 5 and its blocked version in Fig. 11 7. Matrix multiplication has reuse along every dimension of its three dimensional iteration space. In the original code, the in nermost loop has n iterations where n is unknown and can be large. Our simple model assumes that only the data reused across iterations in the innermost loop is found in the cache.

In the blocked version the three innermost loops execute a three dimension al block of computation with B iterations on each side. The block size B is chosen by the compiler to be small enough so that all the cache lines read and written within the block of computation. t into the cache. Thus reused data across iterations in the third outermost loop can be found in the cache.

We refer to the innermost set of loops with small known bounds as the *inner most block* It is desirable that the innermost block include all the dimensions of the iteration space that carry reuse if possible Maximizing the lengths of each side of the block is not as important. For the matrix multiply example 3 dimensional blocking reduces the amount of data accessed for each matrix by a factor of B^2 . If reuse is present it is better to accommodate higher dimensional blocks with shorter sides than lower dimensional blocks with longer sides

We can optimize locality of the innermost fully permutable loop nest by blocking the subset of loops that share reuse. We can generalize the notion of blocking to exploit reuses found among iterations of outer parallel loops also. Observe that blocking primarily interleaves the execution of a small number of instances of the innermost loop. In matrix multiplication, each instance of the innermost loop computes one element of the array answer there are n^2 of them. Blocking interleaves the execution of a block of instances computing B iterations from each instance at a time. Similarly, we can interleave iterations in parallel loops to take advantage of reuses between them

We de ne two primitives below that can reduce the distance between reuses across di erent iterations. We apply these primitives repeatedly starting from the outermost loop until all the reuses are moved adjacent to each other in the innermost block.

Interleaving Inner Loops in a Parallel Loop

Consider the case where an outer parallelizable loop contains an inner loop To exploit reuse across iterations of the outer loop we interleave the executions of

11 10 LOCALITY OPTIMIZATIONS

a xed number of instances of the inner loop as shown in Fig 11 63 Creating two dimensional inner blocks this transformation reduces the distance between reuse of consecutive iterations of the outer loop

```

S
```

a Source program

b Transformed code

Figure 11 63 Interleaving 4 instances of the inner loop

The step that turns a loop

into

is known as *stripmining* In the case where the outer loop in Fig. 11 63 has a small known bound we need not stripmine it but can simply permute the two loops in the original program

Interleaving Statements in a Parallel Loop

Consider the case where a parallelizable loop contains a sequence of statements $s_1 \ s_2 \ s_m$ If some of these statements are loops themselves statements from consecutive iterations may still be separated by many operations. We can exploit reuse between iterations by again interleaving their executions as shown in Fig. 11.64. This transformation distributes a stripmined loop across the statements. Again if the outer loop has a small exed number of iterations we need not stripmine the loop but simply distribute the original loop over all the statements

We use s_i j to denote the execution of statement s_i in iteration j Instead of the original sequential execution order shown in Fig. 11.65 a the code executes in the order shown in Fig. 11.65 b

Example 11 70 We now return to the multigrid example and show how we exploit reuse between iterations of outer parallel loops. We observe that references $DW \ 1 \ k \ j \ i \ DW \ 1 \ k \ 1 \ j \ i$ and $DW \ 1 \ k \ 1 \ j \ i$ in the innermost loops of the code in Fig. 11 62 have rather poor spatial locality. From reuse analysis as discussed in Section 11 5 the loop with index i carries spatial

```

for i ii i min n ii 4 i
S2
```

a Source program

b Transformed code

Figure 11 64 The statement interleaving transformation

locality and the loop with index k carries group reuse. The loop with index k is already the innermost loop, so we are interested in interleaving operations on DW from a block of partitions with consecutive i values

We apply the transform to interleave statements in the loop to obtain the code in Fig 11 66 then apply the transform to interleave inner loops to obtain the code in Fig 11 67 Notice that as we interleave B iterations from loop with index i we need to expand variables AP AM T into arrays that hold B results at a time \Box

11 11 Other Uses of A ne Transforms

So far we have focused on the architecture of shared memory machines but the theory of a ne loop transforms has many other applications. We can ap ply a ne transforms to other forms of parallelism including distributed memory

machines vector instructions SIMD Single Instruction Multiple Data instructions as well as multiple instruction issue machines. The reuse analysis introduced in this chapter also is useful for data *prefetching* which is an elective technique for improving memory performance.

11 11 1 Distributed Memory Machines

For distributed memory machines where processors communicate by sending messages to each other it is even more important that processors be assigned large independent units of computation such as those generated by the a ne partitioning algorithm Besides computation partitioning a number of additional compilation issues remain

- 1 Data allocation If processors use di erent portions of an array they each only have to allocate enough space to hold the portion used We can use projection to determine the section of arrays used by each processor. The input is the system of linear inequalities representing the loop bounds the array access functions and the an empartitions that map the iterations to processor IDs. We project away the loop indices and and for each processor ID the set of array locations used
- 2 Communication code We need to generate explicit code to send and receive data to and from other processors At each synchronization point
 - a Determine the data residing on one processor that is needed by other processors
 - b Generate the code that nds all the data to be sent and packs it into a bu er
 - c Similarly determine the data needed by the processor unpack re ceived messages and move the data to the right memory locations

Again if all accesses are a ne these tasks can be performed by the compiler using the a ne framework

3 Optimization It is not necessary for all the communications to take place at the synchronization points. It is preferable that each processor sends data as soon as it is available and that each processor does not start waiting for data until it is needed. Such optimizations must be balanced by the goal of not generating too many messages since there is a nontrivial overhead associated with processing each message.

Techniques described here have other applications as well For example a special purpose embedded system may use coprocessors to o oad some of its computations. Or instead of demand fetching data into the cache an embedded system may use a separate controller to load and unload data into and out of the cache or other data but ers while the processor operates on other data. In these cases similar techniques can be used to generate the code to move data around

11 11 2 Multi Instruction Issue Processors

We can also use a ne loop transforms to optimize the performance of multi instruction issue machines. As discussed in Section 10.5 the performance of a software pipelined loop is limited by two factors cycles in precedence constraints and the usage of the critical resource. By changing the makeup of the innermost loop, we can improve these limits

First we may be able to use loop transforms to create innermost paralleliz able loops thus eliminating precedence cycles altogether. Suppose a program has two loops with the outer being parallelizable and the inner not. We can permute the two loops to make the inner loop parallelizable and so create more opportunities for instruction level parallelism. Notice that it is not necessary for iterations in the innermost loop to be completely parallelizable. It is su cient that the cycle of dependences in the loop be short enough so that all the hardware resources are fully utilized.

We can also relax the limit due to resource usage by improving the usage balance inside a loop Suppose one loop only uses the adder and another uses only the multiplier. Or suppose one loop is memory bound and another is compute bound. It is desirable to fuse each pair of loops in these examples together so as to utilize all the functional units at the same time

11 11 3 Vector and SIMD Instructions

Besides multiple instruction issue there are two other important forms of in struction level parallelism—vector and SIMD operations—In both cases—the issue of just one instruction causes the same operation to be applied to a vector of data

As mentioned previously many early supercomputers used vector instructions. Vector operations are performed in a pipelined manner, the elements in the vector are fetched serially and computations on different elements are overlapped. In advanced vector machines, vector operations can be *chained* as the elements of the vector results are produced, they are immediately consumed by operations of another vector instruction without having to wait for all the results to be ready. Moreover, in advanced machines with *scatter gather* hardware, the elements of the vectors need not be contiguous, an index vector is used to specify where the elements are located.

SIMD instructions specify that the same operation be performed on contiguous memory locations. These instructions load data from memory in parallel store them in wide registers and compute on them using parallel hardware. Many media graphics and digital signal processing applications can bene to from these operations. Low end media processors can achieve instruction level parallelism simply by issuing one SIMD instruction at a time. Higher end processors can combine SIMD with multiple instruction issue to achieve higher performance.

SIMD and vector instruction generation share many similarities with locality

optimization As we nd independent partitions that operate on contiguous memory locations we stripmine those iterations and interleave these operations in innermost loops

SIMD instruction generation poses two additional di-culties. First some machines require that the SIMD data fetched from memory be aligned. For example, they might require that 256 byte SIMD operands be placed in addresses that are multiples of 256. If the source loop operates on just one array of data, we can generate one main loop that operates on aligned data and extra code before and after the loop to handle those elements at the boundary. For loops operating on more than one array however, it may not be possible to align all the data at the same time. Second, data used by consecutive it erations in a loop may not be contiguous. Examples include many important digital signal processing algorithms, such as Viterbi decoders and fast Fourier transforms. Additional operations to shue the data around may be necessary to take advantage of the SIMD instructions.

11 11 4 Prefetching

No data locality optimization can eliminate all memory accesses for one data used for the rst time must be fetched from memory. To hide the latency of memory operations prefetch instructions have been adopted in many high performance processors. Prefetch is a machine instruction that indicates to the processor that certain data is likely to be used soon, and that it is desirable to load the data into the cache if it is not present already

The reuse analysis described in Section 11 5 can be used to estimate when caches misses are likely. There are two important considerations when gener ating prefetch instructions. If contiguous memory locations are to be accessed we need to issue only one prefetch instruction for each cache line. Prefetch instructions should be issued early enough so that the data is in the cache by the time it are used. However, we should not issue prefetch instructions too far in advance. The prefetch instructions can displace data that may still be needed also the prefetched data may be ushed before it is used.

Example 11 73 Consider the following code

Suppose the target machine has a prefetch instruction that can fetch two words of data at a time and that the latency of a prefetch instruction takes about the time to execute six iterations of the loop above. The prefetch code for the above example is shown in Fig. 11 68

We unroll the innermost loop twice so a prefetch can be issued for each cache line. We use the concept of software pipelining to prefetch data six iterations before it is used. The prolog fetches the data used in the rst six iterations. The

steady state loop prefetches six iterations ahead as it performs its computation. The epilog issues no prefetches but simply executes the remaining iterations \Box

11 12 Summary of Chapter 11

- ◆ Parallelism and Locality from Arrays The most important opportunities for both parallelism and locality based optimizations come from loops that access arrays These loops tend to have limited dependences among accesses to array elements and tend to access arrays in a regular pattern allowing e cient use of the cache for good locality
- ♦ A ne Accesses Almost all theory and techniques for parallelism and locality optimization assume accesses to arrays are a ne the expressions for the array indexes are linear functions of the loop indexes
- ◆ Iteration Spaces A loop nest with d nested loops de nes a d dimensional iteration space The points in the space are the d tuples of values that the loop indexes can assume during the execution of the loop nest In the a ne case the limits on each loop index are linear functions of the outer loop indexes so the iteration space is a polyhedron
- ◆ Fourier Motzkin Elimination A key manipulation of iteration spaces is to reorder the loops that dene the iteration space Doing so requires that a polyhedral iteration space be projected onto a subset of its dimensions. The Fourier Motzkin algorithm replaces the upper and lower limits on a given variable by inequalities between the limits themselves.
- → Data Dependences and Array Accesses A central problem we must solve in order to manipulate loops for parallelism and locality optimizations is whether two array accesses have a data dependence can touch the

CHAPTER 11 OPTIMIZING FOR PARALLELISM AND LOCALITY

same array element When the accesses and loop bounds are a ne the problem can be expressed as whether there are solutions to a matrix vector equation within the polyhedron that de nes the iteration space

- → Matrix Rank and Data Reuse The matrix that describes an array access
 can tell us several important things about that access If the rank of the
 matrix is as large as possible minimum of the number of rows and number
 of columns then the access never touches the same element twice as the
 loops iterate If the array is stored in row column major form then the
 rank of the matrix with the last rst row deleted tells us whether the
 access has good locality i e elements in a single cache line are accessed
 at about the same time
- ◆ Data Dependence and Diophantine Equations Just because two accesses to the same array touch the same region of the array does not mean that they actually access any element in common The reason is that each may skip some elements e g one accesses even elements and the other accesses odd elements In order to be sure that there is a data dependence we must solve a Diophantine integer solutions only equation
- ◆ Solving Diophantine Linear Equations The key technique is to compute the greatest common divisor GCD of the coe cients of the variables Only if that GCD divides the constant term will there be integer solutions
- → Space Partition Constraints To parallelize the execution of a loop nest we need to map the iterations of the loop to a space of processors which can have one or more dimensions. The space partition constraints say that if two accesses in two different iterations share a data dependence if either access the same array element, then they must map to the same processor. As long as the mapping of iterations to processors is a network and the problem in matrix vector terms.
- ◆ Primitive Code Transformations The transformations used to parallelize programs with a ne array accesses are combinations of seven primitives loop fusion loop—ssion re indexing adding a constant to loop indexes scaling multiplying loop indexes by a constant—reversal—of a loop index permutation—of the order of loops—and skewing—rewriting loops so the line of passage through the iteration space is no longer along one of the axes
- ◆ Synchronization of Parallel Operations Sometimes more parallelism can be obtained if we insert synchronization operations between steps of a program. For example, consecutive loop nests may have data dependences but synchronizations between the loops can allow the loops to be parallelized separately.
- ◆ Pipelining This parallelization technique allows processors to share data by synchronously passing certain data typically array elements from one

11 13 REFERENCES FOR CHAPTER 11

processor to an adjacent processor in the processor space. The method can improve the locality of the data accessed by each processor

- ◆ Time Partition Constraints To discover opportunities for pipelining we need to discover solutions to the time partition constraints. These say that whenever two array accesses can touch the same array element, then the access in the iteration that occurs are must be assigned to a stage in the pipeline that occurs no later than the stage to which the second access is assigned.
- ◆ Solving Time Partition Constraints Farkas Lemma provides a power ful technique for nding all the a ne time partition mappings that are allowed by a given loop nest with array accesses The technique is essentially to replace the primal formulation of the linear inequalities that express the time partition constraints by their dual
- ◆ Blocking This technique breaks each of several loops in a loop nest into two loops each The advantage is that doing so may allow us to work on small sections blocks of a multidimensional array one block at a time That in turn improves the locality of the program letting all the needed data reside in the cache while working on a single block
- ◆ Stripmining Similar to blocking this technique breaks only a subset of the loops of a loop nest into two loops each A possible advantage is that a multidimensional array is accessed a strip at a time which may lead to the best possible cache utilization

11 13 References for Chapter 11

For detailed discussions of multiprocessor architectures we refer the reader to the text by Hennessy and Patterson 9

Lamport 13 and Kuck Muraoka and Chen 6 introduced the concept of data dependence analysis Early data dependence tests used heuristics to prove a pair of references to be independent by determining if there are no solutions to Diophantine equations and systems of real linear inequalities 5 6 26 May dan Hennessy and Lam 18 formulated the data dependence test as integer linear programming and showed that the problem can be solved exactly and e ciently in practice The data dependence analysis described here is based on work by Maydan Hennessy and Lam 18 and Pugh and Wonnacott 23 which in turn use techniques of Fourier Motzkin elimination 7 and Shostak s algorithm 25

The 70 s and early 80 s saw the use of loop transformations to improve vectorization and parallelization loop fusion 3 loop ssion 1 stripmining 17 and loop interchange 28 There were three major experimental paral lelizer vectorizing projects going on at the time Parafrase led by Kuck at the University of Illinois Urbana Champaign 21 the PFC project led by Kennedy

at Rice University 4 and the PTRAN project led by Allen at IBM Research 2

McKellar and Co man 19 rst discussed using blocking to improve data locality Lam Rothbert and Wolf 12 provided the rst in depth empirical analysis of blocking on caches for modern architectures Wolf and Lam 27 used linear algebra techniques to compute data reuse in loops Sarkar and Gao 24 introduced the optimization of array contraction

Lamport 13 was the rst to model loops as iteration spaces and used hyper planing a special case of an a ne transform to nd parallelism for multipro cessors A ne transforms have their root in systolic array algorithm design 11 Intended as parallel algorithms directly implemented in VLSI systolic arrays require communication to be minimized along with parallelization. Algebraic techniques were developed to map the computation onto space and time coordinates. The concept of an ane schedule and the use of Farkas Lemma in a ne transformations were introduced by Feautrier 8. The ane transformation algorithm described here is based on work by Lim et al. 15, 14, 16.

Porter eld 22 proposed one of the rst compiler algorithms to prefetch data Mowry Lam and Gupta 20 applied reuse analysis to minimize the prefetch overhead and gain an overall performance improvement

Appendix A

A Complete Front End

The complete compiler front end in this appendix is based on the informally described simple compiler of Sections 2 5 2 8 The main difference from Chapter 2 is that the front end generates jumping code for boolean expressions as in Section 6 6 We begin with the syntax of the source language described by a grammar that needs to be adapted for top down parsing

The Java code for the translator consists of ve packages main lexer symbols parser and inter Package inter contains classes for the language constructs in the abstract syntax Since the code for the parser interacts with the rest of the packages it will be discussed last Each package is stored as a separate directory with a leper class

Going into the parser the source program consists of a stream of tokens so object orientation has little to do with the code for the parser. Coming out of the parser the source program consists of a syntax tree with constructs or nodes implemented as objects. These objects deal with all of the following construct a syntax tree node check types and generate three address intermediate code see package inter

A 1 The Source Language

A program in the language consists of a block with optional declarations and statements Token **basic** represents basic types

```
egin{array}{lll} program & block & decls \ block & decls \ stmts & decls \ decl & type \ type \ type \ num \ stmts & stmts \ \end{array}
```

Treating assignments as statements rather than as operators within expressions simplifies translation

Object Oriented Versus Phase Oriented

With an object oriented approach all the code for a construct is collected in the class for the construct. Alternatively with a phase oriented approach the code is grouped by phase so a type checking procedure would have a case for each construct, and a code generation procedure would have a case for each construct, and so on

The tradeo is that an object oriented approach makes it easier to change or add a construct such as for statements and a phase oriented approach makes it easier to change or add a phase such as type checking With objects a new construct can be added by writing a self contained class but a change to a phase such as inserting code for coercions requires changes across all the a ected classes With phases a new construct can result in changes across the procedures for the phases

```
bool
stmt
            loc
            if
                bool
                       stmt
            if
                bool
                       stmt else stmt
            while
                     bool stmt
            do stmt while bool
            break
            block
 loc
            loc
                 bool
                         \parallel id
```

The productions for expressions handle associativity and precedence of operators. They use a nonterminal for each level of precedence and a nonterminal factor for parenthesized expressions identifiers array references and constants

```
bool

```

A 2 Main

Execution begins in method main in class Main Method main creates a lexical analyzer and a parser and then calls method program in the parser

A 3 LEXICAL ANALYZER

```
3 public class Main
4 public static void main String args throws IOException
5 Lexer lex new Lexer
6 Parser parse new Parser lex
7 parse program
8 System out write n
9
```

A 3 Lexical Analyzer

Package lexer is an extension of the code for the lexical analyzer in Section 2.6.5 Class Tag de nes constants for tokens

```
File Tag java
1 package lexer
2 public class Tag
     public final static int
4
        AND
                256 BASIC
                             257
                                   BREAK
                                           258
                                                 DO
                                                        259 ELSE
                                                                     260
5
        ΕQ
                261
                     FALSE
                             262
                                   GE
                                           263
                                                 ID
                                                        264 IF
                                                                     265
6
                                                        269 NUM
                                                                     270
        TNDEX
               266
                     L.E.
                             267
                                   MINUS
                                           268
                                                 NE.
                                   TEMP
                                                        274 WHILE
8
```

Three of the constants INDEX MINUS and TEMP are not lexical tokens they will be used in syntax trees

Classes Token and Num are as in Section 2 6 5 with method toString added

```
1 package lexer
                                  File Token java
2 public class Token
     public final int tag
4
     public Token int t tag
     public String toString
                                           char tag
                            return
                                  File Num java
1 package lexer
 public class Num extends Token
     public final int value
     public Num int v
                       super Tag NUM
                                        value
5
     public String toString
                               return
                                           value
```

Class Word manages lexemes for reserved words identi ers and composite tokens like — It is also useful for managing the written form of operators in the intermediate code like unary minus for example the source text—2 has the intermediate form minus 2

APPENDIX A A COMPLETE FRONT END

```
8
               new Word
                                Tag EQ

14
        reserve Word True
15
         reserve Type Int
                               reserve Type Char
16
         reserve Type Bool
                               reserve Type Float
```

Function readch line 18 is used to read the next input character into variable peek. The name readch is reused or overloaded lines 19 24 to help recognize composite tokens. For example, once input is seen the call readch reads the next character into peek and checks whether it is

```
18
      void readch
                    throws IOException
                                         peek
                                                  char System in read
19
      boolean readch char c throws IOException
20
         readch
         if peek
21
                     c return false
22
         peek
23
         return true
24
```

A 3 LEXICAL ANALYZER

Function scan begins by skipping white space lines 26 30 It recognizes composite tokens like lines 31 44 and numbers like 365 and 3 14 lines 45 58 before collecting words lines 59 70

```
public Token scan
                        throws IOException
26
        for
               readch
27
           if peek
                             peek
                                     t
                                          continue
                             n line line 1
28
           else if peek
29
           else break
30
31
         switch peek
32
         case
                            return Word and else return new Token
33
           if readch
34
         case
35

A 4 Symbol Tables and Types

Package symbols implements symbol tables and types

Class Env is essentially unchanged from Fig 2 37 Whereas class Lexer maps strings to words class Env maps word tokens to objects of class Id which is de ned in package inter along with the classes for expressions and statements

```
1 package symbols
                                    File Env java
2 import java util
                      import lexer
                                     import inter
3 public class Env
     private Hashtable table
     protected Env prev
     public Env Env n
                        table new Hashtable
                                                prev
7
     public void put Token w Id i table put w i
8
     public Id get Token w
9
        for Env e this e
                             null e e prev
                     Id e table get w
10
           Id found
11
           if found
                      null return found
12
13
         return null
14
```

We de ne class Type to be a subclass of Word since basic type names like int are simply reserved words to be mapped from lexemes to appropriate objects by the lexical analyzer. The objects for the basic types are Type. Int. Type. Float. Type. Char. and Type. Bool. lines 7.10. All of them have inherited. eld tag set to Tag. BASIC so the parser treats them all alike.

```
1 package symbols
                                   File Type java
2 import lexer
\bar{3} public class Type extends Word
     public int width 0
                                      width is used for storage allocation
     public Type String s int tag int w super s tag width w
     public static final Type
        Int new Type int
                                  Tag BASIC 4
        Float new Type
                         float
                                 Tag BASIC
9
        Char
              new Type
                          char
                                  Tag BASIC
               new Type
10
        Bool
                         bool
                                  Tag BASIC
```

Functions $\operatorname{numeric}$ lines 11 14 and max lines 15 20 are useful for type conversions

```
public static boolean numeric Type p
12
         if p Type Char
                            p Type Int
                                                    Type Float return true
13
         else return false
14
15
      public static Type max Type p1 Type p2
16
         if numeric p1
                              numeric p2
                                              return null
         else if p1 Type Float p2 else if p1 Type Int p2
17
                                            Type Float return Type Float
                                            Type Int
18
                                                         return Type Int
19
         else return Type Char
20
21
```

A 5 INTERMEDIATE CODE FOR EXPRESSIONS

Conversions are allowed between the numeric types Type Char Type Int and Type Float When an arithmetic operator is applied to two numeric types the result has the max of the two types

Arrays are the only constructed type in the source language. The call to super on line 7 sets eld width which is essential for address calculations. It also sets lexeme and tok to default values that are not used

```
1 package symbols
                                      File Array java
2 import lexer
3 public class Array extends Type
                                          array of type
     public Type of
     public int size
                                          number of elements
      public Array int sz Type p
6
                     Tag INDEX sz p width
7
        super
                                             size
                                                    sz
                                                         οf
9
     public String toString
                                 return
                                                            of toString
                                              size
10
```

A 5 Intermediate Code for Expressions

Package inter contains the Node class hierarchy Node has two subclasses Expr for expression nodes and Stmt for statement nodes. This section introduces Expr and its subclasses. Some of the methods in Expr deal with booleans and jumping code they will be discussed in Section A 6 along with the remaining subclasses of Expr.

Nodes in the syntax tree are implemented as objects of class Node For error reporting eld lexline line 4 le *Node java* saves the source line number of the construct at this node Lines 7 10 are used to emit three address code

```
File Node java
1 package inter
2 import lexer
3 public class Node
     int lexline 0
            lexline
                       Lexer line
6
     void error String s throw new Error near line
                                                       lexline
     static int labels 0
     public int newlabel
                            return labels
9
     public void emitlabel int i System out print L
10
     public void emit String s
                                 System out println
```

Expression constructs are implemented by subclasses of Expr Class Expr has elds op and type lines 4.5 le Expr java representing the operator and type respectively at a node

```
1 package inter File Expr java
2 import lexer import symbols
3 public class Expr extends Node
4 public Token op
5 public Type type
6 Expr Token tok Type p op tok type p
```

APPENDIX A A COMPLETE FRONT END

Method gen line 7 returns a term that can t the right side of a three address instruction Given expression E E_1 E_2 method gen returns a term x_1 x_2 where x_1 and x_2 are addresses for the values of E_1 and E_2 respectively. The return value this is appropriate if this object is an address subclasses of Expr typically reimplement gen

Method reduce line 8 computes or reduces an expression down to a single address that is it returns a constant an identi er or a temporary name Given expression E method reduce returns a temporary t holding the value of E Again this is an appropriate return value if this object is an address

We defer discussion of methods jumping and emitjumps lines 9 18 until Section A 6 they generate jumping code for boolean expressions

```
public Expr gen
                        return this
      public Expr reduce
                          return this
9
     public void jumping int t int f
                                       emitjumps toString
                                                           t f
10
     public void emitjumps String test int t int f
                   f 0
11
        if t 0
12
           emit if
                     test
                               goto L
13
           emit goto L
                          f
14
        else if t
                     0 emit if
15
                                             goto L
16
                   0 emit iffalse test
                                               goto L
        else if f
                 nothing since both t and f fall through
17
18
19
     public String toString
                              return op toString
20
```

Class Id inherits the default implementations of gen and reduce in class Expr since an identi er is an address

The node for an identi er of class Id is a leaf. The call super id p line 5 le *Id java* saves id and p in inherited elds op and type respectively. Field offset line 4 holds the relative address of this identi er

Class Op provides an implementation of reduce lines 5 10 le *Op java* that is inherited by subclasses Arith for arithmetic operators. Unary for unary operators and Access for array accesses. In each case reduce calls gen to generate a term emits an instruction to assign the term to a new temporary name and returns the temporary

```
1 package inter File Op java
2 import lexer import symbols
3 public class Op extends Expr
4 public Op Token tok Type p super tok p
5 public Expr reduce
6 Expr x gen
```

$A\ 5$ INTERMEDIATE CODE FOR EXPRESSIONS

```
7 Temp t new Temp type
8 emit t toString x toString
9 return t
10
11
```

Class Arith implements binary operators like and Constructor Arith begins by calling super tok null line 6 where tok is a token representing the operator and null is a placeholder for the type. The type is determined on line 7 by using Type max which checks whether the two operands can be coerced to a common numeric type the code for Type max is in Section A 4. If they can be coerced type is set to the result type otherwise a type error is reported line 8. This simple compiler checks types but it does not insert type conversions.

```
1 package inter
                                   File Arith java
2 import lexer
                   import symbols
3 public class Arith extends Op
      public Expr expr1 expr2
5
      public Arith Token tok Expr x1 Expr x2
6
         super tok null expr1 x1 expr2 x2
7
         \verb"type Type max expr1 type expr2 type"
         if type
                    null error type error
9
10
      public Expr gen
         return new Arith op expr1 reduce
11
                                              expr2 reduce
12
      public String toString
13
14
         return expr1 toString
                                     op toString
                                                       expr2 toString
15
16
```

Method gen constructs the right side of a three address instruction by reducing the subexpressions to addresses and applying the operator to the addresses line 11 le $Arith\ java$ For example suppose gen is called at the root for a b c. The calls to reduce return a as the address for subexpression a and a temporary t as the address for b c. Meanwhile reduce emits the instruction t b c. Method gen returns a new Arith node with operator and addresses a and t as operands 1

¹For error reporting — eld lexline in class Node records the current lexical line number when a node is constructed—We leave it to the reader to track line numbers when new nodes are constructed during intermediate code generation

²An alternative approach might be for the constructor to take an expression node as a parameter so it can copy the type and lexical position of the expression node

```
4
      static int count
     int number 0
5
     public Temp Type p
                           super Word temp p
                                             number
                                                          count
      public String toString
                               return t
                                            number
 Class Unary is the one operand counterpart of class Arith
                                  File Unary java
1 package inter
2 import lexer
                  import symbols
3
   public class Unary extends Op
     public Expr expr
     public Unary Token tok Expr x
                                            handles minus for
6
         super tok null expr x
7
         type Type max Type Int expr type
8
         if type
                   null
                          error type error
     public Expr gen
10
                         return new Unary op expr reduce
      public String toString
11
                               return op toString
                                                        expr toString
```

A 6 Jumping Code for Boolean Expressions

12

Jumping code for a boolean expression B is generated by method jumping which takes two labels t and f as parameters called the true and false exits of B respectively. The code contains a jump to t if B evaluates to true and a jump to f if B evaluates to false. By convention, the special label 0 means that control falls through B to the next instruction after the code for B

We begin with class Constant The constructor Constant on line 4 takes a token tok and a type p as parameters. It constructs a leaf in the syntax tree with label tok and type p. For convenience, the constructor Constant is overloaded line 5 to create a constant object from an integer

```
File Constant java
1 package inter
2 import lexer
                 import symbols
3 public class Constant extends Expr
     public Constant Token tok Type p
                                       super tok p
     public Constant int i
                            super new Num i Type Int
     public static final Constant
        True new Constant Word True
                                      Type Bool
        False new Constant Word False Type Bool
9
     public void jumping int t int f
10
        if this True t 0 emit goto L
                               f
        else if this False
                                   0 emit goto L
11
12
13
```

Method jumping lines 9 12 le Constant java takes two parameters labels t and f If this constant is the static object True de ned on line 7 and t is not the special label 0 then a jump to t is generated Otherwise if this is the object False de ned on line 8 and f is nonzero then a jump to f is generated

A 6 JUMPING CODE FOR BOOLEAN EXPRESSIONS

Class Logical provides some common functionality for classes Or And and Not expr1 and expr2 line 4 correspond to the operands of a logical opera tor Although class Not implements a unary operator for convenience it is a subclass of Logical The constructor Logical tok a b lines 5 10 builds a syntax node with operator tok and operands a and b In doing so it uses function check to ensure that both a and b are booleans Method gen will be discussed at the end of this section

```
File Logical java
1 package inter
2 import lexer
                  import symbols
3 public class Logical extends Expr
      public Expr expr1 expr2
      Logical Token tok Expr x1 Expr x2
6
         super tok null
                                                  null type to start
7
         expr1 x1 expr2 x2
         type check expr1 type expr2 type
8
g
         if type
                   null error type error
10
11
      public Type check Type p1 Type p2
        if p1 Type Bool
                                p2 Type Bool return Type Bool
12
13
         else return null
14
15
      public Expr gen
16
         int f newlabel
                                    newlabel
                            int a
17
         Temp temp new Temp type
18
         this jumping 0 f
19
         emit temp toString
                                   true
20
         emit goto L
                       a
21
         emitlabel f
                      emit temp toString
                                                 false
22
         emitlabel a
^{23}
         return temp
24
25
      public String toString
26
         return expr1 toString
                                    op toString
                                                      expr2 toString
27
28
```

In class \mathtt{Or} method jumping lines 5 10 generates jumping code for a boolean expression B B_1 B_2 For the moment suppose that neither the true exit \mathtt{t} nor the false exit \mathtt{f} of B is the special label 0 Since B is true if B_1 is true the true exit of B_1 must be \mathtt{t} and the false exit corresponds to the rst instruction of B_2 The true and false exits of B_2 are the same as those of B

```
1 package inter
                                  File Or java
2 import lexer
                  import symbols
3 public class Or extends Logical
     public Or Token tok Expr x1 Expr x2
                                             super tok x1 x2
5
     public void jumping int t int f
6
        int label t 0
7
        expr1 jumping label
        expr2 jumping t f
9
        if t 0 emitlabel label
10
11
```

APPENDIX A A COMPLETE FRONT END

In the general case t the true exit of B can be the special label 0 Variable label line 6 le $Or\ java$ ensures that the true exit of B_1 is set properly to the end of the code for B If t is 0 then label is set to a new label that is emitted after code generation for both B_1 and B_2

The code for class And is similar to the code for Or

```
1 package inter
                                  File And java
2 import lexer
                  import symbols
 3 public class And extends Logical
     public And Token tok Expr x1 Expr x2
                                              super tok x1 x2
     public void jumping int t int f
6
        int label f 0 f
                               newlabel
7
        expr1 jumping 0 label
        expr2 jumping t f
9
        if f 0 emitlabel label
10
11
```

Class Not has enough in common with the other boolean operators that we make it a subclass of Logical even though Not implements a unary operator. The superclass expects two operands so x2 appears twice in the call to super on line 4. Only expr2 declared on line 4. le Logical java is used in the methods on lines 5.6. On line 5 method jumping simply calls expr2 jumping with the true and false exits reversed.

Class Rel implements the operators and Function check lines 5 9 checks that the two operands have the same type and that they are not arrays For simplicity coercions are not permitted

```
1 package inter
                                  File Rel java
2 import lexer
                  import symbols
3 public class Rel extends Logical
     public Rel Token tok Expr x1 Expr x2
                                              super tok x1 x2
     public Type check Type p1 Type p2
6
        if p1 instanceof Array p2 instanceof Array return null
         else if p1 p2 return Type Bool
7
8
         else return null
10
     public void jumping int t int f
11
        Expr a expr1 reduce
12
                expr2 reduce
         Expr b
13
   String test a toString
                                     op toString
                                                          b toString
14
         emitjumps test t f
15
16
```

A 6 JUMPING CODE FOR BOOLEAN EXPRESSIONS

Method jumping lines 10 15 le *Rel java* begins by generating code for the subexpressions expr1 and expr2 lines 11 12 It then calls method emitjumps de ned on lines 10 18 le *Expr java* in Section A 5 If neither t nor f is the special label 0 then emitjumps executes the following

At most one instruction is generated if either ${\tt t}$ or ${\tt f}$ is the special label 0 again from le ${\it Expr\ java}$

For another use of emitjumps consider the code for class Access The source language allows boolean values to be assigned to identi ers and array elements so a boolean expression can be an array access Class Access has method gen for generating normal code and method jumping for jumping code Method jumping line 11 calls emitjumps after reducing this array access to a temporary The constructor lines 6.9 is called with a attened array a an index i and the type p of an element in the attened array Type checking is done during array address calculation

```
File Access java
1 package inter
2 import lexer
                   import symbols
3 public class Access extends Op
      public Id array
      public Expr index
      public Access Id a Expr i Type p
                                                  p is element type after
                              Tag INDEX
7
         super new Word
                                                  flattening the array
8
         arrav
                a index
9
10
      public Expr gen
                          return new Access array index reduce
      public void jumping int t int f emitjumps reduce
                                                            toString t f
11
12
      public String toString
13
         return array toString
                                           index toString
14
15
```

Jumping code can also be used to return a boolean value Class Logical earlier in this section has a method gen lines 15 24 that returns a temporary temp whose value is determined by the ow of control through the jumping code for this expression. At the true exit of this boolean expression temp is assigned true at the false exit temp is assigned false. The temporary is declared on line 17 Jumping code for this expression is generated on line 18 with the true exit being the next instruction and the false exit being a new label for The next instruction assigns true to temp line 19 followed by a jump to a new label a line 20. The code on line 21 emits label for and an instruction that assigns false to temp. The code fragment ends with label a generated on line 22. Finally gen returns temp line 23.

A 7 Intermediate Code for Statements

Each statement construct is implemented by a subclass of Stmt The elds for the components of a construct are in the relevant subclass for example class While has elds for a test expression and a substatement as we shall see

Lines 3 4 in the following code for class Stmt deal with syntax tree construction. The constructor Stmt does nothing since the work is done in the subclasses. The static object Stmt Null line 4 represents an empty sequence of statements.

Lines 5 7 deal with the generation of three address code. The method gen is called with two labels b and a where b marks the beginning of the code for this statement and a marks the rst instruction after the code for this statement. Method gen line 5 is a placeholder for the gen methods in the subclasses. The subclasses While and Do save their label a in the eld after line 6 so it can be used by any enclosed break statement to jump out of its enclosing construct. The object Stmt Enclosing is used during parsing to keep track of the enclosing construct. For a source language with continue statements we can use the same approach to keep track of the enclosing construct for a continue statement.

The constructor for class If builds a node for a statement if E S Fields expr and stmt hold the nodes for E and S respectively. Note that expr in lower case letters names a eld of class Expr similarly stmt names a eld of class Stmt

```
File If java
 1 package inter
2 import symbols
3 public class If extends Stmt
      Expr expr Stmt stmt
      public If Expr x Stmt s
5
6
        expr x stmt s
                                     expr error boolean required in if
         if expr type
                         Type Bool
8
      public void gen int b int a
9
10
         int label newlabel
                                   label for the code for stmt
         expr jumping 0 a
                                  fall through on true goto a on false
11
12
         emitlabel label stmt gen label a
13
```

The code for an If object consists of jumping code for expr followed by the code for stmt As discussed in Section A 6 the call expr jumping 0 a on line

A 7 INTERMEDIATE CODE FOR STATEMENTS

11 speci es that control must fall through the code for expr if expr evaluates to true and must ow to label a otherwise

The implementation of class Else which handles conditionals with else parts is analogous to that of class If

```
1 package inter
                                  File Else java
2 import symbols
3 public class Else extends Stmt
     Expr expr Stmt stmt1 stmt2
     public Else Expr x Stmt s1 Stmt s2
6
        expr x stmt1 s1 stmt2
                                    s2
7
        if expr type Type Bool
                                    expr error boolean required in if
8
9
     public void gen int b int a
10
        int label1 newlabel
                                     label1 for stmt1
        int label2 newlabel
                                     label2 for stmt2
11
12
        expr jumping 0 label2
                                     fall through to stmt1 on true
13
        emitlabel label1 stmt1 gen label1 a
                                               emit goto L
        emitlabel label2 stmt2 gen label2 a
14
15
16
```

The construction of a While object is split between the constructor While which creates a node with null children line 5—and an initialization function init x s—which sets child expr to x and child stmt to s—lines 6–9—Function gen b—a for generating three address code—lines 10–16—is in the spirit of the corresponding function gen—in class If—The di—erence is that label a is saved in—eld after—line 11—and that the code for stmt is followed by a jump to b—line 15—for the next iteration of the while loop

```
1 package inter
                                  File While java
2 import symbols
3 public class While extends Stmt
      Expr expr Stmt stmt
                   expr null stmt
      public While
                                         null
5
     public void init Expr x Stmt s
7
        expr x stmt s
        if expr type Type Bool
8
                                    expr error boolean required in while
9
10
     public void gen int b int a
        after a
                                    save label a
11
12
         expr jumping 0 a
13
        int label newlabel
                                    label for stmt
14
         emitlabel label stmt gen label b
15
        emit goto L
16
```

Class Do is very similar to class While

APPENDIX A A COMPLETE FRONT END

```
5
     public Do
                  expr null stmt
                                      null
     public void init Stmt s Expr x
6
7
        expr x stmt s
8
        if expr type
                         Type Bool
                                     expr error boolean required in do
9
10
     public void gen int b int a
        after a
11

                                    label for expr
12
        stmt gen b label
13
14
        emitlabel label
15
         expr jumping b 0
16
17
```

Class Set implements assignments with an identifier on the left side and an expression on the right. Most of the code in class Set is for constructing a node and checking types. lines 5.13. Function gen emits a three address instruction lines 14.16.

```
1 package inter
                                   File Set java
2 import lexer
                  import symbols
3 \  \  \, {\tt public \ class \ Set \ extends \ Stmt}
      public Id id public Expr expr
      public Set Id i Expr x
5
        id i expr x
7
        if check id type expr type
                                          null error type error
8
9
      public Type check Type p1 Type p2
10
        if Type numeric p1 Type numeric p2 return p2
11
         else if p1 Type Bool p2 Type Bool return p2
         else return null
12
13
14
      public void gen int b int a
15
        emit id toString
                                      expr gen toString
16
17
```

Class SetElem implements assignments to an array element

```
1 package inter
                                  File SetElem java
2 import lexer
                  import symbols
3\, public class SetElem extends Stmt
     public Id array public Expr index public Expr expr
      public SetElem Access x Expr y
5
6
        array x array index x index expr y
7
        if check x type expr type
                                        null error type error
8
9
     public Type check Type p1 Type p2
10
        if p1 instanceof Array p2 instanceof Array return null
11
        \verb|else if p1 p2 return p2|\\
12
        else if Type numeric p1
                                   Type numeric p2
13
        else return null
14
15
     public void gen int b int a
16
        String s1 index reduce toString
17
        String s2 expr reduce toString
```

A 8 PARSER

Class Seq implements a sequence of statements The tests for null state ments on lines 6 7 are for avoiding labels. Note that no code is generated for the null statement Stmt Null since method gen in class Stmt does nothing

```
File Seq java
1 package inter
2 public class Seq extends Stmt
      Stmt stmt1 Stmt stmt2
4
      public Seq Stmt s1 Stmt s2
                                            s1 stmt2
                                    stmt1
                                                       s2
5
      public void gen int b int a
        if stmt1 Stmt Null stmt2 gen b a
6
        else if
                 stmt2
                         Stmt Null stmt1 gen b a
8
         else
9
           int label newlabel
10
            stmt1 gen b label
            emitlabel label
11
12
            stmt2 gen label a
13
14
15
```

A break statement sends control out of an enclosing loop or switch state ment Class Break uses eld stmt to save the enclosing statement construct the parser ensures that Stmt Enclosing denotes the syntax tree node for the enclosing construct. The code for a Break object is a jump to the label stmt after which marks the instruction immediately after the code for stmt

```
1 package inter
                                   File Break java
2 public class Break extends Stmt
      Stmt stmt
      public Break
4
5
         if Stmt Enclosing
                              Stmt Null
                                          error unenclosed break
6
         stmt Stmt Enclosing
      public void gen int b int a
9
         emit goto L stmt after
10
11
```

A 8 Parser

The parser reads a stream of tokens and builds a syntax tree by calling the appropriate constructor functions from Sections A 5 A 7 The current symbol table is maintained as in the translation scheme in Fig 2 38 in Section 2 7

Package parser contains one class Parser

APPENDIX A A COMPLETE FRONT END

```
3 public class Parser
     private Lexer lex
                             lexical analyzer for this parser
     private Token look
                             lookahead token
     Env top null
6
                             current or top symbol table
     int used 0
                             storage used for declarations
      public Parser Lexer 1 throws IOException lex 1 move
8
     void move throws IOException look lex scan
      void error String s throw new Error near line lex line
     void match int t throws IOException
11
        if look tag t move
12
13
        else error syntax error
14
```

Like the simple expression translator in Section 2.5 class Parser has a procedure for each nonterminal. The procedures are based on a grammar formed by removing left recursion from the source language grammar in Section A.1

Parsing begins with a call to procedure program which calls block line 16 to parse the input stream and build the syntax tree Lines 17 18 generate intermediate code

```
15 public void program throws IOException program block
16 Stmt s block
17 int begin s newlabel int after s newlabel
18 s emitlabel begin s gen begin after s emitlabel after
19
```

Symbol table handling is shown explicitly in procedure block ³ Variable top declared on line 5 holds the top symbol table variable savedEnv line 21 is a link to the previous symbol table

```
Stmt block
                  throws IOException
                                          block
                                                     decls stmts
21
                   Env savedEnv top
        match
                                         top new Env top
22
         decls
                 Stmt s stmts
23
        match
                    top savedEnv
^{24}
        return s
```

Declarations result in symbol table entries for identi ers see line 30 Al though not shown here declarations can also result in instructions to reserve storage for the identi ers at run time

```
26
      void decls throws IOException
27
         while look tag
                           Tag BASIC
                                             D
                                                  type ID
28
           Type p type
                           Token tok look match Tag ID
                                                           match
29
           Id id new Id Word tok p used
30
           top put tok id
           used used p width
31
32
33
34
      Type type
                 throws IOException
35
        Type p
                  Type look
                                          expect look tag
                                                            Tag BASIC
```

 $^{^3}$ An attractive alternative is to add methods push and pop to class Env with the current table accessible through a static variable Env top

A 8 PARSER

```
36
         match Tag BASIC
         if look tag
37
                              return p
                                           Т
                                               basic
38
         else return dims p
                                           return array type
39
      Type dims Type p \, throws IOException
40
         match
41
                     Token tok look match Tag NUM
                                                         match
         if look tag
42
43
           p dims p
                           Num tok value p
44
         return new Array
45
```

Procedure stmt has a switch statement with cases corresponding to the productions for nonterminal Stmt Each case builds a node for a construct using the constructor functions discussed in Section A 7. The nodes for while and do statements are constructed when the parser sees the opening keyword. The nodes are constructed before the statement is parsed to allow any enclosed break statement to point back to its enclosing loop. Nested loops are handled by using variable Stmt Enclosing in class Stmt and savedStmt declared on line 52 to maintain the current enclosing loop.

```
46
      Stmt stmts
                 throws IOException
47
        if look tag return Stmt Null
48
        else return new Seq stmt
49
     Stmt stmt throws IOException
51
        Expr x Stmt s s1 s2
52
        Stmt savedStmt
                                  save enclosing loop for breaks
53
        switch look tag
54
        case
55
56
           return Stmt Null
57
         case Tag IF

A 9 Creating the Front End

The code for the packages appears in ve directories main lexer symbol parser and inter The commands for creating the compiler vary from system to system The following are from a UNIX implementation

```
javac lexer java
javac symbols java
javac inter java
javac parser java
javac main java
```

The javac command creates class les for each class. The translator can then be exercised by typing java main Main followed by the source program to be translated e.g. the contents of le test

On this input the front end produces

Appendix B

Finding Linearly Independent Solutions

Algorithm B 1 Finds a maximal set of linearly independent solutions for Ax = 0 and expresses them as rows of matrix B

INPUT An m matrix A

OUTPUT A matrix B of linearly independent solutions to Ax = 0

METHOD The algorithm is shown in pseudocode below. Note that X y denotes the yth row of matrix X X y z denotes rows y through z of matrix X and X y z u v denotes the rectangle of matrix X in rows y through z and columns u through v
