1. Definition	308
2. Statics	309
3. Kinematics	322
4. Kinetics	335
5. Friction	352
Bibliography	357
4. Selection of Metals for Structural Design	358
<i>Matthew J. Donachie</i>	
1. Introduction	359
2. Common Alloy Systems	359

3.	What Are Alloys and What Affects Their Use?	359
4.	What Are the Properties of Alloys and How Are Alloys Strengthened?	360
5.	Manufacture of Alloy Articles	363
6.	Alloy Information	363
7.	Metals at Lower Temperatures	373
8.	Metals at High Temperatures	373
9.	Melting and Casting Practices	376
10.	Forging, Forming, Powder Metallurgy, and Joining of Alloys	379
11.	Surface Protection of Materials	381
12.	PostService Refurbishment and Repair	383
13.	Alloy Selection: A Look at Possibilities	384
14.	Level of Property Data	385
15.	Thoughts on Alloy Systems	385
16.	Selected Alloy Information Sources	390
	Bibliography	391
5.	Plastics: Information and Properties of Polymeric Materials	392
	<i>Edward N. Peters</i>	
1.	Introduction	393
2.	Polyolefin Thermoplastics	395
3.	Side-Chain-Substituted Vinyl Thermoplastics	396
4.	Polyurethane and Cellulosic Resins	401
5.	Engineering Thermoplastics: Condensation Polymers	402
6.	High-Performance Materials	409
7.	Fluorinated Thermoplastics	414
8.	Thermosets	416
9.	General-Purpose Elastomers	420
10.	Specialty Elastomers	420
	References	420
6.	Overview of Ceramic Materials, Design, and Application	422
	<i>R. Nathan Katz</i>	
1.	Introduction	422
2.	Processing of Advanced Ceramics	423
3.	Brittleness and Brittle Materials Design	424
4.	Applications	425
5.	Information Sources	431
6.	Future Trends	432
	References	432
7.	Mechanics of Deformable Bodies	434
	<i>Neal F. Enke and Bela I. Sandor</i>	
1.	Introduction to Stress and Strain	434
2.	Beams and Bending	447
3.	Torsion and Shafts	460
4.	Plates, Shells, and Contact Stresses	464
5.	Nonlinear Response of Materials	474

PREFACE

In the years 1934–1936, when Ovid Wallace Eshbach (1893–1958) was preparing the first edition of the handbook that still bears his name, he was employed as special assistant in the Personnel Relations Department of AT&T. An electrical engineering graduate with honors from Lehigh University in 1915, he was well known in engineering education circles, particularly at schools which offered a cooperative option to their undergraduates. He coordinated the Bell System–MIT Cooperative Plan, an option in the Electrical Engineering Department at MIT, which permitted selected students to alternate study terms at MIT with terms of work, either with the Bell System or with the General Electric Company. In a memoir (available on the Northwestern University web site), to which I am indebted for this information, Eshbach's son wrote that his father, in addition to interviewing, hiring, and placing students within the Bell System, monitored their progress, counseled them, and followed their careers. He was also an adjunct MIT professor and taught electrical engineering courses for students co-opting at Bell. Eshbach served on committees of the Society for the Promotion of Engineering Education and the American Institute of Electrical Engineers. He was a member of the Regional Accrediting Committee of the Engineers' Council for Professional Development as well as the Special Advisory Committee to the President's Committee on Civil Service Improvement. In 1932 he had directed a survey of adult technical education for the Chamber of Commerce of the State of New York.

Several years after he published his handbook, Eshbach was approached to become dean of the Northwestern engineering school. Northwestern had established a new engineering school in the early 1900s, initially as a department within the College of Liberal Arts. In the mid-1920s the College of Engineering became the autonomous School of Engineering, with faculty members devoted exclusively to engineering. There was a crisis in engineering education at Northwestern in 1937 when, after years of declining enrollments, the school was denied accreditation during a national survey of engineering schools carried out by the Engineers' Council for Professional Development. A major criticism was that the curriculum was too heavily weighted with nonprofessional courses. But in 1939, Walter P. Murphy, a wealthy inventor of railroad equipment, donated \$6.7 million for the construction of

Northwestern's Technological Institute building. When the construction of Tech, as the engineering school was then known, was completed in 1942, Northwestern received an additional bequest of \$28 million from Murphy's estate to provide for an engineering school "second to none." Although Murphy insisted that the school not be named for him—he would not appear in public or on programs of ceremonies, such as at the cornerstone laying or the dedication of the new building—the cooperative engineering education program bears his name to commemorate his interest in "practical education." Over the next 45 years cooperative engineering education remained a constant requirement at Tech, now known as the Robert R. McCormick School of Engineering and Applied Science.

Eshbach remained Tech's dean for the rest of his life as far as I can tell. His son reports in his memoir that Eshbach always had himself assigned to teach an undergraduate quiz section, usually in physics. And his name lives on at Northwestern. There is the Ovid W. Eshbach Society, in which alumni and other donors provide funds to strengthen undergraduate engineering education through support for such needs as laboratory equipment, undergraduate research, design competitions, and instructional software. There is also the Ovid W. Eshbach Award, established in 1948 by Tech's first graduating class, which is awarded for overall excellence in scholarship and leadership. Each spring, nominations are accepted from the graduating class on who they feel most closely typify the ideal engineering student.

The team that Ovid W. Eshbach put together for the first edition of his handbook, which was called *Handbook of Engineering Fundamentals*, included 40 representatives from academia, industry, and government, most of them based in the northeast and some in the midwest. The handbook was the first volume in the **Wiley Engineering Handbook Series**, which also included the eleventh edition of the two-volume *Kent's Mechanical Engineers' Handbook* (one volume covered power, the second design and shop practice); the third edition of the two-volume *Handbook for Electrical Engineers* (one volume covered electric power, the second communications and electronics); and the third edition of the one-volume *Mining Engineers' Handbook*. Tables of contents for all handbooks in the series

were included on pages following the index of the Eshbach volume.

The *Handbook of Engineering Fundamentals*, published in 1936 jointly by Wiley in New York and Chapman & Hall in London, contains 13 sections (chapters) and 1081 pages. Eshbach wrote in the Editor's Preface: "This handbook has been prepared for the purpose of embodying in a single volume those fundamental laws and theories of science which are basic to engineering practice. It is essentially a summary of the principles of mathematics, physics, and chemistry, the properties and uses of engineering materials, the mechanics of solids and fluids and the commonly used mathematics and physical tables, to which has been added a discussion of contract relations. Thus, with the exception of the technics of surveying and drawing, there is included the fundamental technology common to all engineering curricula."

The **second edition** of *Handbook of Engineering Fundamentals* was published in 1952. It was still part of the **Wiley Engineering Handbook Series**, to which had been added *Handbook of Mineral Dressing*. Again, it was jointly published by Wiley and Chapman & Hall. The copy that I have is from the fourth printing, May 1954. On the front cover, COLLEGE EDITION is stamped underneath the name ESHBACH.

Eshbach made numerous changes for the **second edition**. He went west to find contributors—one from Texas and four from California were among the 38 contributors to this edition. With a new section on aerodynamics, he increased the number of sections to 14. He expanded the contracts section and renamed it Engineering Law. In addition, he enlarged the engineering tables to include standard structural sizes for aluminum and data on tangents and offsets for civil engineers; revised the mathematics section to eliminate "simple and commonly known items previously introduced for completeness" and put greater stress on "statistics, determinants, and vector analysis"; thoroughly revised the sections on solid and fluid mechanics; completely revised the section on electricity and magnetism; and in the sections on metallic and non-metallic materials, "much material, more detailed, and of interest to special groups, has been eliminated to keep the volume within practical size."

By 1975, when the **third edition** was published, Eshbach had been dead for 17 years. Dr. Mott Souders, a chemical engineer from Piedmont, California, had taken over the editorship, although Eshbach's name was the only one stamped on the spine and front cover of the book. Souders, too, had died, in 1974, before the book was published, this time solely by Wiley, which now had offices in London, Sydney, and Toronto as well as New York. The handbook was still part of the **Wiley Engineering Handbook Series**. The center of gravity of contributor locations had shifted further west. In addition to seven contributors from the West Coast and one from Texas, the roster of 40 contributors included 18 on the staff of the U.S. Air

Force Academy, who contributed a section of over 180 pages on aeronautics and astronautics.

The **third edition** has 16 sections and 1562 pages. In his Preface, written in February 1974, Souders noted that the handbook contained new sections on astronautics, heat transfer, electronics, automatic control, and engineering economy. The sections on aeronautics and chemistry had been completely rewritten. New material had been added to the sections on mathematical and physical tables; mathematics, including an article on elements of Fortran; physical units and standards; as well as radiation, light, and acoustics. In the single section on properties of materials, all text was eliminated to provide space for more charts and tables. Souders also eliminated the section on engineering law. But the **third edition** did feature, on two pages following the Preface, canons of ethics of engineers approved by the Engineer's Council for Professional Development on September 30, 1963.

By the latter 1980s, the handbook's editorship had passed to Byron Tapley, a professor in the Department of Aerospace Engineering and Engineering Mechanics at the University of Texas at Austin. The **fourth edition's** size and scope increased dramatically. Whereas the trim size of the previous three editions had been $5\frac{1}{2}$ by $8\frac{3}{8}$ inches, the new edition was 7 by 10. The number of sections remained the same, at 16, but the number of pages increased dramatically to close to 2100. The number of contributors nearly doubled, to 77 and included, for the first time, one from overseas, in Athens, Greece. The rest were located throughout the United States—the East Coast orientation of the first edition was a thing of the distant past. As a result of the increased scope and complexity of the undertaking, a recently retired Wiley employee, Thurman Poston, was brought on board to assist Tapley in preparing the new edition.

The **fourth edition**, published in 1990, also had a new name. It was now called *Eshbach's Handbook of Engineering Fundamentals*. Also, major topic areas were placed into "chapters" and the term "sections" was now being used for subtopics. The most important changes to the handbook were undertaken in "recognition," Tapley wrote in his Preface, in November 1989, "given to the dramatic change that computers and computer technology have made in the way we generate, receive, and display information." Tapley continued: "The handbook has been modified to account for this impact in three substantial ways: (1) the chapter on mathematical and trigonometric tables has been reduced substantially in recognition of the fact that both small handheld computers and desktop personal computers allow a rapid generation of much of the information contained in this chapter, (2) a specific chapter dealing with computers and computer science has been added, and (3) specific applications where computers are useful have been included in many of the chapters." Tapley added sections on differential equations and the finite-element method; expanded the control theory chapter; split the aeronautics and

astronautics chapter into two distinct chapters (due, I have been told, to usage of the handbook by students at the U.S. Air Force Academy for some years); and extensively revised the chapters on electromagnetics and circuits, electronics, radiation, light, acoustics, and engineering economics. In addition, international standard units were adopted throughout the handbook.

My approach to the **fifth edition**, which is being published nearly two decades after the appearance of the previous edition, has been to revise or update the chapters where there has been substantial change over the intervening years, but the scope of those chapters does not require substantial expansion or alteration; add new chapters in areas where the scope was insufficient and engineers need more basic information; and eliminate chapters superseded by the ubiquity of the digital environment. So the overall goal has been to add more knowledge essential to engineers while reducing the size of the handbook. As a result, there are fewer pages but more chapters.

The chapters that have been substantially updated and revised, but where the scope has remained unaltered for the most part, include those on mechanics of incompressible fluids, electromagnetics and circuits, acoustic, and engineering economy. All except the electromagnetics and circuits chapter have new contributors.

There are numerous chapters that either cover topics new to the handbook or replace chapters, or sections of chapters, where more basic information is essential for practicing engineers and students at

any level. These chapters include Selection of Metals for Design; Plastics: Thermoplastics, Thermosets, and Elastomers; Ceramics; Nondestructive Testing; Aerodynamics of Wings; Mathematical Models of Dynamic Physical Systems; Basic Control Systems Design; Thermodynamics Fundamentals; Heat Transfer Fundamentals; and Electronics (with sections on bipolar transistors, data acquisition and conversion, data analysis, diodes, electronic components, input devices, instruments, integrated circuits, microprocessors, oscilloscopes, and power devices).

I have eliminated the chapter on computers and computer science, inasmuch as contributors now routinely absorb the digital world into their work whenever appropriate, as well as the over 250 pages of materials properties data, which have been replaced by a chapter, Sources of Materials Data, which is a current description of where and how to find reliable materials properties data on the Internet, the standard practice in this digital age. In addition, I have left alone those chapters which contain basic and theoretical information that does not change.

Eshbach has gone through a great many iterations in its long life, yet the handbook remains true to its creator's original vision. My thanks to him as well as to the legion of contributors whose efforts have graced the pages of the five editions of this great reference work.

*This chapter is a revision and extension of Sections 1 and 3 of the third edition, which were written by Mott Souders and Ernst Weber, respectively. Section 4.4 is derived principally from ASTM's *Standard for Metric Practice*, ASTM E380-82, Philadelphia, 1982 (with permission). Section 6.1 is derived from *MIS Newsletter*, General Electric Co., 1980 (with permission).

$a^{-n}, 1/a^n$

$3.14 \times 10^4 = 31,400$

$3.14 \times 10^{-4} = 0.000314$

Miscellaneous \bar{a} , mean value of a $a!$, $= 1 \cdot 2 \cdot 3 \dots a$, factorial a $|a|$ = absolute value of a

$P(n, r) = n(n-1)(n-2) \dots (n-r+1)$

$C(n, r) = \frac{P(n, r)}{r!} = \binom{n}{r}$ = binomial coefficients

 i (or j) = $\sqrt{-1}$, imaginary unit $\pi = 3.1416$, ratio of the circumference to the diameter of a circle ∞ , infinity*Plane Geometry* \angle , angle Δ , triangle \parallel , parallel \perp , perpendicular \odot , circle \square , parallelogram \therefore , therefore $^\circ$, $'$, $''$, degree, minute, second $'$, $''$, feet, inches*Logarithms and Exponentials* $\log a = \log_{10} a$, common logarithm of a or log of a to the base 10 $\ln a = \log_e a$, natural logarithm of a or log of a to the base e ($e = 2.718$) $\log^{-1} a$, number whose log is a $\log_2 x$ or $\log_2 x$ = binary logarithm of x exponential of x , $\exp x$, e^x *Trigonometry*

sin, cos, tan

cosec or csc, sec, cot or ctn } trigonometric

vers, covers } functions

 \sin^{-1} , \cos^{-1} , etc. } inverse of the functions
 \arcsin , \arccos }
Analytic Geometry $x, y, z; \xi, \eta, \zeta$, rectangular coordinates ρ, s , intrinsic coordinates ρ , radius of curvature s , length of arc r, θ , polar coordinates ψ , angle from radius vector to tangent r, θ, ϕ , spherical coordinates θ , colatitude ϕ , longitude r, θ, z , cylindrical coordinates e , eccentricity in conics p , semi latus rectum in conics $l = \cos \alpha, m = \cos \beta, n = \cos \gamma$, direction cosines*Calculus* $y = f(x)$, y is a function of x $y' = f'(x) = \frac{dy}{dx} = D_x y$, derivative of $y = f(x)$ with respect to x $y'' = f''(x) = \frac{d(y')}{dx} = D_x^2 y = \frac{d^2 y}{dx^2}$, second derivative of $y = f(x)$ with respect to x $u = f(x, y)$, u is a function of x and y $u_x = f_x(x, y) = D_x(u) = \frac{\partial u}{\partial x}$, partial derivative of $u = f(x, y)$ with respect to x $u_{xy} = f_{xy}(x, y) = D_y(D_x u) = \frac{\partial^2 u}{\partial y \partial x}$, second partial derivativeof $u = f(x, y)$ with respect to x and y Δy , increment of y dy , differential of y δy , variation of y $\sum_{i=a}^b$, summation over i from a to b $\lim_{x \rightarrow a} (y) = b$, $y \rightarrow b$ as $x \rightarrow a$ \int , integral of \int_a^b , definite integral of*Vector Analysis* i, j, k , unit vectors along the axes (right-handed system) $a \cdot b = (ab) = Sab$, scalar product of a and b $a \times b = [ab] = Vab$, vector product of a and b

Vectors are indicated in print by boldfaced type.

 $|A|, A$, absolute value $\partial/\partial r, \nabla$, differential vector operatorgrad $\varphi, \nabla \varphi$, gradientdiv $A, \nabla \cdot A$, divergencecurl $A, \text{rot } A, \nabla \times A$, curl $\Delta \varphi, \nabla^2 \varphi$, Laplacian $\square \varphi, \square^2 = \frac{1}{c^2} \frac{\partial^2}{\partial t^2} - \nabla^2$, D'Alembertian*Logic and Boolean Algebra* $a \in A$, a is contained in set A $A \cap B, A \cdot B$, logical multiplication. Intersection of set A and set B , A AND B $A \cup B, A + B$, logical addition. Union of set A and set B . A OR B $A \oplus B$, exclusive OR $A \supset B$, logical inclusion. Inclusion of set B in set A $A \ominus B$, complement of set B in set A \bar{A}, \bar{A} , logical complementation. NOT set A . Negation $\emptyset, 0$, logical impossibility. Empty (null) set. Zero state $I, 1$, logical certainty. Universal set. One state^a References: Mathematic signs and symbols for use in the physical sciences and technology, ANSI Y10.20 — 1975.

Table 3 Abbreviations^a for Scientific and Engineering Terms^b

Name of Term	Abbreviation	Name of Term	Abbreviation
absolute	abs	cubic centimeter	cu cm, cm ³ (liquid, meaning milliliter, ml)
acre	spell out		
acre-foot	acre-ft		
air horsepower	air hp		
alternating-current (as adjective)	a-c	cubic foot	cu ft
ampere	amp or A	cubic feet per minute	cfm
ampere-hour	amp-hr	cubic feet per second	cfs
amplitude, an elliptic function	am.	cubic inch	cu in.
Angstrom unit	A	cubic meter	cu m or m ³
antilogarithm	antilog	cubic micron	cu μ or μ^3 or cu μ
atmosphere	atm		
atomic weight	at. wt.	cubic millimeter	cu mm or mm ³
average	avg	cubic yard	cu yd
avoirdupois	avdp	current density	spell out
azimuth	az or α	cycles per second	spell out or cps or Hz
		cylinder	cyl
barometer	bar.		
barrel	bbl	day	spell out
Baumé	Bé	decibel	db
board feet (feet board measure)	fbm	degree ^d	deg or °
boiler pressure	spell out	degree centigrade	C
boiling point	bp	degree Fahrenheit	F
brake horsepower	bhp	degree Kelvin	K
brake horsepower-hour	bhp-hr	degree Rankine	R
Brinell hardness number	Bhn	delta amplitude, an elliptic function	dn
British thermal unit ^c	Btu or B	diameter	diam
bushel	bu	direct-current (as adjective)	d-c
		dollar	\$
calorie	cal	dozen	doz
candle	c	dram	dr
candle-hour	c-hr		
candlepower	cp	efficiency	eff
cent	c or ¢	electric	elec
center to center	c to ¢	electromotive force	emf
centigram	cg	elevation	el
centiliter	cl	equation	eq
centimeter	cm	external	ext
centimeter-gram-second (system)	cgs		
chemical	chem	farad	spell out or F
chemically pure	cp	feet board measure (board feet)	fbm
circular	cir	feet per minute	fpm
circular mils	cir mils	feet per second	fps
coefficient	coef	fluid	fl
cologarithm	colog	foot	ft
concentrate	conc	foot-candle	ft-c
conductivity	cond	foot-Lambert	ft-L
constant	const	foot-pound	ft-lb
continental horsepower	cont hp	foot-pound-second (system)	fps
cord	cd	foot-second (see cubic feet per second)	
cosecant	csc	franc	fr
cosine	cos	free aboard ship	spell out
cosine of the amplitude, an elliptic function	cn	free alongside ship	spell out
cost, insurance, and freight	cif	free on board	fob
cotangent	cot	freezing point	fp
coulomb	spell out or C	frequency	spell out
counter electromotive force	cemf	fusion point	fnp
cubic	cu		

(Continues)

Table 3 (Continued)

Name of Term	Abbreviation	Name of Term	Abbreviation
gallons per minute	gpm	low-pressure (as adjective)	
gallons per second	gps		l-p
grain	spell out	lumen	lm
gram	g	lumen-hour	lm-hr
gram-calorie	g-cal	lumens per watt	lpw
greatest common divisor	gcd		
haversine	hav	mass	spell out
hectare	ha	mathematics (ical)	math
henry	H	maximum	max
high-pressure (adjective)	h-p	mean effective pressure	mep
hogshead	hhd	mean horizontal candlepower	mhcp
horsepower	hp	megacycle	spell out
horsepower-hour	hp-hr	megohm	spell out
hour	hr	melting point	mp
hour (in astronomical tables)	h	meter	m
hundred	C	meter-kilogram	m-kg
hundredweight (112 lb)	cwt	mho	spell out
hyperbolic cosine	cosh	microampere	μ a or μ a
hyperbolic sine	sinh	microfarad	μ F
hyperbolic tangent	tanh	microinch	μ in.
		micromicron	$\mu\mu$ or μ mu
inch	in.	micron	μ or μ mu
inch-pound	in. lb	microvolt	μ v
inches per second	ips	microwatt	μ w or μ w
indicated horsepower	ihp	mile	spell out
indicated horsepower-hour	ihp-hr	miles per hour	mph
inside diameter	ID	miles per hour per second	mphps
intermediate-pressure (adjective)	i-p	milliampere	ma
internal	int	milligram	mg
joule	J	millihenry	mH
		millilambert	mL
kilocalorie	kcal	milliliter	ml
kilocycles per second	kcps	millimeter	mm
kilogram	kg	millimicron	m μ or m μ
kilogram-calorie	kg-cal	million	spell out
kilogram-meter	kg-m	million gallons per day	mgd
kilograms per cubic meter	kg per cu m or kg/m ³	millivolt	mV
kilograms per second	kgps	minimum	min
kiloliter	kl	minute	min
kilometer	km	minute (angular measure)	
kilometers per second	kmps	minute (time) (in astronomical tables)	m
kilovolt	kv	mole	spell out
kilovolt-ampere	kva	molecular weight	mol. wt
kilowatt	kw	month	spell out
kilowatthour	kwhr	National Electrical Code	NEC
lambert	L	ohm	spell out or Ω
latitude	lat or ϕ	ohm-centimeter	ohm-cm
least common multiple	lcm	ounce	oz
linear foot	lin ft	ounce-foot	oz-ft
liquid	liq	ounce-inch	oz-in.
lira	spell out	outside diameter	OD
liter	L	parts per million	ppm
logarithm (common)	log	peck	pk
logarithm (natural)	log _e or ln	penny (pence)	d
longitude	long. or λ	pennyweight	dwt

Table 3 (Continued)

Name of Term	Abbreviation	Name of Term	Abbreviation
per	(see Fundamental Rules)	sine of the amplitude, an elliptic function	sn
peso	spell out	specific gravity	sp gr
pint	pt	specific heat	sp ht
potential	spell out	spherical candle power	scp
potential difference	spell out	square	sq
pound	lb	square centimeter	sq cm or cm ²
pound-foot	lb-ft	square foot	sq ft
pound-inch	lb-in.	square inch	sq in.
pound sterling	£	square kilometer	sq km or km ²
pounds per brake horsepower-hour	lb per bhp-hr	square meter	sq m or m ²
pounds per cubic foot	lb per cu ft	square micron	sq μ or sq mu or μ ²
pounds per square foot	psf	square millimeter	sq mm or mm ²
pounds per square inch	psi	square root of mean square	rms
pounds per square inch absolute	psia	standard	std
power factor	spell out or pf	steradian	sr
quart	qt	tangent	tan
radian	spell out	temperature	temp
reactive kilovolt-ampere	kvar	tensile strength	ts
reactive volt-ampere	var	thousand	M
revolutions per minute	rpm	thousand foot-pounds	kip-ft
revolutions per second	rps	thousand pound	kip
rod	spell out	ton	spell out
root mean square	rms	ton-mile	spell out
secant	sec	versed sine	vers
second	sec	volt	V
second (angular measure)	"	volt-ampere	Va
second-foot (see cubic feet per second)		volt-coulomb	spell out
second (time) (in astronomical tables)	s	watt	W
shaft horsepower	shp	watthour	Whr
shilling	s	watts per candle	Wpc
sine	sin	week	spell out
		weight	wt
		yard	yd
		year	yr

^aThese forms are recommended for readers whose familiarity with the terms used makes possible a maximum of abbreviations. For other classes of readers, editors may wish to use less contracted combinations made up from this list. For example, the list gives the abbreviation of the term "feet per second" "fps." To some readers ft/sec will be more easily understood.

^bThis list of abbreviations is adapted from the recommendations of the American National Standards Institute [see ANSI Y1.1-1972 (R1984)].

^cAbbreviation recommended by the American Society of Mechanical Engineers (ASME) Power Test Codes Committee. B = 1 Btu, kB = 1000 Btu, mB = 1,000,000 Btu. The American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE) recommends the use of Mb = 1000 Btu and Mbh = 1000 Btu/hr.

^dThere are circumstances under which one or the other of these forms is preferred. In general the sign^o is used where space conditions make it necessary, as in tabular matter, and when abbreviations are cumbersome, as in some angular measurements, i.e., 59°23' 42". In the interest of simplicity and clarity the Committee has recommended that the abbreviation for the temperature scale, °F, °C, K, etc., always be included in expressions for numerical temperatures, but, wherever feasible, the abbreviation for "degree" be omitted; as 69 F.

Table 4 Symbols for Physical Quantities^{a,b}

Name of Quantity	Symbol	Name of Quantity	Symbol
Absorption factor	α	Circular frequency ($2\pi f$)	ω
Acceleration		Circulation, strength of single vortex	Γ
Angular	α	Coefficient	
Linear, general	a	Absolute	C
Acceleration due to gravity		General	C
General	g	Of contraction	C_c
International adopted standard	g_0	Of discharge	C
Local	g_L	Of discharge	C_q
Gravitational conversion factor	g_c	Of energy per unit weight in $C_e(V^2/2g)$	C_e
Activity	a	Of flow (Chézy)	C
Activity coefficient, molal basis	γ	Of friction (Weisbach–Darcy)	f
Adiabatic factor	X	Of friction	μ, f
Admittance	Y	Of momentum per unit weight in $C_m(V/g)$	C_m
Advanced ratio of propeller	J	Of roughness (Bazin)	m
Altitude	h, z	Of roughness (Kutter and Manning)	n
Amplitude	A	Of heat transfer overall	V
Angle	α	Of velocity	C_v
Angle	β, ϕ	Compressibility factor	z
Blade angle	β	Concentrated load	F, P, Q
Effective helix	ψ	Concentration	C, c
Dihedral	Γ	Concentration, volumetric	c
Helical angle of advance	ϕ	Concentration factor, stress	K
Of attack	α	Conductance	
Of downwash	ε	Electrical	G
Of radiation	θ	Thermal	$1/R$
Of sideslip	β	Per unit area	$1/RA$
Of sidewash	σ	Conductivity	
Solid	ω	Electrical	γ, σ
Angular		Equivalent	Λ
Acceleration	α	Thermal	k
Displacements	δ	Contraction, coefficient of	C_c
Frequency	ω	Correlation coefficient	R
Momentum	H	Coupling coefficient	k
Velocity	ω	Critical state or indicating critical value (subscript)	c
Area	A	Current ^d	I
Area ^c	S	Damping	
Aspect ratio	A, AR	Coefficient	c
Atomic weight	A	Constant or coefficient	δ
Attack, angle of	α	Factor	λ
Attenuation	a	Deflection	δ
Axes		Of beam, maximum	δ
Of aircraft (left handed)		Density	ρ
Earth-bound coordinate system	x, y, z	Relative to standard air density	σ
Lateral	Y	Depth	h
Longitudinal	X	Depth	y
Normal	Z	Of flow, channels	y
Bazin's coefficient of roughness	m	Diameter	D
Blade width (propellers)	b	Dielectric constant	ε
Boundary layer thickness	δ	Difference between values	Δ
Breadth	b	Difference of potential ^{d,e}	E, e
Capacitance, capacity	C	Diffusion coefficient	D_v
Capacitance	ε	Diffusivity	α
Of evacuated space	ε_v	Diffusivity, thermal	α
Relative	ε_r	Of vapor	D_v
Charge, electric or quantity of electricity	Q	Discharge	
Charge density		Coefficient of	C_q
Line density of charge	λ	Coefficient of	C
Surface density of charge	σ	Rate of; or flow	Q
Volume density of charge	ρ		
Chézy's coefficient	C		
Chord length	c		

Table 4 (Continued)

Name of Quantity	Symbol	Name of Quantity	Symbol
Per unit width	q	Force	F
Displacement, electric	D	Electromotive ^e	E, e
Distance		Magnetomotive	M, \mathcal{F}
From center of gravity to center of pressure of horizontal tail surface	f	Moment of	M
Linear	s	Normal	N
Drag, absolute coefficient of	D	Shearing force in beam section	V
Dynamic (or impact) pressure	q	Total load	F
Eccentricity of application of load	e	Forces or loads, concentrated	P, Q, F
Efficiency	η	Fraction	
Elastance	S	By volume	x_v
Mutual	S_m, S_{rc}	By weight	x_w
Self	S, S_{cc}	Free energy	
Elasticity		Gibbs	G
Bulk modulus, of liquids	K	Helmholtz	A
Kinematic K/ρ	e	Frequency	f
Modulus of	E	Circular ($2\pi f$)	θ
Elasticity	σ	Of radiant energy	ν
Electric potential ^{d,e}	E, e	Reduced (flutter)	k
Electricity, quantity of	Q, q	Rotational	n
Electromotive force ^d	E, e	Frequency, angular	ω
Electronic charge, absolute value	e	Friction	
Electrostatic flux	ψ	Coefficient of sliding	f, μ
Elevation		Factor used in expressing pipeloss	f
Above datum	Z	In energy balance	F
Above stream bed	Z_0	Fugacity	f
Elongation, total	δ	Gas constant	R
Emissivity, total	ε	Gibbs function, total potential function	G, g
Energy	W	Gyration, radius of	k
Work total	E	Head	
Energy	E	Atmospheric	h_a
Internal; intrinsic ^f	U, u	Lost ^c	h
Kinetic	E_k, T	Potential	h_{pz}
Per unit time (power)	P	Pressure	h_p
Potential	E_p, V	Velocity	h_v
Enthalpy ^f	H or h	Heat	
Enthalpy	H	Content; enthalpy ^f	H, h
Of dry saturated vapor	h_g	Content of dry saturated vapor; enthalpy of dry saturated vapor	h_g
Of saturated liquid	h_f	Content of saturated liquid; enthalpy of saturated liquid	h_f
Per unit weight	h	Equivalent of work	$1/J$
Entropy	S, s	Flow rate	q
Error signal	ε	Across a boundary surface	h
Expansion, exponent of polytropic	n	Latent, of evaporation	λ, h_{fg}
Cubical, thermal coefficient	β	Mechanical equivalent of	J
Linear, thermal coefficient	α	Of vaporization at constant pressure ^f	$H_{fg}, \lambda, \text{ or } h_{fg}$
Factor of safety	N	Specific, at constant pressure	c_p
Film thickness, effective	B	Specific, at constant volume	c_v
Flow rate	w	Ratio of specific heats	$\gamma, \kappa, \text{ or } k$
In pounds per unit of time	w	Transfer, overall coefficient of	U
Volumetric	q	Transfer, surface coefficient of	h
Fluidity	$1/\mu$	Height	h
Flux		Crest, weirs	z
Density, magnetic	B	Helix, effective angle	Φ
Displacement	ψ		
Magnetic	Φ		
Force	F		

(Continues)

Table 4 (Continued)

Name of Quantity	Symbol	Name of Quantity	Symbol
Helmholtz free energy; internal potential function ^f	A, a	Per unit distance	w, q
Humidity	H	Total	W, P
Density of water vapor; weight of water vapor per unit of volume of space	ρ_H	Mach	
Density of water vapor at saturation	ρ_s	Angle	μ
Enthalpy of the mixture minus the enthalpy of the liquid at the temperature of adiabatic saturation; carrier sigma function	h_Σ	Number	M
Humid volume, volume of mixture per unit of weight of dry air	v_H	Magnetic	
Partial pressure of water vapor	p_H	Flux	Φ
Percentage humidity by weight	w_H/w_s	Intensity	\mathbf{H}
Relative humidity; ratio of an actual partial pressure of water vapor in air to the saturation partial pressure	H_R	Magnetomotive force	M, \mathcal{F}
Saturation pressure of water vapor	p_s	Mass	m
Saturation weight of water vapor per unit of weight of air	H_s, w_s	Flow rate	w
Weight of water vapor per unit of weight of dry air	H, w_H	Velocity	G
Hydraulic radius	R_H	Mean free path	λ
Mean in a reach	R_m	Mechanical equivalent of heat	J
Of cross-sectional area	R	Microscale (turbulence)	λ
Hydraulic slope	S_w	Modulus	
Impedance	Z	Bulk, of elasticity of liquids	K
Impulse	I	Of elasticity	E
Inductance	L	Of elasticity in shear	G
Magnetic	B	Section	Z
Mutual	L_m	Shear	G
Self	L, L_{cc}	Molecular weight	M
Inertia, moment of	I	Moment	
Inertia, moment of		Electric	\mathbf{p}
Polar	J	Magnetic	\mathbf{m}
Rectangular	I	Of any area about a given axis, statical	Q
Product moment of	I_{xy}	Of force, including bending moment	M
Intensity		Of inertia, polar	J
Electric	\mathbf{E}, \mathbf{K}	Rectangular	I
Magnetic	\mathbf{H}	Mutual inductance	L_m
Iisentropic factor	X	Neutral axis, distance to extreme fiber	c
Joule-Thomson coefficient	μ	Nozzle divergence factor	λ
Kutter coefficient of roughness	n	Number in general	N
Length	L	Of conductors or turns	N
Length	l	Of moles, pound-moles, kilogram-moles, etc.	n
Lift	L	Of phases	m
Linear expansion, coefficient	α	Of poles	p
Linear velocity	v	Of revolutions per unit of time	n
Load		Perimeter, wetted, of a sectional area	P
Concentrated	F, P, Q	Period	T
Eccentricity of application of	e	Permeability	
Factor	n	Magnetic	μ
		Of evacuated space	μ_c
		Relative	μ_r
		Permeance	\mathcal{P}, Λ
		Permittivity	ϵ
		Phase	
		Angle	ϕ
		Constant	β
		Displacement	ϕ
		Pitch, geometric	p
		Planck constant	h
		Poisson ratio	μ, ν
		Polarization, magnetic	B_i
		Pole strength	m

Table 4 (Continued)

Name of Quantity	Symbol	Name of Quantity	Symbol
Potential		Richness; equivalence ratio (combustion)	R
Electric ^{d,e}	V	Rotation	
Function	ϕ	Rate of	n
Function, internal; Helmholtz free energy	A, a	Speed of	n
Function, total; Gibbs function	G, g	Safety factor	N
Magnetic	\mathbf{M}, \mathcal{F}	Saturation pressure of water vapor	p_s
Magnetic vector	\mathbf{A}	Section modulus	Z
Retarded vector	\mathbf{A}_r	Self-inductance	L, L_{cc}
Power		Set of control surfaces, angle of ^c	δ
Active	P	Shape factor	S
Apparent	S	Shearing force in beam section	V
Factor	F_p	Slip	s
Reactive	Q	Slope	
Pressure		Of channel bed	S_0
Dynamic	q	Of cuts and embankments	s
Intensity; force per unit area	p	Of energy grade line	S
Relative	δ	Of hydraulic grade line	S_w
Saturation of water vapor	p_s	Of lift curve	a
Propagation constant	γ	Solidity, propellers	σ
Poynting vector	\mathbf{II}	Span	b
Q factor of a reactor	Q	Effectiveness	e
Quality of vapor	x	Specific	
Quantity		Gravity	G
Of electricity	Q	Heat	c
Of heat per unit mass or unit weight	q	Heat at constant pressure	C_p
Of heat per unit time	q	Molar	C_p
Of matter	W	Heat at constant volume	C_v
Total, of a fluid, water, gas, heat (by volume)	Q	Molar	C_v
		Heats, ratio	γ or k or k
Radiant density	u	Volume	v
Radiant energy	U	Weight	γ
Radiant flux	Φ	Speed	
Density	W	Linear	V, v, u
Radiant intensity	J	Of rotation	n
Radiation, intensity of	N	Spring constant	k
Radii	r, R	Stefan–Boltzmann constant	σ
Radius	r	Strain	
Of gyration	k	Normal	ϵ
Range	R	Shear	γ
Reactance	X	Stream function	ψ
Capacitive	X_c	Stress	
Inductive	X_L	Concentration factor	K
Mutual	X_m, X_{rc}	Normal	σ, S
Self	X, X_{cc}	Shear	τ, S_s
Reactive factor	F_q	Supercompressibility factor	z
Recovery factor	η_r	Surface coefficient of heat transfer	h
Reduced frequency (flutter)	k	Surface per unit volume	a
Reflection factor	ρ	Surface tension	σ
Reluctance	\mathcal{R}	Kinematic σ/ρ	ω
Reluctivity	v	Susceptance	B
Resistance		Susceptibility	
Electrical	R	Dielectric	η
Temperature coefficient	α	Magnetic	κ
Thermal	R	Sweepback angle	Λ
Per unit area	RA		
Resistivity		Taper ratio	λ
Electrical	ρ	Temperature	
Thermal	$1/k$	Absolute ^g (^o F abs or K)	T or Θ
Revolutions per unit time	n	Ordinary ^g (^o F or ^o C)	t or θ
Reynolds number	R		

(Continues)

Table 4 (Continued)

Name of Quantity	Symbol	Name of Quantity	Symbol
Ratio	θ	Of wave celerity	c
Thermal		Relative	v
Conductance	$1/R$	Temporal means of	$\bar{u}, \bar{v}, \bar{w}$
Per unit area; "unit conductance"	$1/RA$	components	
Conductivity	k	Vibration constant	p
Diffusivity	α	Viscosity	
Resistance	R	Absolute; coefficient of	μ
Resistance of unit area	RA	Kinematic	ν
Resistivity	$1/k$	Relative (to absolute viscosity of water)	μ/μ_w
Transfer factor	j	Relative kinematic	use ν/ν_w
Transmission	q	Voltage ^d	E, e
Thickness	$d, t, \text{ or } h$	Volume	V
Thrust		Molar	V, V_m
Stream	F	Specific	v
Propeller	T	Total	V, V_L
Time	t	Volume rate; discharge by	q, Q
Time ^h	$t \text{ or } \tau$	volume, fluid rate of flow by	
Time constant	τ	volume	
Torque	Q	Wavelength	λ
Torque	$T \text{ or } M$	Constant	β
Transmission		Weight	
Factor	τ	Molecular	M
Thermal	q	Per unit time per unit area of	G
Turbulence exchange, coefficient	ε	cross section; "mass velocity"	
Turbulence scale	L	Per unit volume	γ
Vaporization, heat of, at constant pressure	H_{fg}, h_{fg}, λ	Rate; per unit of power; for unit of time	w
Velocity	V	Rate of flow per unit of breadth	Γ
Velocity	$V \text{ or } v$	Specific, with g_c	γ
Acoustic	V_a	Total	W
Angular	ω	Weirs	
Average	\bar{V}	Crest height	z
Belanger critical	V_c	Crest length	b
Components in x, y, z directions, respectively	u, v, w	Degree of submergence	N
Linear	v	Wetted perimeter	L_p
Local	u	Width (same as breadth)	b
Mass, mass flow, per unit cross-sectional area, per unit time	G	Of stream bed	b
Mean (Q/A)	\bar{V}	Width, channel surface	b_w
Of light	c	Wing setting, angle of (angle between the wing chord and the thrust line)	i_w
Of sound	a, c	Work	W
Of uniform flow	V_0	External	W_e
		Heat equivalent of	$1/J \text{ or } A$
		Per unit weight	w, w_k

^aThe most frequently used American Standard and Tentative Standard Symbols are included in this table. Sources used are publications of the American National Standards Institute shown in the bibliography below.

^bWhere possible, capital letters denote total quantities and small letters denote specific quantities, or quantities per unit.

^cUse with appropriate subscript.

^dWhere distinctions between maximum, instantaneous, effective (root-mean-square), and average values are necessary, E_m, I_m, P_m are recommended for maximum values; e, i, p for instantaneous values; E, I for effective (rms) values; and P for average value.

^eWhere a distinction between electromotive force and difference of electric potential is desirable, the symbols E, e , and V, v , respectively, may be used.

^fIn each instance uppercase italics may be used optionally for values in general or per mole. Molal values may have subscript M . Lowercase italics are to be used for specific values (per pound, gram, liter, etc.). Molecular values may be represented by lowercase italics or by lowercase italics with subscript m .

^g θ is preferable only when t is used for time in the same discussion. Θ is preferable only when θ is used for ordinary temperature.

^h τ should be used only when t is used for ordinary temperature in the same discussion.

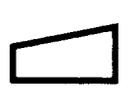

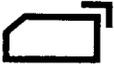

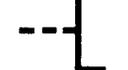

BIBLIOGRAPHY FOR LETTER SYMBOLS

Acoustics, Letter Symbols and Abbreviations for Quantities Used in, ANSI/ASME Y10.11-1984.
 Aeronautical Sciences, Letter Symbols for, ANSI Y10.7-1954.
 Chemical Engineering, Letter Symbols for, ANSI Y10.12-1955(R1973).
 Glossary of Terms Concerning Letter Symbols, ANSI Y10.1-1972.
 Heat and Thermodynamics, Letter Symbols for, ANSI Y10.4-1982.
 Hydraulics, Letter Symbols for, ANSI Y10.2-1958.
 Illuminating Engineering, Letter Symbols for, ANSI Y10.18-1967(R1977).

Letter Symbols for SI Units and Certain Other Units of Measurement, ANSI/IEEE 260-1978.
 Mathematic signs and Symbols for Use in Physical Sciences and Technology (includes supplement ANSI Y10.20a-1975), ANSI Y10.20-1975.
 Mechanics and Time-Related Phenomena, ANSI/ASME Y10.3M-1984.
 Meteorology, Letter Symbols for, ANSI Y10.10-1953(R1973).
 Quantities Used in Electrical Science and Electrical Engineering, Letter Symbols for, ANSI/IEEE 280-1985.
 Selecting Greek Letters Used as Letter Symbols for Engineering Mathematics, Guide for, ANSI Y10.17-1961 (R1973).

Table 5 Graphic Symbols (after Dreyfus, 1972)

Symbols are a graphical referrent to information and have been used for millennia as devices for convenient shorthand notation, to restrict interpretation only to *cognoscenti*, or for compression of data. Examples from several engineering fields are shown here. ISO recommendations are indicated by ¶ and ISO draft recommendations by ¶¶.

Table 8 Computer Graphics Codes and Standards

Modern computer-aided design (CAD), computer-aided manufacturing (CAM), and computer-aided engineering (CAE) are heavily dependent on computer graphics. A standard computer graphics metafile (CGM) is necessary in order to:

1. Allow picture information to be stored in an organized way on a graphical software system.
2. Facilitate transfer of picture information between different graphical software systems.
3. Enable picture information to be transferred between graphical devices.
4. Enable picture information to be transferred between different computer graphics installations.

More particularly, the CGM should provide these capabilities in a device-independent manner. To accomplish this, the standard defines the form (syntax) and functional behavior (semantics) of a set of elements that may occur in the CGM. There are eight classes of elements:

1. Delimiter Elements — delimit significant structures within the metafile.
2. Metafile Descriptor Elements — describe the functional content, default conditions, identification, and characteristics of the CGM.
3. Picture Descriptor Elements — set the interpretation modes of attribute elements for each picture.
4. Control Elements — allow picture boundaries and coordinate representation to be modified.
5. Graphical Primitive Elements — describe the visual components of a picture in the CGM.
6. Attribute Elements — describe the appearance of graphical primitive elements.
7. Escape Elements — describe device- or system-dependent elements used to construct a picture; however, the elements are not otherwise standardized.
8. External Elements — communicate information not directly related to the generation of a graphical image.

A computer graphics metafile is a collection of elements from this standardized set. The BEGIN METAFILE and END METAFILE elements each occur exactly once in a complete metafile; as many or as few of the elements in the other classes may occur as are needed. A metafile needs to be interpreted in order to display its pictorial content on a graphics device. The descriptor elements give the interpreter sufficient data to interpret metafile elements and to make informed decisions concerning the resources needed for display.

A CGM contains delimiter elements; in addition it may include control elements for metafile interpretation, picture descriptor elements for declaring parameter modes of attribute elements, graphical primitive elements for defining graphical entities, attribute elements for defining the appearance of the graphical primitive elements, escape elements for accessing nonstandardized features of particular devices, and external elements for communication of information external to the definition of the pictures in the CGM.

Full description and depiction of all the elements thus far defined in this standardized set is beyond the scope of this handbook. The interested reader is referred to ANSI standard X3.122-1986 and Smith, B. M., et al. "Initial Graphics Exchange Specification (IGES), Version 2.0," NBS (R82-2631) (AF) Feb. (1983) 26 pp.

Table 11 Common and Natural Logarithms of Numbers

The common logarithm of a number is the index of the power to which the base 10 must be raised in order to equal the number.

The common logarithm of every positive number not an integral power of 10 consists of an *integral* and a *decimal part*. The integral part or whole number is called the *characteristic* and may be either *positive* or *negative*. The decimal or fractional part is a positive number called the *mantissa* and is the same for all numbers which have the same sequential digits.

The characteristic of the logarithm of any positive number greater than 1 is positive and is 1 less than the number of digits before the decimal point.

The characteristic of the logarithm of any positive number less than 1 is negative and is 1 more than the number of ciphers immediately after the decimal point.

A negative number or number less than zero has no real logarithm.

Examples: log₁₀ 25,400. = 4.404834, log₁₀ 0.0254 = 2.404834, or 8.404834 - 10

(Continues)

Table 11 (Continued)

The two systems of logarithms in general use are the common or Briggsian logarithms, introduced in 1615 by Henry Briggs, a contemporary of John Napier, the inventor of logarithms, and the natural or less appropriately termed Napierian or hyperbolic logarithms, which developed somewhat accidentally from Napier's original work. The latter have a base denoted by e , an irrational number, which is

$$\lim_{u \rightarrow \infty} \left(1 + \frac{1}{u}\right)^u = 1 + 1 + \frac{1}{2!} + \frac{1}{3!} + \frac{1}{4!} + \dots = 2.7182818$$

To obtain the natural logarithm, the common logarithm is multiplied by $\log_e 10$, which is 2.302585, or $\log_e N = 2.302585 \log_{10} N$.

The natural logarithm of a number is the index of the power to which the base e ($= 2.7182818$) must be raised in order to equal the number.

Example: $\log_e 4.12 = \ln 4.12 = 1.4159$.

Natural logarithms of numbers from 1.00 to 9.99 may be obtained directly; the natural logarithms of numbers outside of that range by the addition or subtraction of the natural logarithms of powers of 10.

Examples: $\log_e 679 = \log_e 6.79 + \log_e 10^2 = 1.9155 + 4.6052 = 6.5207$
 $\log_e 0.0679 = \log_e 6.79 - \log_e 10^2 = 1.9155 - 4.6052 = -2.6897$

Natural Logarithms of Powers of 10

$\log_e 10 = 2.302\ 585$	$\log_e 10^4 = 9.210\ 340$	$\log_e 10^7 = 16.118\ 096$
$\log_e 10^2 = 4.605\ 170$	$\log_e 10^5 = 11.512\ 925$	$\log_e 10^8 = 18.420\ 681$
$\log_e 10^3 = 6.907\ 755$	$\log_e 10^6 = 13.815\ 511$	$\log_e 10^9 = 20.723\ 266$

To obtain the common logarithm, the natural logarithm is multiplied by $\log_{10} e$, which is 0.434294, or $\log_{10} N = 0.434294 \log_e N$.

A negative number or number less than zero has no real logarithm.

Tabulations of common and natural logarithms are no longer provided in this handbook because of ready access to them on modern pocket and desk calculators.

Values and Logarithms of Exponentials and Hyperbolic Functions

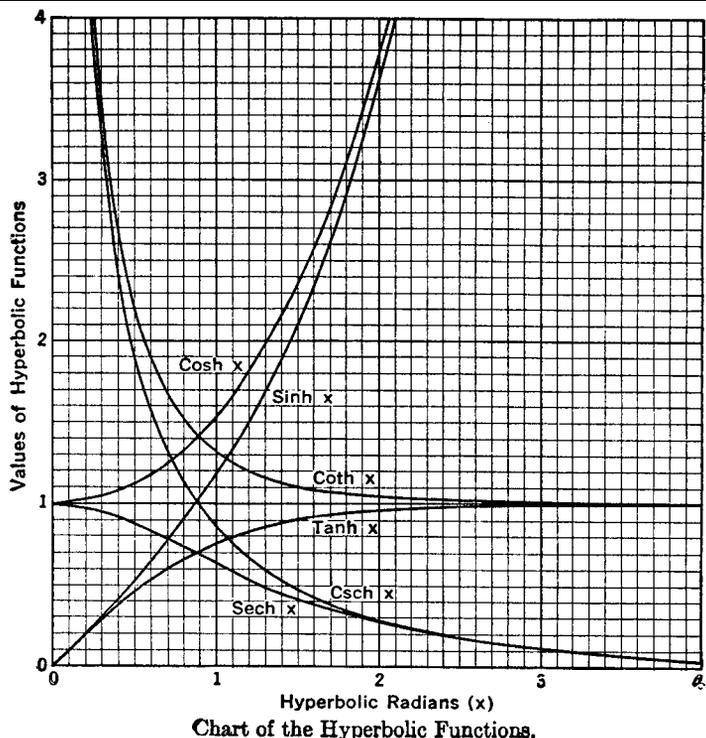

Many calculators directly give values of e^x , e^{-x} , $\sinh x$, $\cosh x$, and $\tanh x$ for any value of x . These quantities are therefore not tabulated here.

For values of x greater than 6, e^x may be computed from the relationship $e^x = \log^{-1}(x \log_{10} e) = \log^{-1} 0.43429x$; e^{-x} approaches zero; $\sinh x$ and $\cosh x$ are approximately equal and become $0.5e^x$; and $\tanh x$ and $\coth x$ have values approximately equal to unity.

Where more accurate values of the exponentials and functions are required they may be computed from the following relationships:

$$\begin{array}{lll}
 e = 2.7182818285 & \frac{1}{e} = 0.3678794412 & \\
 M = \log_{10} e = 0.4342944819 & \frac{1}{M} = \log_e 10 = 2.3025850930 & \\
 e^x = \log^{-1} Mx & e^{-x} = \log^{-1}(-Mx) & \\
 \sin hx = \frac{e^x - e^{-x}}{2} & \cos hx = \frac{e^x + e^{-x}}{2} & \tan hx = \frac{e^x - e^{-x}}{e^x + e^{-x}} \\
 \operatorname{csch} x = \frac{1}{\sin hx} & \operatorname{sech} x = \frac{1}{\cos hx} & \cot hx = \frac{1}{\tan hx}
 \end{array}$$

Table 11 (Continued)

Values of the hyperbolic functions are shown in the figure.

Table 18 Table of Integrals

Elementary Indefinite Integrals

- $\int a \, dx = ax$
- $\int (u + v + w + \dots) \, dx = \int u \, dx + \int v \, dx + \int w \, dx + \dots$
- $\int u \, dv = uv - \int v \, du$, integration by parts
- $\int f(x) \, dx = \int f[\phi(y)]\phi'(y) \, dy$, $x = \phi(y)$, change of variable
- $\int x^n \, dx = \frac{x^{n+1}}{n+1}$ ($n \neq -1$)
- $\int \frac{dx}{x} = \log_e x + c = \log_e c_1x$, [$\log_e x = \log_e(-x) + (2k + 1)\pi i$]
- $\int e^{ax} \, dx = \frac{1}{a}e^{ax}$

Table 18 (Continued)

Elementary Indefinite Integrals (Continued)

8. $\int a^x dx = \frac{a^x}{\log_e a}$
9. $\int a^x \log_e a dx = a^x$.
10. $\int \sin ax dx = -\frac{1}{a} \cos ax$
11. $\int \cos ax dx = \frac{1}{a} \sin ax$
12. $\int \tan ax dx = -\frac{1}{a} \log_e \cos ax = \frac{1}{a} \log_e \sec ax$
13. $\int \cot ax dx = \frac{1}{a} \log_e \sin ax = -\frac{1}{a} \log_e \csc ax$
14. $\int \sec ax dx = \frac{1}{a} \log_e(\sec ax + \tan ax) = \frac{1}{a} \log_e \tan \left(\frac{ax}{2} + \frac{\pi}{4} \right)$
15. $\int \csc ax dx = \frac{1}{a} \log_e(\csc ax - \cot ax) = \frac{1}{a} \log_e \tan \frac{ax}{2}$
16. $\int \frac{dx}{\sqrt{a^2 - x^2}} = \sin^{-1} \frac{x}{a} = -\cos^{-1} \frac{x}{a} \quad (x^2 < a^2)$
17. $\int \frac{dx}{a^2 + x^2} = \frac{1}{a} \tan^{-1} \frac{x}{a} = -\frac{1}{a} \cot^{-1} \frac{x}{a}$
18. $\int \sinh ax dx = \frac{1}{a} \cosh ax$
19. $\int \cosh ax dx = \frac{1}{a} \sinh ax$
20. $\int \tanh ax dx = \frac{1}{a} \log_e(\cosh ax)$
21. $\int \coth ax dx = \frac{1}{a} \log_e(\sinh ax)$
22. $\int \operatorname{sech} ax dx = \frac{1}{a} \sin^{-1}(\tanh ax) = \frac{1}{a} \tan^{-1}(\sinh ax)$
23. $\int \operatorname{csch} ax dx = \frac{1}{a} \log_e \left(\tanh \frac{ax}{2} \right)$
24. $\int \sin^2 ax dx = \frac{1}{2}x - \frac{1}{2a} \sin ax \cos ax = \frac{1}{2}x - \frac{1}{4a} \sin 2ax$
25. $\int \cos^2 ax dx = \frac{1}{2}x + \frac{1}{2a} \sin ax \cos ax = \frac{1}{2}x + \frac{1}{4a} \sin 2ax$
26. $\int \tan^2 ax dx = \frac{1}{a} \tan ax - x$
27. $\int \cot^2 ax dx = -\frac{1}{a} \cot ax - x$
28. $\int \sec^2 ax dx = \frac{1}{a} \tan ax$
29. $\int \csc^2 ax dx = -\frac{1}{a} \cot ax$
30. $\int \sin^{-1} ax dx = x \sin^{-1} ax + \frac{1}{a} \sqrt{1 - a^2 x^2}$
31. $\int \cos^{-1} ax dx = x \cos^{-1} ax - \frac{1}{a} \sqrt{1 - a^2 x^2}$
32. $\int \tan^{-1} ax dx = x \tan^{-1} ax - \frac{1}{2a} \log_e(1 + a^2 x^2)$

Table 18 (Continued)

Elementary Indefinite Integrals (Continued)

$$33. \int \cot^{-1} ax \, dx = x \cot^{-1} ax + \frac{1}{2a} \log_e(1 + a^2x^2)$$

$$34. \int \sec^{-1} ax \, dx = x \sec^{-1} ax - \frac{1}{a} \log_e(ax + \sqrt{a^2x^2 - 1})$$

$$35. \int \csc^{-1} ax \, dx = x \csc^{-1} ax + \frac{1}{a} \log_e(ax + \sqrt{a^2x^2 - 1})$$

 Integrals Involving $ax + b$

$$36. \int (ax + b)^n \, dx = \frac{1}{a(n+1)}(ax + b)^{n+1} \quad (n \neq -1)$$

$$37. \int \frac{dx}{ax + b} = \frac{1}{a} \log_e(ax + b)$$

$$38. \int x(ax + b)^n \, dx = \frac{1}{a^2(n+2)}(ax + b)^{n+2} - \frac{b}{a^2(n+1)}(ax + b)^{n+1} \quad (n \neq -1, -2)$$

$$39. \int \frac{x \, dx}{ax + b} = \frac{x}{a} - \frac{b}{a^2} \log_e(ax + b)$$

$$40. \int \frac{x \, dx}{(ax + b)^2} = \frac{b}{a^2(ax + b)} + \frac{1}{a^2} \log_e(ax + b)$$

$$41. \int \frac{x^2 \, dx}{ax + b} = \frac{1}{a^3} \left[\frac{1}{2}(ax + b)^2 - 2b(ax + b) + b^2 \log_e(ax + b) \right]$$

$$42. \int \frac{x^2 \, dx}{(ax + b)^2} = \frac{1}{a^3} \left[(ax + b) - 2b \log_e(ax + b) - \frac{b^2}{ax + b} \right]$$

$$43. \int \frac{x^2 \, dx}{(ax + b)^3} = \frac{1}{a^3} \left[\log_e(ax + b) + \frac{2b}{ax + b} - \frac{b^2}{2(ax + b)^2} \right]$$

^aValues of $\Gamma(n) = \int_0^\infty e^{-x}x^{n-1} dx$; $\Gamma(n + 1) = n\Gamma(n)$.

For large positive integers, Stirling's formula gives an approximation in which the relative error decreases as *n* increases:

$$\Gamma(n + 1) = (2\pi n)^{1/2} \left(\frac{n}{e}\right)^n$$

$${}^nC_m = \binom{n}{m} = \frac{n!}{[(n-m)!m!]} = \binom{n}{n-m}, \binom{n}{0} = 1,$$

$$(\rho + q)^n = \rho^n + \binom{n}{1} \rho^{n-1} q + \dots + \binom{n}{s} \rho^s q^t + \dots + q^n, \quad s + t = n.$$

Tables 23–25 from Burington, *Handbook of Math Tables and Formulas*, published by McGraw-Hill.

Probability Let p be the probability of an event e in one trial and q the probability of failure of e . The probability that, in n trials, the event e will occur exactly $n - t$ times is $\binom{n}{t} p^{n-t} q^t$. The probability that an event e will happen at least r times in n trials is $\sum_{t=0}^{n-r} \binom{n}{t} p^{n-t} q^t$; at most r times in n trials is $\sum_{t=n-r}^n \binom{n}{t} p^{n-t} q^t$.

In a *point binomial*, $(p + q)^n$, distribution, the mean number of favorable events is np ; the mean number of unfavorable events is nq ; the *standard deviation* is $\sigma = \sqrt{pqn}$; and $a_3 = (p - q)/\sigma$. The *mean deviation from the mean* MD is $\sigma\sqrt{2/\pi} = 0.7979\sigma$; the *semiquartile deviation from the mean* is $0.6745\sigma = 0.845$ MD.

The probability that a deviation of an individual measure from the average lies between $y = -a$ and $y = a$ is

$$\frac{1}{\sqrt{\pi}} \int_{y=-a}^{y=a} h e^{-h^2 y^2} dy = \frac{1}{\sigma\sqrt{2\pi}} \int_{y=-a}^{y=a} e^{-y^2/2\sigma^2} dy$$

$$= \frac{1}{\sqrt{2\pi}} \int_{x=-b}^{x=b} e^{-x^2/2} dx$$

where $x = hy\sqrt{2}$, $b = ha\sqrt{2}$, and $\sigma = 1/h\sqrt{2}$; h is called the *modulus of precision* and σ the *standard (quadratic mean) deviation*.

Table 24 Probability Functions

$$\frac{1}{2}(1 + \alpha) = \int_{-\infty}^{\alpha} \Phi(x) dx = \text{area under } \Phi(x) \text{ from } -\infty \text{ to } \alpha$$

The sum of those terms of

$$(p + q)^n \equiv \sum_{t=0}^n \binom{n}{t} p^{n-t} q^t \quad p + q = 1$$

in which t ranges from a to b inclusive, a and b being integers ($a \leq t \leq b$), is (if n is large enough) approximately

$$\int_{x_1}^{x_2} \phi(x) dx + \left[\frac{q-p}{6\sigma} \phi^{(2)}(x) + \frac{1}{24} \left(\frac{1}{\sigma^2} - \frac{6}{n} \right) \phi^{(3)}(x) \right]_{x_1}^{x_2}$$

where $x_1 = (a - \frac{1}{2} - qn)/\sigma$, $x_2 = (b + \frac{1}{2} - qn)/\sigma$.

The sum of the first $t + 1$ terms of

$$(p + q)^n \equiv \sum_{t=0}^n \binom{n}{t} p^{n-t} q^t \quad p + q = 1$$

is approximately

$$\int_x^\infty \phi(x) dx + \frac{q-p}{6\sigma} \phi^{(2)}(x) - \frac{1}{24} \left(\frac{1}{\sigma^2} - \frac{6}{n} \right) \phi^{(3)}(x)$$

where $x = (s - \frac{1}{2} - np)/\sigma$, $s = n - t$. The sum of the last $s + 1$ terms is approximately

$$\int_x^\infty \phi(x) dx - \frac{q-p}{6\sigma} \phi^{(2)}(x) - \frac{1}{24} \left(\frac{1}{\sigma^2} - \frac{6}{n} \right) \phi^{(3)}(x)$$

where $x = (t - \frac{1}{2} - nq)/\sigma$.

Table 26 Statistics and Probability Formulas

$p(x) = dP(x)/dx$	Differential probability (density) function of random variable x ; univariate frequency function
$P(x) = \int_{-\infty}^x p(x') dx'$	Cumulative probability function of random variable x ; univariate distribution function
$P(A < x < B)$	Cumulative probability that x is between A and B
$P(E \cap F)$	Probability of simultaneous (joint) occurrence of E and F
$P(E \cup F)$	Probability of occurrence of E or F or both
$P(E F) = P(E \cap F)/P(F)$	Conditional probability; probability of occurrence of E provided F has occurred
$E[f(x)] = \int_{-\infty}^{\infty} f(x)p(x) dx$	Expected value of function of a random variable x
$E(x) = \bar{x} = \int_{-\infty}^{\infty} xp(x) dx$	Expected (mean) value of random variable x
$\alpha_r = E(x^r)$	r th moment of random variable x ; r th moment about the origin
$\mu_r = E(x - \bar{x})^r$	r th moment of random variable x from mean value; r th central moment
$\text{Var } x = E[(x - \bar{x})^2] = \overline{(x - \bar{x})^2}$ $= \overline{x^2} - \bar{x}^2$	Variance value of random variable x
$\sigma = (\text{Var } x)^{1/2}$	Standard deviation of random variable x
$M_x(s) = E(e^{sx})$	Moment generating function associated with random variable x
$\psi_x(q) = E(e^{iqx})$	Characteristic function associated with random variable x
$\psi_g(q) = E[e^{iqg(x)}]$	Characteristic function of $g(x)$ with random variable x
$p(x, y) = d^2P(x, y)/dx dy$	Differential probability (density) function of random variables x and y ; bivariate frequency function
$P(x, y) = \int_{-\infty}^x \int_{-\infty}^y p(x', y') dx' dy'$	Cumulative probability function of random variables x and y ; bivariate distribution function
$P(A < x < B, C < y < D)$	Cumulative probability that x is between A and B and that also y is between C and D ; cumulative joint probability
$\text{Cov}(x, y) = E[(x - \bar{x})(y - \bar{y})]$ $= (x - \bar{x})(y - \bar{y})$	Covariance value of random variables x and y
$\rho(x, y) = \text{Cov}(x, y)/\sigma_x \sigma_y$	Correlation coefficient of random variables x and y

Source: Giacoletto, *Electronic Designers' Handbook*, Copyright © 1977 by McGraw-Hill, pp. 1-8.

The *probable error* of a single observation in a series of n measures, t_1, t_2, \dots, t_n , the arithmetic mean of which is m , is

$$e = \frac{0.6745}{\sqrt{n-1}} \sqrt{(m-t_1)^2 + (m-t_2)^2 + \dots + (m-t_n)^2}$$

the probable error of the mean is

$$E = \frac{0.6745}{\sqrt{n(n-1)}} \times \sqrt{(m-t_1)^2 + (m-t_2)^2 + \dots + (m-t_n)^2}$$

Approximate values of e and E are

$$e = 0.8453 \frac{\sum_{i=1}^n d_i}{\sqrt{n(n-1)}} \quad E = 0.8453 \frac{\sum_{i=1}^n d_i}{n\sqrt{n-1}}$$

where $\sum_{i=1}^n d_i$ is the sum of the deviations $d_i = |t_i - m|$.

4 UNITS AND STANDARDS

4.1 Physical Quantities and Their Relations

Mathematics is concerned with relations between numerical quantities, either constant or varying in a specific manner over a specific range of values. The numerical values are unique, absolute, and the same all over the world, being the expression of a fundamental perception of the mind. Any *mathematical equation* define the values of one numerical quantity, known as the dependent, in terms of constants and one or more other numerical quantities, known as the independent variables, as, for example,

$$z = r^2 + 3x + 4 \quad y = c \cdot \int_0^x \frac{x^2}{\cos x} dx \quad (1)$$

where z and y are dependent variables, r and x independent variables, and c a constant.

Physics, comprising the knowledge of inanimate nature and its laws, is concerned fundamentally with the measuring of the various quantities founded or created by definition as, for example, *length, mass, and electric charge*. In order to specify a *physical quantity* it is not sufficient to state merely a number. The value of a physical quantity can be determined only by comparison of the sample with a known amount of the same quantity by the process of *measuring*. The reference amount is called a unit, and the result of any measurement must be a statement of "how many times the sample was found to contain the reference amount." Thus a physical quantity Q naturally appears to be the product of a numerical value N and a unit U ,

$$Q = N \cdot U \quad (2)$$

as, for example: The length of a particular rod is 3.5 ft, or the rod is $3\frac{1}{2}$ times the length of 1 ft. Obviously, the reproduction of a unit must be possible at any time in order to facilitate correct measurements. This is being done by means of the "standards," which are simply a set of fundamental unit quantities kept under normalized conditions in order to preserve their values as accurately as facilities permit.

Any physical relation must be the result of a more or less obvious measurement, so that equations in physics are not merely numerical relations but express dependencies between physical quantities. Mathematics does not know "standards"; physics cannot be without "standards." The fact that physics often uses the methods of mathematics must not lead to the identification of the two sciences; it is merely an overlapping in the border regions.

Relations between Units. A unit is a particular amount of the physical quantity to be measured define in terms of a standard. The choice of a unit depends on convenience, facility of reproduction, and easy subdivision so as to obtain smaller units if desired. The value of a physical quantity Q must be independent of the units used, so that for two different units of the same type

$$Q = N_1 \cdot U_1 = N_2 \cdot U_2 \quad (3)$$

The size of the unit and the numerical value of the quantity are inversely related: the larger the unit the smaller the number of units.

A unit relation is an equation between two different units of the same type,

$$U_1 = N_{12} \cdot U_2 \quad (4)$$

and serves to convert from one unit U_1 to a different one U_2 . The conversion is achieved by replacing U_1 , taken as a factor, by its equivalent according to Eq. (4) so that

$$Q = N_1 \cdot U_1 = N_1 \cdot (N_{12} \cdot U_2) = (N_1 \cdot N_{12}) \cdot U_2 \quad (5)$$

As an example, express the length 3.5 ft in centimeters. The unit relation is 1 ft = 30.5 cm, and therefore $l = 3.5 \text{ ft} = 3.5 \times (30.5 \text{ cm}) = 106.75 \text{ cm}$. No error is possible if this rule is followed properly.

Physical Equations. Relations between physical quantities are usually given in the form of equations. It is always possible, by the proper use of unit relations (see previous paragraph), to express each side in the same units. Since units are to be considered as factors, they may be canceled and a numerical identity must result. This fact always can be used to check the proper numerical relations and the consistency of the units used.

There are two fundamental types of physical equations:

1. The **mathematical definition** of a physical quantity determines a new quantity uniquely in terms of known quantities. An example is Newton's definition of mass by $f = m \cdot a$, where f is the force and a the acceleration of a moving body. If f and a are measured, m can be computed as a physical quantity with numerical value $N(f)/N(a)$ and unit $U(f)/U(a) = U(m)$. A definition should be in agreement with all the other known relations in a particular field of science; it can only be of restricted value if it contradicts other relations (see later the "absolute" electric systems).

2. The **statement of proportionality** defines one physical quantity as linearly depending on a combination of other, known quantities. It is always the result of an experimental investigation. An example is Newton's law of the gravitational force $f = k(m_1 m_2 / r^2)$, where m_1 and m_2 are the two masses, r their center distance, and k the proportionality factor. In the case of a proportionality it is permissible to choose arbitrary units for all measurable physical quantities involved and to use the equation as a definition of the proportionality constant that, in general, will be a physical constant with numerical value and unit. In the example the value of k would be

$$\frac{N(f) \cdot N(r^2)}{N(m_1) \cdot N(m_2)} \times \frac{U(f) \cdot U(r^2)}{U(m_1) \cdot U(m_2)} = N(k) \cdot U(k)$$

Most of the fundamental laws of physics are statements of proportionalities, leading to universal physical constants, as, for instance, the gravitational constant k , the Planck constant h , the gas constant R , the absolute permeability of free space μ_v , and the absolute dielectric constant of free space ϵ_u . It may be observed that each branch of physics is represented by at least one fundamental proportionality constant.

Derived physical quantities are, in general, the result of mathematical definitions. The units of derived quantities are expressed from the combinations of the units used in the definition. All proportionality constants are ordinarily considered as derived physical quantities.

Fundamental Physical Quantities. The physical quantities, arbitrarily chosen to define new quantities or derived quantities, are called fundamental physical quantities. Their number may vary according to needs and convenience. There is no possibility to designate any physical quantity as absolutely fundamental, or a priori fundamental. Quantities that appear to be fundamental in one special field may be derived quantities in some other field.

4.2 Dimensions and Dimension Systems

Definition of Dimension. To choose a unit for a physical quantity one has an infinity of possibilities. The numerous units of length that were in use about 100 years ago present a good practical illustration. Yet all these units have in common the quality of being a distinct length and not, for example, a volume. It is convenient to state this fact by representing with the notation $[L]$ any unit of length whatsoever. The measurement of a physical quantity Q , therefore, leads to the statement

$$Q = N \cdot [Q] \quad (6)$$

where N is a numeric denoting the number of general units $[Q]$ that constitute the total quantity Q . According to Fourier, who first introduced this concept into the literature, $[Q]$ is called the "dimension" of the quantity Q . Be it clearly understood that dimension is simply the expression of a general unit and therefore a characteristic peculiarity of physical quantities not occurring in mathematics. Each new physical quantity gives rise to a new "dimension", as, for instance, time $[T]$, force $[F]$, mass $[M]$, and so on. There are as many dimensions, or general units, as there are kinds of physical quantities.

Derived Dimensions. Many physical quantities have been introduced by mathematical definition. Velocity, for example, is defined as $v = ds/dt$, where s is the length of the path measured from a definite origin and t is the time. A possible expression for the dimension of velocity would be $[V]$. It is customary and convenient, however, to make use of the mathematical definition that is but the rule for the measurement of velocity and to express the dimension in terms of the more familiar dimensions of length and time as a derived dimension $[V] = [L]/[T] = [L][T]^{-1}$. [Read: velocity is of +1 dimension in length and -1 dimension in time.] The use of mathematical definitions leading to derived dimensions of a composite nature, reduces the number of symbols. Thus the measurement of volume, if scientifically conducted, gives $[\text{Vol}] = [L]^3$, or in words, "volume is of +3 dimensions in length $[L]$."

Proportionality constants of physics have, in general, *derived dimensions*, as they are defined by the corresponding physical equations.

Fundamental Dimensions. The more familiar dimensions used to express derived dimensions are referred to as fundamental dimensions. It is advantageous to use as few of these fundamental dimensions as possible, not because the physical relations become simpler or clearer, but merely as a matter of economy in symbols. In fact, any dimension can be chosen to be a fundamental dimension in a particular field and a derived dimension in some other field of physics. No fundamental dimension can be made a starting point of natural philosophy.

Dimensional Equations. Since a physical equation constitutes in fact two equations, one for the units and one for the numerics, one can disregard the numerical factors entirely and write the general units or dimensions only, arriving thus at a dimensional equation. For instance, the law of gravitation would read $[F] = [k][M]^2[L]^{-2}$ using $[F]$, $[k]$, $[M]$, and $[L]$ as dimensions for force, gravitation constant, mass, and length, respectively. From this dimensional equation a derived dimension can be obtained for any quantity involved. Conversely, dimensional equations are used to check the correctness of physical relations if all dimensions can be made to cancel. Finally, the validity of dimensional equations leads to the method of dimensional analysis.

A set of fundamental dimensions is any group of fundamental dimensions convenient and useful to express all the physical quantities of a particular field in terms of derived dimensions. The number of fundamental dimensions to make a set may vary according to the field of application. Whether or not a set of fundamental dimensions can be used beyond the field for which it was originally intended will depend upon its suitability as a dimension system. (See next paragraph.) In no case should it be used where it can lead to confusion.

A set of fundamental dimensions is *incomplete* when the number of fundamental dimensions composing it is less than the number required for a dimension system. Incomplete sets of fundamental dimensions should not be used outside the very restricted field for which they are defined; they necessarily would lead to confusing relations.

A *dimension system* is composed of the smallest number of fundamental dimensions that will form a consistent and complete set for a field of science. Since each relation between physical quantities can be split up into one relation of numerics and another one of dimensions (as general units), it is possible to combine all known relations of dimensions. In setting up these relations, all proportionality factors must be taken as physical quantities. If there are m independent relations known, $m + p$ dimensions may be involved, of which m dimensions can be expressed by any p "fundamental" dimensions chosen arbitrarily.

This set of p "fundamental" dimensions is then called a dimension system. From the theory of numbers, therefore, it is known that one generally has a

choice of $\binom{m+p}{p}$ possible dimension systems. Thus,

if $p = 3, m = 3$, then one has $\binom{6}{3} = 20$ different possibilities.

A necessary condition, however, is that *each* independent relation involve at least $p + 1$ dimensions. If this is not the case, then the number of possible

dimension systems is less, so that $\binom{m+p}{p}$ indicates the *upper* limit.

Any dimension system chosen in the described manner is consistent, as well as correct, and never leads to ambiguity with respect to the expression of physical quantities. Complete dimension systems in mechanics must have three, in thermodynamics four, and in electromagnetism four fundamental dimensions. It seems, according to present knowledge, that five fundamental dimensions suffice for the entire range of physics, namely, the three fundamental dimensions of mechanics, an additional one for thermodynamics, and another additional one for electromagnetism.

All the known dimension systems use length $[L]$ and time $[T]$ as primary fundamental dimensions, adding various fundamental dimensions from the available physical quantities of the field of physics. The choice of $[L]$ and $[T]$ reduces at once the maximum number of possible dimension systems to $\binom{m+p-2}{p-2}$.

Why Dimension Systems? Since the proper choice of units is the ultimate goal of any critical analysis of physical quantities, the question may be asked: Why is it necessary to discuss dimension of systems? The answer is that each physical quantity may be measured by an infinite variety of units but has only one dimension within a given dimension system. The process of deciding upon the fundamental dimensions before fixing the units within the scope of the fundamental dimensions is, therefore, essentially a matter of economy and logic.

4.3 Dimension and Unit Systems

In the past different dimension systems were introduced for various fields of technology (mechanics, heat, electromagnetism) and based on different choices of fundamental dimensions, for example, for mechanics, length and time plus mass or force or energy or gravitational constant gave potentially four different dimension system classes. In turn, for a given dimensional system, a unit system could be developed, choosing for each fundamental dimension a unit desirably related to a fundamental standard or standards. In seeking to define units with appropriate size values, relationships, and so on, many different unit systems, for example, centimeter-gram-second (cgs), meter-kilogram-second (mks), "absolute," "technical," and so on, have been introduced over the years. (See O. W. Eshbach and M. Souders, *Handbook of Engineering Fundamentals*, 3rd ed., Wiley, New York, 1975, for a detailed exposition of the subject.)

In recent years a major step toward simplification and standardization has been taken by the increasing adoption of the International System of Units (SI).

4.4 The International System of Units

The SI system, composed of six fundamental units, has been adopted by the Conference Générale (BIPM Sevres, Paris, 1954 and 1960) to cover the whole range of physics and one in which all international reports are to be expressed.

Quantity	Unit	Symbol
<i>Fundamental Units</i>		
Length	Meter	m
Mass	Kilogram	kg
Time	Second	s
Intensity of electric current	Ampere	A
Thermodynamic temperature	Degree kelvin	K
Luminous intensity	Candela	cd
Amount of substance	Mole	mol
<i>Derived Units with Special Names</i>		
Area	Square meter	m ²
Volume	Cubic meter	m ³
Frequency	Hertz	Hz
Density (mass density)	Kilogram per cubic meter	kg/m ³
Velocity	Meter per second	m/s
Angular velocity	Radian per second	rad/s
Acceleration	Meter per square second	m/s ²
Angular acceleration	Radian per square second	rad/s ²
Force	Newton	N, kg·m/s ²
Pressure, stress	Newton per square meter	N/m ²
Kinematic viscosity	Square meter per second	m ² /s
Dynamic viscosity	Newton-second per square meter	N·s/m ²
Work, energy, heat (quantity of heat)	Joule	J, N·m
Power, radiant flux	Watt	W, J/s
Plane angle	Radian	rad
Solid angle	Steradian	sr
Electric charge	Coulomb	C, A·s
Electric potential, potential difference, electromotive force	Volt	V, W/A
Electric field strength	Volt per meter	V/m
Resistance (to direct current)	Ohm	Ω, V/A
Electric conductance	Siemens	S, A/V
Capacitance	Farad	F, A·s/V
Magnetic flux	Weber	Wb, V·s
Inductance	Henry	H, V·s/A
Magnetic flux density (magnetic induction)	Tesla	T, Wb/m ²
Magnetic field strength	Ampere per meter	A/m
Magnetomotive force	Ampere	A
Luminous flux	Lumen	lm, cd·sr
Luminance	Candela per square meter	cd/m ²
Illumination	Lux	lx, lm/m ²
Activity (of a radionuclide)	Becquerel	Bq, 1/S
Absorbed dose	Gray	Gy, J/kg
Dose equivalent	Sievert	Sv, J/kg
<i>Other Common Derived Units</i>		
Absorbed dose rate	Gray per second	Gy/s
Acceleration	Meter per second squared	m/s ²
Angular acceleration	Radian per second squared	rad/s ²
Angular velocity	Radian per second	rad/s
Area	Square meter	m ²
Concentration (of amount of substance)	Mole per cubic meter	mol/m ³
Current density	Ampere per square meter	A/m ²

Quantity	Unit	Symbol
<i>Other Common Derived Units (Continued)</i>		
Density, mass	Kilogram per cubic meter	kg/m ³
Electric charge density	Coulomb per cubic meter	C/m ³
Electric field strength	Volt per meter	V/m
Electric flux density	Coulomb per square meter	C/m ²
Energy density	Joule per cubic meter	J/m ³
Entropy	Joule per kelvin	J/K
Exposure (X and gamma rays)	Coulomb per kilogram	C/kg
Heat capacity	Joule per kelvin	J/K
Heat flux density	Watt per square meter	W/m ²
Irradiance	Watt per square meter	W/m ²
Luminance	Candela per square meter	cd/m ²
Magnetic field strength	Ampere per meter	A/m
Molar energy	Joule per mole	J/mol
Molar entropy	Joule per mole kelvin	J/(mol · K)
Molar heat capacity	Joule per mole kelvin	J/(mol · K)
Moment of force	Newton meter	N · m
Permeability (magnetic)	Henry per meter	H/m
Permittivity	Farad per meter	F/m
Power density	Watt per square meter	W/m ²
Radiance	Watt per square meter steradian	W/(m ² · sr)
Radiant intensity	Watt per steradian	W/sr
Specific heat capacity	Joule per kilogram kelvin	J/(kg · K)
Specific energy	Joule per kilogram	J/kg
Specific entropy	Joule per kilogram kelvin	J/(kg · K)
Specific volume	Cubic meter per kilogram	m ³ /kg
Surface tension	Newton per meter	N/m
Thermal conductivity	Watt per meter kelvin	W/(m · K)
Velocity	Meter per second	m/s
Viscosity, dynamic	Pascal second	Pa · s
Viscosity, kinematic	Square meter per second	m ² /s
Volume	Cubic meter	m ³
Wave number	1 per meter	1/m

Definitions of Derived Units of the International System Having Special Names

Quantity	Unit and Definition
1. Absorbed dose	The <i>gray</i> is the absorbed dose when the energy per unit mass imparted to matter by ionizing radiation is one joule per kilogram. <i>Note:</i> The gray is also used for the ionizing radiation quantities: specific energy imparted, kerma, and absorbed dose index, which have the SI unit joule per kilogram.
2. Activity	The <i>becquerel</i> is the activity of a radionuclide decaying at the rate of one spontaneous nuclear transition per second.
3. Celsius temperature	The <i>degree Celsius</i> is equal to the kelvin and is used in place of the kelvin for expressing Celsius temperature (symbol <i>t</i>) defined by the equation $t = T - T_0$, where <i>T</i> is the thermodynamic temperature and $T_0 = 273.15$ K by definition.
4. Dose equivalent	The <i>sievert</i> is the dose equivalent when the absorbed dose of ionizing radiation multiplied by the dimensionless factors <i>Q</i> (quality factor) and <i>N</i> (product of any other multiplying factors) stipulated by the International Commission on Radiological Protection is one joule per kilogram.

(Continues)

Quantity	Unit and Definitio
5. Electric capacitance	The <i>farad</i> is the capacitance of a capacitor between the plates of which there appears a difference of potential of one volt when it is charged by a quantity of electricity equal to one coulomb.
6. Electric conductance	The <i>siemens</i> is the electric conductance of a conductor in which a current of one ampere is produced by an electric potential difference of one volt.
7. Electric inductance	The <i>henry</i> is the inductance of a closed circuit in which an electromotive force of one volt is produced when the electric current in the circuit varies uniformly at a rate of one ampere per second.
8. Electric potential difference, electromotive force	The <i>volt</i> (unit of electric potential difference and electromotive force) is the difference of electric potential between two points of a conductor carrying a constant current of one ampere when the power dissipated between these points is equal to one watt.
9. Electric resistance	The <i>ohm</i> is the electric resistance between two points of a conductor when a constant difference of potential of one volt, applied between these two points, produces in this conductor a current of one ampere, this conductor not being the source of any electromotive force.
10. Energy	The <i>joule</i> is the work done when the point of application of a force of one newton is displaced a distance of one meter in the direction of the force.
11. Force	The <i>newton</i> is that force that, when applied to a body having a mass of one kilogram, gives it an acceleration of one meter per second squared.
12. Frequency	The <i>hertz</i> is the frequency of a periodic phenomenon of which the period is one second.
13. Illuminance	The <i>lux</i> is the illuminance produced by a luminous flu of one lumen uniformly distributed over a surface of one square meter.
14. Luminous flu	The <i>lumen</i> is the luminous flu emitted in a solid angle of one steradian by a point source having a uniform intensity of one candela.
15. Magnetic flu	The <i>weber</i> is the magnetic flu that, linking a circuit of one turn, produces in it an electromotive force of one volt as it is reduced to zero at a uniform rate in one second.
16. Magnetic flu density	The <i>tesla</i> is the magnetic flu density given by a magnetic flu of one weber per square meter.
17. Power	The <i>watt</i> is the power that gives rise to the production of energy at the rate of one joule per second.
18. Pressure or stress	The <i>pascal</i> is the pressure or stress of one newton per square meter.
19. Quantity of electricity	The <i>coulomb</i> is the quantity of electricity transported in one second by a current of one ampere.

Prefixes. The SI system has adopted the following standard set of prefixes

Multiplication Factor	Prefi	Symbol
1 000 000 000 000 000 000 = 10^{18}	Exa	E
1 000 000 000 000 000 = 10^{15}	Peta	P
1 000 000 000 000 = 10^{12}	Tera	T
1 000 000 000 = 10^9	Giga	G
1 000 000 = 10^6	Mega	M
1 000 = 10^3	Kilo	k
100 = 10^2	Hecto ^a	h
10 = 10^1	Deka ^a	da
0.1 = 10^{-1}	Deci ^a	d
0.01 = 10^{-2}	Centi ^a	c
0.001 = 10^{-3}	Milli	m
0.000 001 = 10^{-6}	Micro	μ
0.000 000 001 = 10^{-9}	Nano	n
0.000 000 000 001 = 10^{-12}	Pico	p
0.000 000 000 000 001 = 10^{-15}	Femto	f
0.000 000 000 000 000 001 = 10^{-18}	Atto	a

Application of SI Prefixes

General. In general the SI prefix should be used to indicate orders of magnitude, thus eliminating non-significant digits and leading zeros in decimal fractions and providing a convenient alternative to the powers-of-10 notation preferred in computation. For example,

12,300 mm becomes 12.3 m

12.3×10^3 m becomes 12.3 km

0.00123 μ A becomes 1.23 nA

Selection. When expressing a quantity by a numerical value and a unit, a prefix should preferably be chosen so that the numerical value lies between 0.1 and 1000. To minimize variety, it is recommended that prefix representing 1000 raised to an integral power be used. However, three factors may justify deviation:

1. In expressing area and volume, the prefix hecto-, deka-, deci-, and centi- may be required, for example, square hectometer, cubic centimeter.
2. In tables of values of the same quantity or in a discussion of such values within a given context, it is generally preferable to use the same unit multiple throughout.
3. For certain quantities in particular applications, one particular multiple is customarily used. For example, the millimeter is used for linear dimensions in mechanical engineering drawings even when the values lie far outside the range 0.1–1000 mm; the centimeter is often used for body measurements and clothing sizes.

Prefixes in Compound Units.* It is recommended that only one prefix be used in forming a multiple of a compound unit. Normally the prefix should be attached to a unit in the numerator. One exception to this is when the kilogram occurs in the denominator. For example,

V/m, *not* mV/mm, and MJ/kg, *not* kJ/g

Compound Prefixes. Compound prefixes formed by the juxtaposition of two or more SI prefixes are not to be used. For example, use

1 nm, *not* 1 $\mu\mu$ m

1 pF, *not* 1 $\mu\mu$ F

If values are required outside the range covered by the prefixes they should be expressed by using powers of 10 applied to the base unit.

*A compound unit is a derived unit that is expressed in terms of two or more units rather than by a single special name.

Powers of Units. An exponent attached to a symbol containing a prefix indicates that the multiple or sub-multiple of the unit (the unit with its prefix is raised to the power expressed by the exponent. For example,

$$1 \text{ cm}^3 = (10^{-2} \text{ m})^3 = 10^{-6} \text{ m}^3$$

$$1 \text{ ns}^{-1} = (10^{-9} \text{ s})^{-1} = 10^9 \text{ s}^{-1}$$

$$1 \text{ mm}^2/\text{s} = (10^{-3} \text{ m})^2/\text{s} = 10^{-6} \text{ m}^2/\text{s}$$

Calculations. Errors in calculations can be minimized if the base and the coherent derived SI units are used and the resulting numerical values are expressed in powers-of-10 notation instead of using prefixes

Other Units

Units from Different Systems. To assist in preserving the advantage of SI as a coherent system, it is advisable to minimize the use with it of units from other systems. Such use should be limited to units listed in this section.

A following section presents conversion factors to and from SI units.

4.5 Length, Mass, and Time

English Units and Standards

Units of Length. The *foot* (ft) is the *fundamental* unit of length in the foot–pound–second (fps) system. It equals, by definition one-third of a *yard* (yd), which is the English legalized *standard* unit of length. The *U.S. yard* was defined by Act of Congress, July 28, 1866, as 3600/3937 the length of the *meter*. (See discussion of metric system for definition of metric length.)

In Great Britain, the *Imperial yard* is measured by a bronze bar preserved in the Standards Office, Westminster. Its length, in terms of the *international prototype meter*, is 3600/3937.0113 m. For engineering purposes, the U.S. and British *yards* may be considered identical.

As subunits, the *inch* (in.) is defined as one-twelfth of one standard foot, and the *mil* as the one-thousandth part of one inch. The *nautical mile* (mi) is defined as one minute of arc on the earth's surface at the equator, whereas the U.S. mile (U.S. mi statute) is exactly 5280 ft and practically identical with the British mile.

Unit of Capacity (Dry). The *bushel* (bu) is the *standard* unit of *dry* capacity. The *Winchester bushel* (U.S. standard) has a volume of 2150.42 in.³

In Great Britain, the *Imperial bushel* (bu) is defined as the volume of 80 lb of pure water at 62°F weighed against brass weights in air at the same temperature as the water and with the barometer at 30 in. Its volume is approximately 2219.36 in.³

Unit of Capacity (Liquid). The *gallon* (gal) is the *standard* unit of *liquid* capacity. The *U.S. gallon* has a volume of 231 in.³

In Great Britain, the *Imperial gallon* is defined as the volume of 10 lb of pure water at 62°F weighed against brass weights in air at the same temperature as the water and with the barometer at 30 in. Its volume is approximately 277.420 in.³ The Imperial gallon (liquid measure) equals exactly one-eighth of the Imperial bushel (dry measure). Subunits are the quart (qt), which is one-fourth of the standard gallon, and the pint (pt), which is $\frac{1}{2}$ qt.

Units of Mass. The *pound (avoirdupois)* (lb avdp) is the *fundamental* unit of mass in the fps system.* It is also the English legalized *standard* unit of mass. The U.S. *pound (avoirdupois)* was defined by Act of Congress, 1866, as 1/2.2046 kg, but since 1895 there has been used, for greater accuracy, a value that agrees with that given by law as far as the latter is given, namely, 453.5924277 g. This value is now used by the Bureau of Standards as an exact definition and is the basis of the customary U.S. weights (Circular 47, Bureau of Standards).

In Great Britain, the *Imperial pound (avoirdupois)* is the mass of a *platinum cylinder* preserved in the Standards Office, Westminster. Its legal equivalent is 453.59243 g. For engineering purposes, the U.S. and British pounds (avoirdupois) may be considered as identical.

Subunits of mass are the grain (gr), defined as $\frac{1}{7000}$ of the standard pound (avoirdupois) and the ounce (avoirdupois) (oz-avdp), which is $\frac{1}{16}$ of the standard pound (avoirdupois). The grain was used as a fundamental unit in the so-called foot-gram-second (fgs) system of units prior to 1873.

Weight versus Mass. Unfortunately, the word "weight" is used in two different senses, namely, (1) by the layman (as well as loosely by the scientist) to designate a given *mass* or quantity of matter and (2) by the scientist to designate the *pull* in standard gravitational force units that is exerted by the earth upon a piece of matter. The result of the commercial act of "weighing" a specific quantity is independent of the local gravitational pull of the earth, since both spring scales and balances are calibrated locally by comparison with standard masses.

Auxiliary Fundamental Units. Auxiliary Fundamental Units and their principal derived units are defined and discussed under the sections of this handbook pertaining to the topics to which they apply. In general, however, conversion factors are included in the tables of Section 5.

For an interesting and rather complete history see *British Weights and Measures*, London, 1910, by Sir C. M. Watson.

Metric (or SI) Units and Standards The development of the SI system and the operations of the international bodies (BIPM, CIPM, and CGPM) having cognizance over weights and measures are described in appendices to ASTM's *Standard for Metric Practice* (ASTM E380-82, American Society for Testing and Materials, Philadelphia, 1982).

Units of Length. The *centimeter* (cm) is the *fundamental* unit of length in the cgs system. It equals, by definition $\frac{1}{100}$ of a *meter* (m). The meter has been standardized by international agreement as 1,650,763.73 times the wavelength in vacuum of the unperturbed transition ($2p_{10}-5d_5$) of krypton 86. The *basic* meter for international comparisons is the *international prototype meter*, which is the distance, at zero degrees Centigrade, between two lines on a platinum-iridium bar located at the International Bureau of Weights and Measures at Sèvres, France. This meter is the nearest to a duplicate ever constructed of the *original* meter, which was constructed and deposited in the Archives of the French Republic in 1799. The meter is very nearly equal to one ten-millionth of the distance, measured at sea level, from the equator to either pole.

An interesting history of the development of the *international prototype meter* (as well as the *international prototype kilogram*—see discussion on unit of mass) is given by W. Parry, National Bureau of Standards, in *Merriman's Civil Engineers' Handbook*, as follows:

The use of the meter as the basis of geodetic surveys had become so general throughout Europe that a conference was called in Paris, France, in 1870, for the purpose of establishing a central bureau where the standards of the different countries could be compared. As a result of this conference an International Bureau of Weights and Measures was established near Paris in 1875, by the concurrent action of the principal nations of the world. One of the first tasks undertaken by the Bureau was the construction of exact copies of the meter and kilogram deposited in the Archives. Thirty-one standard meters of iridio-platinum and forty kilograms of the same alloy were constructed and carefully compared with the standards of the Archives and with one another. This great work was completed in 1889, and the meter and kilogram which agreed most nearly with the original standards were called international prototypes, and were deposited at the International Bureau, where they are maintained today subject to the authority of the International Committee on Weights and Measures. The remaining meters and kilograms were distributed by lot to the different nations which contributed to the support of the Bureau. The United States secured two copies of the meter and two copies of the kilogram, which are in the custody of

*The slug of mass, which is extensively used by engineers and physicists, is (in the English system) the mass to which an acceleration of one foot per second per second would be given by the application of a one-pound force. Under any gravity conditions, 1 slug of mass = 32.1739 lb of mass.

the Bureau of Standards at Washington. One of the meters, known as No. 27, and one kilogram, No. 20, were selected as the United States standards, while the other meter and kilogram are used as secondary standards. It was the declared intention of the International Committee that the various national prototypes should be returned to the International Bureau at regular intervals for the purpose of recomparing them with the international standards and with one another. In this way all measurements based upon metric standards throughout the world are ultimately referred to the international meter and kilogram.

Unit of Capacity. The liter (L) is the *standard* unit of capacity. It is defined as the volume of one kilogram of pure water at the temperature of maximum density (4°C) under a pressure of 76 cm of mercury. For all practical purposes, the liter may be regarded as the equivalent of the cubic decimeter, although the former is actually slightly greater, in the amount of less than three parts in one hundred thousand.

Unit of Mass. The gram (g) is the *fundamental* unit of mass in the cgs system.* It equals, by definition $\frac{1}{1000}$ of a kilogram (kg), which is the *standard* unit of mass. The *basic* kilogram for international comparisons is the *international prototype kilogram*, which is a cylinder of platinum-iridium located at the International Bureau of Weights and Measures at Sèvres, France. This mass is the nearest to a duplicate ever constructed of the *original* kilogram, which was constructed and deposited in the Archives of the French Republic in 1799. The latter was made as nearly as possible equal to the mass of a cube of pure water at 4°C, the sides of the cube being one-tenth the length of the original meter.

An interesting history of the development of the *international prototype kilogram* was given under the discussion on units of length.

Weight versus Mass. See discussion under this same subheading of the English units and standards.

Auxiliary Fundamental Units. Auxiliary fundamental units and their principal derived units are defined and discussed under the sections of this handbook pertaining to the topics to which they apply. In general, however, conversion factors are included in Tables 27–64.

Standard of Time

Unit of Time. The *second* has been standardized by international agreement as 1/31,556,925.9747 of the

tropical year at 12 hr, ephemeris time, January 0 for the year 1900.0. (This definition has been retained for the time being as an astronomical time standard—the following atomic standard of time interval is 100 times more precise.) The second has been standardized by international agreement as the time taken for 9,192,631,770.0 vibrations of the unperturbed hyperfine transition 4,0–3,0 for the $^2S_{1/2}$ fundamental state of the cesium 133 atom. The ^{133}Cs standard has been adopted provisionally (see resolution 5 of the 12th General Conference of Weights and Measures, BIPM, Sèvres, Paris, Oct. 1964). A more accurate hydrogen maser standard may be available in the near future that is 100 times more accurate than the ^{133}Cs standard.

Measures of Time. A *solar day* is measured by the rotation of the earth about its axis with respect to the sun. In *astronomical computations* and in *nautical time* the day commences at noon, and in the former it is counted throughout the 24 hr. In *civil computations* the day commences at midnight and is divided into two parts of 12 hr each.

A *solar year* is the time in which the earth makes one revolution around the sun. Its average time, called the *mean solar year*, is 365 days, 5 hr, 48 min, and 45.9747 sec, or nearly $365\frac{1}{4}$ days.

4.6 Force, Energy, and Power

Dynamical and Gravitational Units. According to the use of two different dimension and unit systems, the dynamical (or physical, or “absolute”) system and the gravitational (or technical) system, two different sets of units of force, energy, power, and derived quantities are defined in both the English and the metric systems. *One dynamical unit of force* produces an acceleration of unity on unit standard mass. The *gravitational unit of force* is defined as that force required to give a unit standard mass an acceleration equal to that produced by the gravitational pull of the earth. As the acceleration due to gravity, g , varies with location and altitude,† the gravitational unit of force is not constant, and, therefore, its relation to the dynamical unit of force will vary. By international agreement, the value $g_0 = 980.665 \text{ cm/sec}^2 = 32.1739 \text{ ft/sec}^2$ (British) has been chosen as the standard acceleration of gravity to make invariant the gravitational unit of force.

English Units

Units of Force. The dynamical or physical unit of force is the *poundal*, defined as the force required to

*The slug of mass, which is extensively used by engineers and physicists, is (in the metric system) the mass to which an acceleration of one meter per second per second would be given by the application of a one-kilogram force. Under any gravity conditions, 1 slug of mass = 9.80665 kg of mass.

†The variation of g with latitude ϕ and altitude H is given approximately by (ϕ in degrees, H in meters) $g = 978.039 (1 + 0.005295 \sin^2 \phi) - 0.000307H$. See *International Critical Tables*, Vol. 1, p. 395.

give a mass of one pound an acceleration of one foot per second per second.

The *pound-force* (or weight of the pound mass) is the gravitational or technical unit of force. It is, by definition the force required to give a mass of one pound an acceleration of 32.1739 ft/sec². If a force is measured by "weighing," the result in pounds weight must be multiplied by g/g_0 , the ratio of local to standard acceleration of gravity, in order to obtain the absolute value in pound-force units. For engineering purposes this correction can usually be neglected.

Unit of Pressure. This is defined as the unit of force acting upon a unit area. The most commonly employed unit is the *pound (force) per square inch*.

Standard atmospheric pressure is defined to be the force exerted by a column of mercury 760 mm (29.92 in.) high at 0°. This corresponds to 0.101325 MPa or 14.695 psi. Reference or fixed points for pressure calibration exist and are analogous to the phase changes used for temperature standards. These pressure references are based on phase changes or resistance jumps in selected materials.

Units of Work or Energy. The foot-poundal is the physical unit of work or energy and is defined as the work done by a force of one poundal in moving a body through the distance of one foot in the direction of the force.

The *foot-pound (force)* is the technical unit of work or energy and is defined as the work required to raise a mass (or weight) of one pound through a vertical distance of one foot at standard acceleration of gravity g_0 . If measurements are made in places where the local value of the acceleration of gravity g is different from g_0 , a correction factor g/g_0 must be applied if the exact value of work or energy is desired.

The *British thermal unit* (Btu) is the quantity of heat required to raise the temperature of a one-pound mass of water either at 39°F (at its maximum density) or at 60°F and standard pressure through 1°F. The mean British thermal unit is defined as the $\frac{1}{180}$ part of the heat required to raise the temperature of a one-pound mass of water from 32 to 212°F at standard pressure. It is obvious that the reference temperature must be indicated with the unit used.

Units of Power. Power is the time rate at which work is done. Its physical unit is the *foot-poundal per second*, its technical units are the *foot-pound (force) per second*, or the *British thermal unit per second*. The *horsepower* (hp or Hp) is defined as 33,000 ft-lb (force) per minute or 550 ft-lb (force) per second.

Units of Torque. Torque is the effectiveness of a force to produce rotation. It is defined as the product of the force and the perpendicular distance from its line of action to the instantaneous center of rotation. Its physical unit is the poundal-foot, and its technical unit the pound (force)-foot. (Note the reversal of force and

length units in the designation of the units of torque as compared with the units of energy or work.)

Metric Units

Units of Force. The dynamical, or physical, unit of force is the *dyne*, defined as the force required to give a mass of one gram an acceleration of one centimeter per second per second.

The *newton* is the SI unit of force. It is the force required to give a mass of one kilogram an acceleration of one meter per second per second.

The *kilogram force* (or weight of the kilogram mass) is the gravitational or technical unit of force. It is, by definition the force required to give a mass of one kilogram an acceleration of 980.665 cm/sec². If a force is measured by "weighing," the result in kilograms weight must be multiplied by g/g_0 , the ratio of local to standard acceleration of gravity, in order to obtain the absolute value in kilogram-force units. For engineering purposes this correction can usually be neglected.

In the electrotechnical system of units the systematic unit of force is defined as the *joule per meter*, based on the fundamental definition of the joule. (See discussion on metric units of energy.)

Unit of Pressure. This is defined as the unit of force acting upon a unit of area.

The *newton per square meter* is the SI unit of pressure and is called the *pascal*.

The *kilogram force per square meter* is the technical unit of pressure. With respect to correction for local gravity, see discussion on force versus weight.

Pressure is measured also by the height in centimeters of the column of water at 4°C, or of the column of mercury at 0°C, which it supports. (See conversion Table 41.)

The *normal atmosphere* (at), or the standard atmospheric pressure, is defined as the pressure exerted by a column of 76 cm of mercury at sea level and 0°C at standard acceleration of gravity g_0 . It is equal to 1.01321 bars or 1.0332 kg/cm² force and is used extensively in the engineering literature. Some confusion exists since the unit of 1 kg/cm² is occasionally called 1 practical atmosphere.

Units of Work or Energy. The *joule* is the physical or so-called absolute unit of work or energy. It is defined as the work done by a force of one newton acting through the distance of one meter. A larger unit is the *theoretical* or "absolute" *joule* defined as 10⁷ ergs; it is a systematic unit in the practical electrical unit systems that is based on the theoretical unit systems. (See discussion on electrical units.)

The *international joule* is defined as the energy expended during one second by an electric current of one international ampere flowing through a resistance of one international ohm. (See discussion on electrical

units.) The latest value of the international joule is equal to 1.000165 theoretical joules.*

The *kilowatt-hour* is the practical unit of energy in electrical metering. It is defined as a theoretical or an international unit (see definition of joule already given) and is equal to 3.6 megajoules.

The *meter-kilogram force* (commonly referred to as the kilogram-meter) is the technical unit of work or energy. It is defined as the work required to raise the mass (or weight) of one kilogram through a vertical distance of one meter at standard acceleration of gravity g_0 . If measurements are made in places where the local value of the acceleration of gravity g is different from g_0 , a correction factor g/g_0 has to be applied, if the exact value of work or energy is desired. (See discussion on force versus weight.)

The *gram-calorie* or small calorie is the physical unit of heat energy. It is defined as the quantity of heat required to raise the temperature of one gram mass of water either from 14.5 to 15.5°C or from 19.5 to 20.5°C at standard pressure. The two values are designated as 15 and 20°C cal, respectively. The mean gram-calorie is defined as $\frac{1}{100}$ part of the quantity of heat required to raise the temperature of one gram mass of water from 0 to 100°C at standard pressure. The same definition apply to kilogram-calorie, or large calorie, if the kilogram mass is used as reference standard mass.

The *Ostwald calorie* is the quantity of heat required to raise the temperature of one gram mass from 0 to 100°C. This unit is frequently used by electrochemists and is equal to 100 mean gram-calories.

The *international kilocalorie* or international steam-table calorie (IT cal) is defined as the $\frac{1}{860}$ part of the international kilowatt-hour. This new unit avoids any reference to the thermal properties of water and was recommended for international adoption at the first International Steam Table Conference (1929).† Its value is very nearly equal to the mean kilocalorie, 1 IT cal = 1.00037 kilogram-calories (mean).

Units of Power. Power is the time rate at which work is done. Its physical unit is the watt, defined as the power which gives rise to the production of energy at the rate of one joule per second.

The *international watt* is defined as the power expended by an electric current of one international ampere flowing through a resistance of one international ohm. (See discussion on electrical units.) The latest value of the international watt is equal to 1.000165 theoretical watts.‡

The *electrical horsepower* is defined as 746 absolute watts and is commonly used in the United States and in England in rating electrical machinery.

The *meter-kilogram force per second* (commonly referred to as the kilogram-meter per second) is the technical unit of power. The *metric horsepower* is defined as 75 kg-m/sec and is the most common mechanical unit of power.

Units of Torque. Torque is the effectiveness of a force to produce rotation. It is defined as the product of the force and the perpendicular distance from its line of action to the instantaneous center of rotation. Its physical unit is the dyne-centimeter, and its technical unit the kilogram force meter. (Note the reversal of force and length units in the designation of the units of torque as compared with the units of energy and work.)

4.7 Thermal Units and Standards

Temperature

Definition of Temperature. The *temperature* of a body may be defined as its thermal state considered from the standpoint of its ability to communicate heat to other bodies. When two bodies are placed in thermal communication, the one that loses heat to the other is said to be at the higher temperature.

Standard Temperatures. Certain thermal states or "temperatures" may be reproduced and recognized by the fact that definite physical phenomena occur at these temperatures. Such thermal states are called "fixed points," and they may, quite apart from any temperature scale, be specified by the physical phenomena characteristic of those temperatures. The two fundamental fixed points are the ice point and the steam point.

The *ice point* is defined as the temperature of melting ice, which is realized experimentally as the temperature at which pure finely divided ice is in equilibrium with pure, air-saturated water under standard atmospheric pressure. The effect of increased pressure is to lower the freezing point to the extent of 0.007°C per atmosphere.

The *steam point* is defined as the temperature of condensing water vapor at standard atmospheric pressure, and it is realized experimentally by the use of a hypsometer so constructed as to avoid superheat of the vapor around the thermometer or contamination with air or other impurities. If the desired conditions have been attained, the observed temperature should be independent of the rate of heat supply to the boiler, except as this may affect the pressure within the hypsometer, and of the length of time the hypsometer has been in operation.

Definition of Temperature Scale. The purpose of establishing a temperature scale is to assign a number to every thermal state or temperature and to provide a means for determining the temperature of any particular body.

**Mechanical Engineering*, Feb., 1930, pp. 122, 139.

†*Mechanical Engineering*, Nov., 1935, p. 710.

‡*Announcement of Changes in Electrical and Photometric Units*, Circular of National Bureau of Standards C459, Washington, DC, 1947.

A *temperature scale* may be defined by (1) selecting definite numbers for certain fixed points, (2) selecting some physical property of a definite substance that varies with temperature, and (3) selecting a mathematical law expressing temperatures on the scale in question in terms of the selected property of the thermometric substance. For example, on the Centigrade mercury-in-glass scale, the ice and steam points are numbered 0 and 100, respectively, the relative or "apparent" expansion of a volume of mercury enclosed in glass of a definite kind is the property used, and the mathematical relation used to express temperature on this scale is that equal increments of apparent volume of the mercury in this glass correspond to equal increments of temperature. If some other substance is substituted for mercury, or if glass of a different kind is used, another scale is obtained that agrees with it at 0 and 100 but not at other temperatures.

Although, in general, a temperature scale depends on the thermometric substance as well as on the expression for the temperature in terms of some property of this substance, Lord Kelvin has shown that, if the property selected is the availability of energy, the scale so defined is wholly independent of the substance and depends only on the mathematical relation chosen. Any scale so defined is known as a thermodynamic scale.

Kelvin Temperature Scale. The temperature scale finally chosen by Lord Kelvin is the one on which the temperature interval from the ice point to the steam point is 100° and the ratio of the values of any two temperatures is equal to the ratio of the heat taken in to the heat rejected by a reversible thermodynamic engine working with a source and refrigerator at the higher and lower temperatures, respectively. On this scale, which is also known as the absolute thermodynamic scale, the lowest attainable temperature is 0 and the ice point is found experimentally to be 273.16° . The steam point therefore is 373.16° or 100° higher.

The *degree Kelvin* ($^\circ\text{K}$) or degree of absolute temperature is the absolute unit of temperature and is, for practical purposes, identical with the degree Centigrade ($^\circ\text{C}$) of the international temperature scale.

Thermodynamic Centigrade Scale. This is derived by subtracting from the Kelvin scale a constant number of the proper magnitude to make the ice point 0° . On this scale, therefore, the ice and steam points are 0 and 100° , respectively, and the so-called absolute zero is -273.16° .

International Centigrade Scale. This is a practical representation of the thermodynamic Centigrade

scale to such a degree of accuracy as is possible with present-day apparatus and methods. It was adopted at the General Conference on Weights and Measures at Sèvres, France, in 1927 and is subject to revision and amendment as improved and more accurate methods of measurement are evolved.

The unit of temperature on the international scale is the *degree Centigrade* ($^\circ$, or $^\circ\text{C}$ int) and is very nearly equal to $\frac{1}{100}$ the difference between the temperature of melting ice and the temperature of condensing water vapor under standard atmospheric pressure. (See discussion on metric units for pressure.)

The standard of the international temperature scale between -190 and $+660^\circ\text{C}$ is deduced from the electrical resistance of a standard platinum resistance thermometer by means of a formula connecting the resistance R_t at any temperature $t^\circ\text{C}$ within the above range with the resistance R_0 at 0°C . The purity of the platinum of which the thermometer is made should be such that the ratio R_t/R_0 for certain fixed temperatures is within specific limits. See also U.S. Bureau of Standards, *Journal of Research*, Vol. 1, p. 636, 1928.

The degree Centigrade is most widely used in scientific publications and increasingly also in the engineering literature. In many countries in Europe it is the common everyday temperature unit. The subdivision into a hundred degrees of the temperature interval between the ice point and the steam point was first used by Celsius, a German, in 1742; therefore, in the European literature " $^\circ\text{C}$ " is read "degree Celsius."

Fahrenheit Temperature Scale. This scale subdivides the temperature interval between the ice point and the steam point into 180 parts, one part of which is chosen as the unit of temperature and named *degree Fahrenheit* ($^\circ\text{F}$). The ice point is assigned the value 32°F , so that the steam point has a temperature of 212°F .

The Fahrenheit unit of temperature is in common everyday use in the English-speaking countries. It was first introduced in England about 1665 by the physicist Fahrenheit; the choice of 32°F for the ice point has its explanation in the fact that Fahrenheit chose as zero the lowest temperature attainable by means of a salt-ice mixture.

Rankine Absolute Temperature Scale ($^\circ\text{R}$). This is the thermodynamic Fahrenheit scale where absolute zero is 0°R (-459.69°F). The ice point is assigned the value 491.69°R and the steam point 671.69°R .

Relations between Temperature Scales. The following table shows the interrelations between the various temperature scales in the form of equations.

Temperature Interrelationships

$x^\circ\text{F} =$	$9/5(t^\circ\text{K} - 273.16) + 32$	$9/5(t^\circ\text{C}) + 32$
$x^\circ\text{K} =$	$5/9(t^\circ\text{F} - 32) + 273.16$	$(t^\circ) + 273.16$
$x^\circ\text{C} =$	$5/9(t^\circ\text{F} - 32)$	$(t^\circ\text{K}) - 273.16$
$x^\circ\text{R} =$	$(t^\circ\text{F}) + 459.699$	$9/5(t^\circ\text{K})$
		$9/5(t^\circ\text{C}) + 491.69$

Here, X indicates the unknown number of chosen temperature units and t the known number of given temperature units:

Quantity of Heat and Some Derived Quantities

Units of Quantity of Heat. Quantity of heat is defined as the energy transferred from one body to another by a thermal process, that is, by radiation or conduction. The units for the quantity of heat are the *British thermal unit* and the *calorie* as specific thermal units and the *erg* and *joule* as general physical units (see discussion on units of energy, metric and English system of units).

Thermal Capacity or Specific Heat of a Substance. This is the quantity of heat required to produce a unit change in temperature in a unit of mass of the substance. The common English unit is the British thermal unit per degree Fahrenheit per pound mass (Btu per °F per lb); the usual metric unit is the gram-calorie per degree Centigrade per gram mass (cal per °C per g); and the general physical unit used in the scientific literature is the erg per degree Centigrade per gram mass (erg per °C per g). In the technical literature thermal capacity of a substance is often expressed in watt-seconds (or joules) per degree Centigrade per kilogram mass (W-sec per °C per kg) on account of the easy comparison with other technical units.

Calorimetric or Water Equivalent. This is the quantity of heat required to produce a unit change in temperature of a body or system. It is numerically equivalent to the mass of water (in units as involved in the definition of the unit of quantity of heat used) that could be raised a unit temperature by the same total quantity of heat. The thermal capacity is expressed in British thermal units per degree Fahrenheit (Btu per °F), calories per degree Centigrade (cal per °C), or watt-seconds per degree Centigrade (W-sec per °C).

Thermal Conductivity. This is the time rate of heat transfer through a unit area across a unit thickness per unit difference in temperature between the end surfaces. It is measured in British thermal units per second per degree Fahrenheit per inch thickness per square inch cross section (Btu per sec per °F per in. per in.²), in calories per second per degree Centigrade

per centimeter thickness per square centimeter cross section (cal per sec per °C per cm per cm²), or in watts per degree Centigrade per meter thickness per square meter cross section (W per °C per m per m²).

Thermal Transmittance. The surface coefficient of transfer is the time rate of heat emitted by a unit area for a unit difference in temperature between the surface in question and the surroundings. It is measured in British thermal units per second per degree Fahrenheit per square inch (Btu per sec per °F per in.²), in calories per second per degree Centigrade per square centimeter (cal per sec per °C per cm²), or in watts per degree Centigrade per square meter (Wa per °C per m²).

Joule Equivalent The **Joule equivalent** is defined as the number of foot-pounds of energy per Btu. The numerical values for the various energy units used in the English and metric systems are shown in the table below.

4.8 Chemical Units and Standards

Atomic Weight. The present definition of atomic weights (1961) is based on ¹²C, which is the most abundant isotope of carbon and whose atomic weight is defined as exactly 12.

Standard Cell Potential. A very large class of chemical reactions are characterized by the transfer of protons or electrons. Substances losing electrons in a reaction are said to be oxidized, those gaining electrons are said to be reduced. Many such reactions can be carried out in a galvanic cell that forms a natural basis for the concept of the half-cell, that is, the overall cell is conceptually the sum of two half-cells, one corresponding to each electrode. The half-cell potential measures the tendency of one reaction, for example, oxidation, to proceed at its electrode; the other half-cell of the pair measures the corresponding tendency for reduction to proceed at the other electrode. Measurable cell potentials are the sum of the two half-cell potentials. Standard cell potentials refer to the tendency of reactants in their standard state to form products in their standard states. The standard conditions are 1 *M* concentration for solutions, 101.325 kPa (1 atm) for gases, and for solids, their most stable form at 25 °C.

	Joules "Absolute"	Foot- pounds (force)	Foot- poundals	Meter- kilogram (force)	Kilowatt- hour "international"
1 British thermal unit (Btu) (mean) =	1055.18	778.26	25.040	107.599	2.93019×10^{-4}
1 gram-calorie (cal) (mean) =	4.1873	3.0884	99.366	0.42699	1.16279×10^{-6}
1 international kilocalorie (IT cal) =	4187.3	3088.4	99.366	426.99	1.16279×10^{-3}
1 Ostwald calorie =	418.73	308.84	9936.6	42.699	1.16279×10^{-4}

Since half-cell potentials cannot be measured directly, numerical values are obtained by assigning the hydrogen gas–hydrogen ion half reaction the half-cell potential of 0 V. Thus, by a series of comparisons referred directly or indirectly to the standard hydrogen electrode, values for the strength of a number of oxidants or reductants can be obtained, and standard reduction potentials can be calculated from established values.

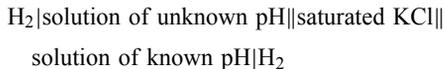

Standard cell potentials are meaningful only when they are calibrated against an electromotive force (emf) scale. To achieve an absolute value of emf, electrical quantities must be referred to the basic metric system of mechanical units. If the current unit ampere and the resistance unit ohm can be defined then the volt may be defined by Ohm's law as the voltage drop across a resistor of one standard ohm (Ω) when passing one standard ampere (A) of current. In the ohm measurement, a resistance is compared to the reactance of an inductor or capacitor at a known frequency. This reactance is calculated from the measured dimensions and can be expressed in terms of the meter and second. The ampere determination measures the force between two interacting coils while they carry the test current. The force between the coils is opposed by the force of gravity acting on a known mass; hence, the ampere can be defined in terms of the meter, kilogram, and second. Such a means of establishing a reference voltage is inconvenient for frequent use and reference is made to a previously calibrated standard cell.

Ideally, a standard cell is constructed simply and is characterized by a high constancy of emf, a low temperature coefficient of emf, and an emf close to 1 v. The Weston cell, which uses a standard cadmium sulfate electrolyte and electrodes of cadmium amalgam and a paste of mercury and mercurous sulfate, essentially meets these conditions. The voltage of the cell is 1.0183 V at 20°C. The alternating current (ac) Josephson effect, which relates the frequency of a superconducting oscillator to the potential difference between two superconducting components, is used by the National Bureau of Standards to maintain the unit of emf, but the definition of the volt remains the Ω/A derivation described.

Concentration. The basic unit of concentration in chemistry is the mole, which is the amount of substance that contains as many entities, for example, atoms, molecules, ions, electrons, protons, and so on, as there are atoms in 12 g of ^{12}C , that is, Avogadro's number $N_A = 6.022045 \times 10^{23}$. Solution concentrations are expressed on either a weight or volume basis. *Molality* is the concentration of a solution in terms of the number of moles of solute per kilogram of solvent. *Molarity* is the concentration of a solution in terms of the number of moles of solute per liter of solution.

A particular concentration measure of acidity of aqueous solutions is pH, which, usually, is regarded as

the common logarithm of the reciprocal of the hydrogen ion concentration (q_{H^+}). More precisely, the potential difference of the hydrogen electrode in normal acid and in normal alkali solution (-0.828 V at 25°C) is divided into 14 equal parts or pH units; each pH unit is 0.0591 V. Operationally, pH is defined by $\text{pH} = \text{pH}(\text{soln}) + E/K$, where E is the emf of the cell:

and $K = 2.303 RT/F$, where R is the gas constant, 8.314 J/(mol·K) [1.987 cal/(mol·K)], T is the absolute temperature, and F is the value of the Faraday, $9.64845 \times 10^4 \text{C/mol}$. pH usually is equated to the negative logarithm of the hydrogen ion activity, although there are differences between these two quantities outside the pH range 4.0–9.2:

$$-\log q_{\text{H}^+} m_{\text{H}^+} = \begin{cases} \text{pH} + 0.014 (\text{pH} - 9.2) & \text{for pH} > 9.2 \\ \text{pH} + 0.009 (4.0 - \text{pH}) & \text{for pH} < 4.0 \end{cases}$$

4.9 Theoretical, or Absolute, Electrical Units

With the general adoption of SI as the form of metric system that is preferred for all applications, further use of cgs units of electricity and magnetism is deprecated. Nonetheless, for historical reasons as well as for comprehensiveness, a brief review is included in this section and section 4.10.

The definition of the *theoretical*, or "*absolute*," units are based on a particular choice of the numerical value of either k_e , the constant in Coulomb's, electrostatic force law, or k_m , the constant in Ampere's electrodynamic force law. The designation absolute units is generally used because of historical tradition; an interesting account of the history can be found in Glazebrook's *Handbook for Applied Physics*, Vol. II, "Electricity," pp. 211 ff., 1922. Because of the theoretical background of the unit definitions they have also been designated as "theoretical" units, which is in good contradistinction to practical units based on physical standards.

Theoretical Electrostatic Units The *theoretical electrostatic units* are based on the cgs system of mechanical units and the choice of the numerical value unity for k_{ev} in Coulomb's law. They are frequently referred to as the *cgs electrostatic units*, but no specific unit names are available. In order to avoid the cumbersome writing, for example, one "theoretical electrostatic unit of charge," it had been proposed to use the theoretical "practical" unit names and prefix them with either stat or E.S. as, for example, statcoulomb, or E.S. coulomb. The first alternative will be used here.

The *absolute dielectric constant (permittivity)* of free space is the reciprocal of the Coulomb constant k_{ev} and is chosen as the fourth fundamental quantity in the theoretical electrostatic system of units. Its numerical value is defined as unity, and it is identical with one statfarad per centimeter if use is made of prefix in the corresponding unit of the "practical" series.

The theoretical electrostatic unit of *charge*, or the *statcoulomb*, is defined as the quantity of electricity that, when concentrated at a point and placed at one centimeter distance from an equal quantity of electricity similarly concentrated, will experience a mechanical force of one dyne in free space. An alternative definition based on the concept of field lines, gives the theoretical electrostatic unit of charge as a positive charge from which in free space exactly 4π displacement lines emerge.

The theoretical electrostatic unit of *displacement flux (dielectric flux)* is the "line of displacement flux," or $\frac{1}{4}\pi$ of the theoretical electrostatic unit of charge. This definition provides the basis for graphical field mapping insofar as it gives a definite rule for the selection of displacement lines to represent the distribution of the field quantitatively.

The theoretical electrostatic unit of *displacement, or dielectric flux density*, is chosen as one displacement line per square centimeter area perpendicular to the direction of the displacement lines. It can be given also as $\frac{1}{4}\pi$ statcoulomb per square centimeter (according to Gauss's law). In isotropic media the displacement has the same direction as the potential gradient, and the surfaces perpendicular to the field lines become the equipotential surfaces; the theoretical electrostatic unit of displacement can then be defined as one displacement line per square centimeter of equipotential surface.

The theoretical electrostatic unit of *electrostatic potential, or the statvolt*, is defined as existing at a point in an electrostatic field if the work done to bring the theoretical electrostatic unit of charge, or the statcoulomb, from infinity to this point equals one erg. This customary definition implies, however, that the potential vanishes at infinite distances and has, therefore, only restricted validity. As it is fundamentally impossible to give absolute values of potential, the use of potential difference and its unit (see below) should be preferred.

The theoretical electrostatic unit of *electrical potential difference or voltage*, is the *statvolt* and is defined as existing between two points in space if the work done to bring the theoretical electrostatic unit of charge, or the statcoulomb, from one of these points to the other equals one erg. Potential difference is counted positive in the direction in which a negative quantity of electricity would be moved by the electrostatic field.

The theoretical electrostatic unit of *capacitance, or the statfarad*, is defined as the capacitance that maintains an electrical potential difference of one statvolt between two conductors charged with equal and

opposite electrical charges of one statcoulomb. In the older literature, the cgs electrostatic unit of capacitance is identified with the "centimeter"; this was replaced by statfarad to avoid confusion.

The theoretical electrostatic unit of *electric potential gradient, or field strength (field intensity)*, is defined to exist at a point in an electric field if the mechanical force exerted upon the theoretical electrostatic unit of charge concentrated at this point is equal to one dyne. It is expressed as one statvolt per centimeter.

The theoretical electrostatic unit of *current, or the statampere*, is defined as the time rate of transfer of the theoretical electrostatic unit of charge and is identical with the statcoulomb per second.

The theoretical electrostatic unit of *electrical resistance, or the statohm*, is defined as the resistance of a conductor in which a current of one statampere is produced if a potential difference of one statvolt is applied at its ends.

The theoretical electrostatic unit of *electromotive force (emf)* is defined as equivalent to the theoretical electrostatic unit of potential difference if it produces a current of one statampere in a conductor of one statohm resistance. It is identical with the statvolt but, according to its concept, requires an independent definition.

The theoretical electrostatic unit of *magnetic intensity* is defined as the magnetic intensity at the center of a circle of 4π centimeters diameter in which a current of one statampere is flowing. This unit is equal to 4π statamperes per centimeter but has no name as the factor 4π excludes the possibility of using the prefix "practical" unit name.

The theoretical electrostatic unit of *magnetic flux, or the statweber*, is defined as the magnetic flux whose time rate of change through a linear conductor loop (linear conductor is used to designate a conductor of infinitesimal small cross section) produces in this loop an emf of one statvolt.

The theoretical electrostatic unit of *magnetic flux density, or induction*, is defined as the electrostatic unit of magnetic flux per square centimeter area, or the statweber per square centimeter.

The *absolute magnetic permeability of free space* is defined as the ratio of magnetic induction to the magnetic intensity. Its unit is the stathenry per centimeter as a derived unit.

The theoretical electrostatic unit of *inductance, or the stathenry*, is defined as connected with a conductor loop carrying a steady current of one statampere that produces a magnetic flux of one statweber. A more general definition applicable to varying fields with nonlinear relation between magnetic flux and current, gives the stathenry as connected with a conductor loop in which a time rate of change in the current of one statcoulomb produces a time rate of change in the magnetic flux of one statweber per second.

Theoretical Electromagnetic Units The *theoretical electromagnetic units* are based on the cgs system of mechanical units and Coulomb's law of mechanical force action between two isolated magnetic quantities m_1 and m_2 (approximately true for very long bar magnets) that must be written as

$$F_m = \frac{k_m}{2} \frac{m_1 m_2}{r^2} \quad (7)$$

where k_m is the proportionality constant of Ampere's law for force action between parallel currents that is more basic, and amenable to much more accurate measurement, than (7). The factor $\frac{1}{2}$ appears here because of the three-dimensional character of the field distribution around point magnets as compared with the two-dimensional field of two parallel currents.

The theoretical electromagnetic units are obtained by defining the numerical value of $k_{mv}/2$ (for vacuum) as unity; they are frequently referred to as the cgs electromagnetic units. Only a few specific unit names are available. In order to avoid cumbersome writing, for example, one "theoretical electromagnetic unit of charge," it had been proposed to use the theoretical "practical" unit names and prefix them with either ab- or E.M. as, for example, ab-coulomb, or E.M. coulomb. The first alternative will be used here.

The *absolute magnetic permeability* of free space is the value $k_{mv}/2$ in (7) and is chosen as the fourth fundamental quantity in the theoretical electromagnetic system of units. Its numerical value is assumed as unity, and it is identical with one abhenry per centimeter if use is made of prefixing the corresponding unit of the "practical" series.

The theoretical electromagnetic unit of *magnetic quantity* is defined as the magnetic quantity that, when concentrated at a point and placed at one centimeter distance from an equal magnetic quantity similarly concentrated, will experience a mechanical force of one dyne in free space. An alternative definition based on the concept of magnetic intensity lines, gives the theoretical electromagnetic unit of magnetic quantity as a positive magnetic quantity from which, in free space, exactly 4π magnetic intensity lines emerge.

The theoretical electromagnetic unit of *magnetic moment* is defined as the magnetic moment possessed by a magnet formed by two theoretical electromagnetic units of magnetic quantity of opposite sign, concentrated at two points one centimeter apart. As a vector, its positive direction is defined from the negative to the positive magnetic quantity along the center line.

The theoretical electromagnetic unit of *magnetic induction (magnetic flux density)*, or the *gauss*, is defined to exist at a point in a magnetic field if the mechanical torque exerted upon a magnet with theoretical electromagnetic unit of magnetic moment and directed perpendicular to the magnetic field is equal to one dyne-centimeter. The lines to which the vector of

magnetic induction is tangent at every point are called induction lines or magnetic flux lines; on the basis of this flux concept, magnetic induction is identical with magnetic flux density.

The theoretical electromagnetic unit of *magnetic flux*, or the *maxwell*, is the "field line" or line of magnetic induction. In free space, the theoretical electromagnetic unit of magnetic quantity issues 4π induction lines; the unit of magnetic flux or the maxwell, is then $1/4\pi$ of the theoretical electromagnetic unit of magnetic quantity times the absolute permeability of free space.

The theoretical electromagnetic unit of *magnetic intensity (magnetizing force)*, or the *oersted*, is defined to exist at a point in a magnetic field in free space where one measures a magnetic induction of one gauss.

The theoretical electromagnetic unit of *current*, or the *abampere*, is defined as the current that flows in a circle of one centimeter diameter and produces at the center of this circle a magnetic intensity of one oersted.

The theoretical electromagnetic unit of *inductance*, or the *abhenry*, is defined as connected with a conductor loop in which a time rate of change of one maxwell per second in the magnetic flux produces a time rate of change in the current of one abampere per second. In the older literature, the cgs electromagnetic unit of inductance is identified with the "centimeter"; this should be replaced by a henry to avoid confusion.

The theoretical electromagnetic unit of *magnetomotive force (mmf)* is defined as the magnetic driving force produced by a conductor loop carrying a steady current of $\frac{1}{4}\pi$ abamperes; it has the name one gilbert. The concept of magnetomotive force as the driving force in a "magnetic circuit" permits an alternative definition of the gilbert as the magnetomotive force that produces a uniform magnetic intensity of one oersted over a length of one centimeter in the magnetic circuit. Obviously, one gilbert equals one oersted-centimeter.

The theoretical electromagnetic unit of *magnetostatic potential* is defined as the potential existing at a point in a magnetic field if the work done to bring the theoretical electromagnetic unit of magnetic quantity from infinity to this point equals one erg. This customary definition implies, however, that the potential vanishes at infinite distances, and the definition has therefore only restricted validity. The unit, thus defined, is identical with one gilbert. The difference in magnetostatic potential between any two points is usually called magnetomotive force (mmf).

The theoretical electromagnetic unit of *reluctance* is defined as the reluctance of a magnetic circuit in which a magnetomotive force of one gilbert produces a magnetic flux of one maxwell.

The theoretical electromagnetic unit of *electric charge*, or the *abcoulomb*, is defined as the quantity of electricity that passes through any section of an electric circuit in one second if the current is one abampere.

The theoretical electromagnetic unit of *displacement flux (dielectric flux)* is the "line of displacement

flux, or $\frac{1}{4}\pi$ of the theoretical electromagnetic unit of electric charge. This definition provides the basis for graphical field mapping insofar as it gives a definite rule for the selection of displacement lines to represent the character of the field.

The theoretical electromagnetic unit of *displacement*, or *dielectric flux density*, is chosen as one displacement line per square centimeter area perpendicular to the direction of the displacement lines. It can also be given as $\frac{1}{4}\pi$ abcoulombs per square centimeter (according to Gauss's law). In isotropic media the theoretical electromagnetic unit of displacement can be defined as one displacement line per square centimeter of equipotential surface. (See discussion on theoretical electrostatic unit of displacement.)

The theoretical electromagnetic unit of *electrical potential difference*, or *voltage*, is the *abvolt* and is defined as the potential difference existing between two points in space if the work done in bringing the theoretical electromagnetic unit of charge, or the abcoulomb, from one of these points to the other equals one erg. Potential difference is counted positive in the direction in which a negative quantity of electricity would be moved by the electrostatic field.

The theoretical electromagnetic unit of *capacitance*, or the *abfarad*, is defined as the capacitance that maintains an electrical potential difference of one abvolt between two conductors charged with equal and opposite electrical quantities of one abcoulomb.

The theoretical electromagnetic unit of *potential gradient*, or *field strength* (field intensity), is defined to exist at a point in an electric field if the mechanical force exerted upon the theoretical electromagnetic unit of charge concentrated at this point is equal to one dyne. It is expressed as one abvolt per centimeter.

The theoretical electromagnetic unit of *resistance*, or the *abohm*, is defined as the resistance of a conductor in which a current of one abampere is produced if a potential difference of one abvolt is applied at its ends.

The theoretical electromagnetic unit of *electromotive force (emf)* is defined as the electromotive force acting in an electric circuit in which a current of one abampere is flowing and electrical energy is converted into other kinds of energy at the rate of one erg per second. This unit is identical with the abvolt.

The *absolute dielectric constant of free space* is defined as the ratio of displacement to the electric field intensity. Its unit is the abfarad per centimeter, a derived unit.

Theoretical Electrodynamical Units The theoretical electrodynamical units are based on the cgs system of mechanical units and are therefore frequently referred to as the *cgs electrodynamical units*. In contradistinction to the theoretical electromagnetic units, these units are derived from a significant experimental law, Ampere's

experiment on the mechanical force between two parallel currents. The units as proposed by Ampere and used by W. Weber differ from the electromagnetic units by factors of 2 and multiples thereof. They can be made to coincide with the theoretical electromagnetic units by proper definition of the fundamental unit of current. Some of the important definitions will be given for this latter case only.

For the *absolute magnetic permeability* of free space, see discussion on theoretical electromagnetic units.

The theoretical electrodynamical unit of *current*, or the *abampere*, is defined as the current flowing in a circuit consisting of two infinitely long parallel wires one centimeter apart when the electrodynamical force of repulsion between the two wires is two dynes per centimeter length in free space. If the more natural choice of one dyne per centimeter length is made, the original proposal of Ampere is obtained and the unit of current becomes $1/\sqrt{2}$ abampere.

The theoretical electrodynamical unit of *magnetic induction* is defined as the magnetic induction inducing an electromotive force of one abvolt in a conductor of one centimeter length and moving with a velocity of one centimeter per second if the conductor, its velocity, and the magnetic induction are mutually perpendicular. The unit thus defined is called one gauss.

The theoretical electrodynamical unit of *magnetic flux*, or the *maxwell*, is defined as the magnetic flux represented by a uniform magnetic induction of one gauss over an area of one square centimeter perpendicular to the direction of the magnetic induction.

The theoretical electrodynamical unit of *magnetic intensity*, or the *oersted*, is defined as the magnetic intensity at the center of a circle of 4π centimeters diameter in which a current of one abampere is flowing.

All the other unit definitions which do not pertain to magnetic quantities, are identical with the definition for the theoretical electromagnetic units.

4.10 Internationally Adopted Electrical Units and Standards

In October 1946, at Paris, the International Committee on Weights and Measures decided to abandon the so-called international practical units based on physical standards (see below) and to adopt effective January 1, 1948, the so-called absolute practical units for international use.

Adopted Absolute Practical Units By a series of international actions, the "absolute" practical electrical units are defined as exact powers of 10 of corresponding theoretical electrodynamical and electromagnetic units because they are based on the choice of the proportionality constant in Ampere's law for free space as $k_{mv} = 2 \times 10^{-7}$ H/m

The *absolute practical unit of current*, or the absolute is define as the current flowin in a circuit consisting of two very long parallel thin wires spaced 1 m apart in free space if the electrodynamic force action between the wires is $2 \times 10^{-7} \text{ N} = 0.02 \text{ dyne}$ per meter length. It is 10^{-1} of the theoretical or absolute electrodynamic or electromagnetic unit of current and was adopted internationally in 1881.

The absolute practical unit of *electric charge*, or the *absolute coulomb*, is define as the quantity of electricity that passes through a cross-sectional surface in one second if the current is one absolute ampere. It is 10^{-1} of the theoretical or absolute electromagnetic unit of electric charge and was adopted internationally in 1881.

The absolute practical unit of *electric potential difference*, or the *absolute volt*, is define as the potential difference existing between two points in space if the work done in bringing an electric charge of one absolute coulomb from one of these points to another is equal to one absolute joule $= 10^7 \text{ ergs}$. It is 10^8 of the theoretical or absolute electromagnetic unit of potential difference and was adopted internationally in 1881.

The absolute practical unit of *resistance*, or the *absolute ohm*, is define as the resistance of a conductor in which a current of one absolute ampere is produced if a potential difference of one absolute volt is applied at its ends. It is 10^9 of the theoretical or absolute electromagnetic unit of resistance and was adopted internationally in 1881.

The absolute practical unit of *magnetic flux*, or the *absolute weber*, is define to be linked with a closed loop of thin wire of total resistance one absolute ohm if upon removing the wire loop from the magnetic fiel a total charge of one absolute coulomb is passed through any cross section of the wire. It is 10^8 of the theoretical or absolute electromagnetic unit of magnetic flux the maxwell, and was adopted internationally in 1933.

The absolute practical unit of *inductance*, or the *absolute henry*, is define as connected with a closed loop of thin wire in which a time rate of change of one absolute weber per second in the magnetic flu produces a time rate of change in the current of one absolute ampere. It is 10^9 of the theoretical or absolute electromagnetic unit of inductance and was adopted internationally in 1893.

The absolute practical unit of *capacitance*, or the *absolute farad*, is define as the capacitance that maintains an electric potential difference of one absolute volt between two conductors charged with equal and opposite electrical quantities of one coulomb. It is 10^{-9} of the theoretical or absolute electromagnetic unit of capacitance and was adopted internationally in 1881.

Abandoned International Practical Units The International System of electrical and magnetic units is a system for electrical and magnetic quantities that takes as the four fundamental quantities resistance, current, length, and time. The units of resistance and current are define by physical standards that were originally aimed to be exact replicas of the "absolute" practical units, namely the absolute ampere and the absolute ohm. On account of long-range variations in the physical standards, it proved impossible to rely upon them for international use and they recently have been replaced by the absolute practical units.

The international practical standards are define as follows:

The *international ohm* is the resistance at 0°C of a column of mercury of uniform cross section having a length of 106.300 cm and a mass of 14.4521 g.

The *international ampere* is define as the current that will deposit silver at the rate of 0.00111800 g/sec.

From these fundamental units, all other electrical and magnetic units can be define in a manner similar to the absolute practical units. Because of the inconvenience of the silver voltameter as a standard, the various national laboratories actually used a volt, definin its value in terms of the other two standards.

At its conference in October 1946 in Paris, the International Committee on Weights and Measures accepted as the best relations between the international and the absolute practical units the following:

$$1 \text{ mean international ohm} = 1.00049 \text{ absolute ohms}$$

$$1 \text{ mean international volt} = 1.00034 \text{ absolute volts}$$

These mean values are the averages of values measured in six different national laboratories. On the basis of these mean values, the specifi unit relation for converting international units appearing on certificate of the National Bureau of Standards, Washington, DC, into absolute practical units are as follows:

$$1 \text{ international ampere} = 0.999835 \text{ absolute ampere}$$

$$1 \text{ international coulomb} = 0.999835 \text{ absolute coulomb}$$

$$1 \text{ international henry} = 1.000495 \text{ absolute henries}$$

$$1 \text{ international farad} = 0.999505 \text{ absolute farad}$$

$$1 \text{ international watt} = 1.000165 \text{ absolute watts}$$

$$1 \text{ international joule} = 1.000165 \text{ absolute joules}$$

Length

Land Measure

7.92 inches = 1 link

25 links = 1 rod = 16.5 feet = 5.5 yards (1 rod = 1 pole = 1 perch)

4 rods = 1 chain (Gunther's) = 66 feet = 22 yards = 100 links

10 chains = 1 furlong = 660 feet = 220 yards = 1000 links = 40 rods

8 furlongs = 1 mile = 5280 feet = 1760 yards = 8000 links = 320 rods = 80 chains

Ropes and Cables

2 yards = 1 fathom 120 fathoms = 1 cable length

Nautical Measure

6080.27 feet = 1 nautical mile = 1.15156 statute miles

3 nautical miles = 1 league (U.S.) 3 statute miles = 1 league (Gr. Britain)

(Note: A nautical mile is the length of a minute of longitude of the earth at the equator at sea level. The British Admiralty uses the round figure of 6080 feet. The word "knot" is used to denote "nautical miles per hour.")

Miscellaneous

3 inches = 1 palm 9 inches = 1 span

4 inches = 1 hand $2\frac{1}{2}$ feet = 1 military pace

Area

Land Measure

$30\frac{1}{4}$ square yards = 1 square rod = $272\frac{1}{4}$ square feet

16 square rods = 1 square chain = 484 square yards = 4356 square feet

$2\frac{1}{2}$ square chains = 1 rood = 40 square rods = 1210 square yards

4 roods = 1 acre = 10 square chains = 160 square rods

640 acres = 1 square mile = 2560 roods = 102,400 square rods

1 section of land = 1 square mile; 1 quarter section = 160 acres

Architect's Measure

100 square feet = 1 square

Circular Inch and Circular Mil A circular inch is the area of a circle 1 inch in diameter = 0.7854 square inch

1 square inch = 1.2732 circular inches

A circular mil is the area of a circle 1 mil (or 0.001 inch) in diameter = 0.7854 square mil

1 square mil = 1.2732 circular mils

1 circular inch = 10^6 circular mils = 0.7854×10^6 square mils

1 square inch = 1.2732×10^6 circular mils = 10^6 square mils

Volume

Cubic Measure

1 cord of wood = pile cut 4 feet long piled 4 feet high and 8 feet on the ground = 128 cubic feet

1 perch of stone = quantity $1\frac{1}{2}$ feet thick, 1 foot high, and $16\frac{1}{2}$ feet long = $24\frac{3}{4}$ cubic feet

(Note: A perch of stone is, however, often computed differently in different localities; thus, in most if not all of the states west of the Mississippi, stone-masons figure rubble by the perch of $16\frac{1}{2}$ cubic feet. In Philadelphia, 22 cubic feet is called a perch. In Chicago, stone is measured by the cord of 100 cubic feet. Check should be made against local practice.)

Board Measure. In board measure, boards are assumed to be one inch in thickness. Therefore, feet board measure of a stick of square timber = length in feet \times breadth in feet \times thickness in inches.

Shipping Measure. For register tonnage or measurement of the entire internal capacity of a vessel, it is arbitrarily assumed, to facilitate computation, that

$$100 \text{ cubic feet} = 1 \text{ register ton}$$

For the measurement of cargo:

$$40 \text{ cubic feet} = 1 \text{ U.S. shipping ton} \\ = 32.143 \text{ U.S. bushels}$$

$$42 \text{ cubic feet} = 1 \text{ British shipping ton} \\ = 32.703 \text{ Imperial bushels}$$

Dry Measure. One U.S. Winchester bushel contains 1.2445 cubic feet or 2150.42 cubic inches. It holds 77.601 pounds distilled water at 62°F.

(Note: This is a *struck* bushel. A *heaped* bushel in general equals $1\frac{1}{4}$ struck bushels, although for apples and pears it contains 1.2731 struck bushels = 2737.72 cubic inches.)

One U. S. gallon (dry measure) = $\frac{1}{8}$ bushel and contains 268.8 cubic inches.

(Note: This is not a legal U.S. *dry measure* and therefore is given for comparison only.)

One British Imperial bushel contains 1.2843 cubic feet or 2219.36 cubic inches. It holds 80 pounds distilled water at 62°F.

1 British Imperial gallon = $\frac{1}{8}$ Imperial bushel and contains 277.42 cubic inches.

1 Winchester bushel = 0.9694 Imperial bushel

1 Imperial bushel = 1.032 Winchester bushels

Same relations as before maintain for gallons (dry measure).

[Note: 1 U.S. gallon (dry) = 1.164 U. S. gallons (liquid).]

U.S. UNITS*

2 pints = 1 quart = 67.2 cubic inches
 4 quarts = 1 gallon = 8 pints = 268.8 cubic inches
 2 gallons = 1 peck = 16 pints = 8 quarts = 537.6 cubic inches
 4 pecks = 1 bushel = 64 pints = 32 quarts = 8 gallons = 2150.42 cubic inches
 1 cubic foot contains 6.428 gallons (dry measure)

Liquid Measure. One U.S. gallon (liquid measure) contains 231 cubic inches. It holds 8.336 pounds distilled water at 62°F.

One British Imperial gallon contains 277.42 cubic inches. It holds 10 pounds distilled water at 62°F.

1 U.S. gallon (liquid) = 0.8327 Imperial gallon

1 Imperial gallon = 1.201 U.S. gallons (liquid)

[Note: 1 U.S. gallon (liquid) = 0.8594 U.S. gallon (dry).]

U.S. UNITS

4 gills = 1 pint = 16 fluid ounces
 2 pints = 1 quart = 8 gills = 32 fluid ounces
 4 quarts = 1 gallon = 32 gills = 8 pints = 128 fluid ounces
 1 cubic foot contains 7.4805 gallons (liquid measure)

Apothecaries' Fluid Measure

60 minims = 1 fluid drachm

8 drachms = 1 fluid ounce

In the United States a fluid ounce is the 128th part of a U.S. gallon, or 1.805 cubic inches or 29.58 cubic centimeters. It contains 455.8 grains of water at 62°F. In Great Britain the fluid ounce is 1.732 cubic inches and contains 1 ounce avoirdupois (or 437.5 grains) of water at 62°F.

*The *gallon* is not a U.S. legal *dry measure*.

Table 31 Plane Angle (No Dimensions)

	Multiply Number of →	to Obtain ↓	by →	Degrees	Minutes	Quadrants	Radians ^a	Revolutions ^a (Circumferences)	Seconds

^aNautical miles per hour.

Linear Velocity

The Miner's Inch. The miner's inch is used in measuring flow of water. An act of the California legislature, May 23, 1901, makes the standard miner's inch 1.5 ft³/min, measured through any aperture or orifice

The term miner's inch is more or less indefinite for the reason that California water companies do not all use the same head above the center of the aperture,

and the inch varies from 1.36 to 1.73 ft³/min, but the most common measurement is through an aperture 2 in. high and whatever length is required and through a plank 1¼ in. thick. The lower edge of the aperture should be 2 in. above the bottom of the measuring box and the plank 5 in. high above the aperture, thus making a 6-in. head above the center of the stream. Each square inch of this opening represents a miner's inch, which is equal to a flow of 1.5 ft³/min.

^aThese same conversion factors apply to the *gravitational* units of force having the corresponding names. The dimensions of these units when used as gravitational units of force are MLT^{-2} ; see Table 40.

^bAvoirdupois pounds and ounces.

Table 39 Density or Mass per Unit Volume [ML^{-3}]

<div style="display: flex; align-items: center; justify-content: center;"> <div style="text-align: right; margin-right: 10px;">to Obtain ↓</div> <div style="text-align: left; margin-left: 10px;"> Multiply Number of → by → </div> </div>	Grams per Cubic Centimeter	Kilograms per Cubic Meter	Pounds per Cubic Foot	Pounds per Cubic Inch
Grams per Cubic Centimeter	1	0.001	1.602×10^{-2}	27.68
Kilograms per Cubic Meter	1000	1	16.02	2.768×10^4
Pounds per Cubic Foot	62.43	6.243×10^{-2}	1	1728
Pounds per Cubic Inch	3.613×10^{-2}	3.613×10^{-5}	5.787×10^{-4}	1
Pounds per Mil Foot ^a	3.405×10^{-7}	3.405×10^{-10}	5.456×10^{-9}	9.425×10^{-6}

^aUnit of volume is a volume one foot long and one circular mil in cross-sectional area.

Avoirdupois Weight. Used Commercially.

- 27.343 grains = 1 drachm
- 16 drachms = 1 ounce (oz) = 437.5 grains
- 16 ounces = 1 pound (lb) = 7000 grains
- 28 pounds = 1 quarter (qr)
- 4 quarters = 1 hundredweight (cwt)
= 112 pounds
- 20 hundredweight = 1 gross or long ton*
- 200 pounds = 1 net or short ton
- 14 pounds = 1 stone
- 100 pounds = 1 quintal

Troy Weight. Used in weighing gold or silver.

- 24 grains = 1 pennyweight (dwt)
- 20 pennyweights = 1 ounce (oz) = 480 grains
- 12 ounces = 1 pound (lb) = 5760 grains

The grain is the same in avoirdupois, troy, and apothecaries' weights. A carat, for weighing diamonds, = 3.086 grains = 0.200 gram (International Standard, 1913.)

1 pound troy = 0.8229 pound avoirdupois

1 pound avoirdupois = 1.2153 pounds troy

Apothecaries' Weight. Used in compounding medicines.

- 20 grains = 1 scruple()
- 3 scruples = 1 drachm() = 60 grains
- 8 drachms = 1 ounce() = 480 grains
- 12 ounces = 1 pound(lb) = 5760 grains

The grain is the same in avoirdupois, troy, and apothecaries' weights.

1 pound apothecaries = 0.82286 pound avoirdupois

1 pound avoirdupois = 1.2153 pounds apothecaries

*The long ton is used by the U.S. custom houses in collecting duties upon foreign goods. It is also used in freighting coal and selling it wholesale.

Pounds per Square Foot	2117											
Pounds per Square Inch	14.70											
Tons (Short) per Square Foot	1.058											
Pascal	1.013×10^5											

^aDefinition: One atmosphere (standard) = 76 cm of mercury at 0°C.

^bTo convert height h of a column of mercury at t degrees Centigrade to the equivalent height h_0 at 0°C use $h_0 = h[1 - (m - t)/(1 + mt)]$, where $m = 0.0001818$ and $l = 18.4 \times 10^{-6}$ if the scale is engraved on brass; $l = 8.5 \times 10^{-6}$ if on glass. This assumes the scale is correct at 0°C; for other cases (any liquid) see *International Critical Tables*, Vol. 1, p. 68.

^c1 g/cm² = 10 kg/m².

^a See note at the bottom of Table 45.

^b Mean calorie and Btu used throughout. One gram-calorie = 0.001 kilogram-calorie; one Ostwald calorie = 0.1 kilogram-calorie.

The IT cal, 1000 international steam table calories, has been defined as the 1/860th part of the international kilowatthour (see *Mechanical Engineering*, Nov. 1935, p. 710). Its value is very nearly equal to the mean kilogram-calorie, 1 IT cal = 1.00037 kilogram-calories (mean). 1 Btu = 251.996 IT cal.

^c Absolute joule, defined as 10^7 ergs. The international joule, based on the international ohm and ampere, equals 1.0003 absolute joules.

Ergs per Second	1.758 × 10 ⁸																								
Foot-Pounds per Minute	778.0																								
Foot-Pounds per Second	12.97																								
Horsepower ^a	2.357 × 10 ⁻²																								
Kilogram-Calories per Minute	0.2520																								
Kilowatts	1.758 × 10 ⁻²																								
Metric Horsepower	2.390 × 10 ⁻²																								
Watts	17.58																								

Note:

1 Cheval-vapeur = 75 kilogram-meters per second

1 Poncelet = 100 kilogram-meters per second

^aThe "horsepower" used in these tables is equal to 550 foot-pounds per second by definition. Other definitions are one horsepower equals 746 watts (U.S. and Great Britain) and one horsepower equals 736 watts (continental Europe). Neither of these latter definitions is equivalent to the first; the "horsepowers" defined in these latter definitions are widely used in the rating of electrical machinery.

^a In this table δ is density in grams per cubic-centimeters. The following names, corresponding respectively to those at the tops of columns, are sometimes used: abohms per centimeter cube; microhms per centimeter cube; microhms per inch cube; ohms per milfoot; ohms per meter-gram. The first four columns are headed by units of *volume* resistivity, the last by a unit of *mass* resistivity. The dimensions of the latter are $Q^{-2}L^6T^{-1}$, not those given in the heading of the table.

^b One ohm (meter, gram) = 5710 ohms (mile, pound).

Table 61 Specific Heat [$L^2T^{-2}t^{-1}$] (t = temperature)

To change specific heat in gram-calories per gram per degree Centigrade to the units given in any line of the following table, multiply by the factor in the last column.

Unit of Heat or Energy	Unit of Mass	Temperature Scale ^a	Factor
Gram-calories	Gram	Centigrade	1
Kilogram-calories	Kilogram	Centigrade	1
British thermal units	Pound	Centigrade	1.800
British thermal units	Pound	Fahrenheit	1.000
Joules	Gram	Centigrade	4.186
Joules	Pound	Fahrenheit	1055
Joules	Kilogram	Kelvin	4.187×10^3
Kilowatt-hours	Kilogram	Centigrade	1.163×10^{-3}
Kilowatt-hours	Pound	Fahrenheit	2.930×10^{-4}

^aTemperature conversion formulas:

$$t_c = \text{temperature in Centigrade degrees}$$

$$t_f = \text{temperature in Fahrenheit degrees}$$

$$t_K = \text{temperature in Kelvin degrees}$$

$$1 \text{ F} = \frac{5}{9} \text{ }^\circ\text{C}$$

$$1 \text{ K} = 1 \text{ }^\circ\text{C}$$

$$t_c = \frac{5}{9}(t_f - 32)$$

$$t_f = \frac{9}{5}t_c + 32$$

$$t_K = t_c + 273$$

6 STANDARD SIZES

6.1 Preferred Numbers

Selection of standard sizes or ratings of many diverse products can be performed advantageously through the use of a geometrically based progression introduced by C. Renard. He originally adopted as a basis a rule that would yield a 10th multiple of the value *a* after every 5th step of the series:

$$a \times q^5 = 10a \quad \text{or} \quad q = \sqrt[5]{10}$$

where the numerical series $a, a[\sqrt[5]{10}], a[\sqrt[5]{10}]^2, a[\sqrt[5]{10}]^3, a[\sqrt[5]{10}]^4, 10a$, the values of which, to five

significant figures, are $a, 1.5849a, 2.5119a, 3.9811a, 6.309a, 10a$.

Renard's idea was to substitute, for these values, more rounded but more practical values. He adopted as *a* a power of 10, positive, nil, or negative, obtaining the series 10, 16, 25, 40, 63, 100, which may be continued in both directions.

From this series, designated by the symbol R5, the R10, R20, R40 series were formed, each adopted ratio being the square root of the preceding one: $\sqrt[10]{10}, \sqrt[20]{10}, \sqrt[40]{10}$. Thus each series provided Renard with twice as many steps in a decade as the preceding one.

Preferred numbers are immediately applicable to commercial sizes and ratings of products. It is advantageous to minimize the number of initial sizes and

also to have adequate provision for logical expansion if and when additional sizes are required. By making the initial sizes correspond to a coarse series such as R5, unnecessary expense can be avoided if subsequent demand for the product is disappointing. If, on the other hand, the product is accepted, intermediate sizes may be selected in a rational manner by using the next finer series R10, and so on. Such a procedure assures a justifiable relationship between successive sizes and is a decided contrast to haphazard selection.

The application of preferred numbers to raw material sizes and to the dimensions of parts also has enormously important potentialities. Under present conditions, commercial sizes of material are the result of a great many dissimilar gauge systems. The current trend in internationally acceptable metric sizing is to use preferred numbers. Even here, though, in the midst of the greatest opportunity for worldwide standardization through the acceptance of Renard series, we have fallen prey to our individualistic nature. The preferred number 1.6 is used by most nations as a standard 1.6 mm material thickness. German manufacturers, however, like 1.5 mm of the International Organization for Standardization (ISO) 497 for a more rounded preferred number. Similarly in metric screw sizes, 6.3 mm is consistent with the preferred number

series; yet, 6.0 mm (more rounded) has been adopted as a standard fastener diameter.

The International Electrochemical Commission (IEC) used preferred numbers to establish standard current ratings in amperes as follows: 1, 1.25, 1.6, 2.5, 3.15, 4.5, 6.3. Notice that R10 series is used except for 4.5, which is a third step R20 series.

The American Wire Gauge size for copper wire is based on a geometric series. However, instead of using 1.1220, the rounded value of $\sqrt[20]{10}$, in $a \times q^{20} = 10a$, the q chosen is 1.123.

A special series of preferred numbers is used for designating the characteristic values of capacitors, resistors, inductors, and other electronic products. Instead of using the Renard series R5, R10, R20, R40, R80 as derived from the geometric series of numbers $10^{N/5}$, $10^{N/10}$, $10^{N/20}$, $10^{N/40}$, $10^{N/80}$, the geometric series used is $10^{N/6}$, $10^{N/12}$, $10^{N/24}$, $10^{N/48}$, $10^{N/96}$, $10^{N/192}$, which are designated respectively E6, E12, E24, E48, E96, E192.

It should be evident that any series of preferred numbers can be generated to serve any specific case. Examples taken from the American National Standards Institute (ANSI) and ISO standards are reproduced in Tables 65–68.

5.60	5.6	5.5
6.30	6.3	6.0
7.10	7.1	7.0

^a Rounded only when using the R5 or R10 series.

Applicable Documents Adoption of Renard's preferred number system by international standardization bodies resulted in a host of national standards being generated for particular applications. The current organization in the United States that is charged with

generating American national standards is the ANSI. Accordingly, the following national and international standards are in use in the United States.

ANSI Z17.1-1973	American National Standard for Preferred Numbers	ISO 497-1973	Guide to the choice of series of preferred numbers and of series containing more rounded values of preferred numbers
ANSI C83.2-1971	American National Standard Preferred Values for Components for Electronic Equipment		
EIA Standard RS-385	Preferred Values for Components for Electronic Equipment (issued by the Electronics Industries Association; Same as ANSI C83.2-1971)		
ISO 3-1973	Preferred numbers—series of preferred numbers		Table 67 shows the expansibility of preferred numbers in the positive direction. The same expansibility can be made in the negative direction. Table 68 shows a deviation by roundings for cases where adhering to a basic preferred number would be absurd as in 31.5 teeth in a gear when clearly 32 makes sense.
ISO 17-1973	Guide to the use of preferred numbers and of series of preferred numbers

^a Assumed specific gravities or densities in grams per cubic centimeter; copper, 8.89; aluminum, 2.71; brass, 8.47.

Wire Gages The sizes of wires having a diameter less than $\frac{1}{2}$ in. are usually stated in terms of certain arbitrary scales called "gages." The size or gage number of a solid wire refers to the cross section of the wire perpendicular to its length; the size or gage number of a stranded wire refers to the total cross section

of the constituent wires, irrespective of the pitch of the spiraling. Larger wires are usually described in terms of their area expressed in circular mils. A circular mil is the area of a circle 1 mil in diameter, and the area of any circle in circular mils is equal to the square of its diameter in mils.

^a Bureau of Standards, Circulars No. 31 and No. 67.

^b For diameters corresponding to metric gage numbers, 1.2, 1.4, 1.6, 1.8, 2.5, 3.5, and 4.5, divide those of 12, 14, etc., by 10.

6.3 Paper Sizes

Table 72 Standard Engineering Drawing Sizes^a

<i>Flat Sizes^b</i>					
Size Designation	Width ^c (Vertical)	Length (Horizontal)	Margin		
			Horizontal	Vertical	
A (horizontal)	8.5	11.0	0.38	0.25	
A (vertical)	11.0	8.5	0.25	0.38	
B	11.0	17.0	0.38	0.62	
C	17.0	22.0	0.75	0.50	
D	22.0	34.0	0.50	1.00	
E	34.0	44.0	1.00	0.50	
F	28.0	40.0	0.50	0.50	

<i>Roll Sizes</i>					
Size Designation	Width ^b (Vertical)	Length ^c (Horizontal)		Margin ^c	
		Min	Max	Horizontal	Vertical
G	11.0	22.5	90.0	0.38	0.50
H	28.0	44.0	143.0	0.50	0.50
J	34.0	55.0	176.0	0.50	0.50
K	40.0	55.0	143.0	0.50	0.50

^a See ANSI Y14.1-1980.

^b All dimensions are in inches.

^c Not including added protective margins.

International Paper Sizes Countries that are committed to the International System of Units (SI) have a standard series of paper sizes for printing, writing, and drafting. These paper sizes are called the “international paper sizes.”

The advantages of the international paper sizes are as follows:

1. The ratio of width to length remains constant for every size, namely:

$$\frac{\text{Width}}{\text{Length}} = \frac{1}{\sqrt{2}} \quad \text{or} \quad \frac{1}{1.414} \text{ approximately}$$

Since this is the same ratio as the D aperture in the unitized 35-mm microfilm frame, the advantages are apparent.

2. If a sheet is cut in half, that is, if the $\sqrt{2}$ length is cut in half, the two halves retain the constant width-to-length ratio of $1/\sqrt{2}$. No other ratio could do this.

3. All international sizes are created from the A-0 size by single cuts without waste. In storing or stacking they fit together like parts of a jigsaw puzzle—without waste.

Table 73 Eleven International Paper Sizes

International Paper Size	Millimeters	Inches, Approximate
A-0	841 × 1189	$33\frac{1}{8} \times 46\frac{3}{4}$
A-1	594 × 841	$23\frac{3}{8} \times 33\frac{1}{8}$
A-2	420 × 594	$16\frac{1}{2} \times 23\frac{3}{8}$
A-3	297 × 420	$11\frac{3}{4} \times 16\frac{1}{2}$
A-4	210 × 297	$8\frac{1}{4} \times 11\frac{3}{4}$
A-5	148 × 210	$5\frac{7}{8} \times 8\frac{1}{4}$
A-6	105 × 148	$4\frac{1}{8} \times 5\frac{7}{8}$
A-7	74 × 105	$2\frac{7}{8} \times 4\frac{1}{8}$
A-8	52 × 74	$2 \times 2\frac{7}{8}$
A-9	37 × 52	$1\frac{1}{2} \times 2$
A-10	26 × 37	$1 \times 1\frac{1}{2}$

6.4 Sieve Sizes

Table 74 Tyler Standard Screen Scale Sieves

This screen scale has as its base an opening of 0.0029 in., which is the opening in 200-mesh 0.0021-in. wire, the standard sieve, as adopted by the Bureau of Standards of the U.S. government, the openings increasing in the ratio of the square root of 2 or 1.414.

Where a closer sizing is required, column 5 shows the Tyler Standard Screen Scale with intermediate sieves. In this series the sieve openings increase in the ratio of the fourth root of 2, or 1.189.

Tyler Standard Screen Scale	Every Other Sieve from 0.0029	Every Other Sieve from 0.0041	Every Fourth Sieve from 0.0029	For Closer Sizing Sieves from 0.0029		Openings in Fractions of inch (approx.)		Diameter of Wire
$\sqrt{2}$ or 1.414 Openings (in.) (1)	to 0.742 in., Ratio of 2 to 1 (2)	to 1.050 in., Ratio of 2 to 1 (3)	to 0.742 in., Ratio of 4 to 1 (4)	to 1.050 in., Ratio $\sqrt[4]{2}$ or 1.189 (5)	openings (mm) (6)	(7)	Mesh (8)	(9)

^a For sieves from the 1000- μm (No. 18) to the 37- μm (No. 400) size, inclusive, not more than 5% of the openings shall exceed the nominal opening by more than one-half of the permissible variation in the maximum opening.

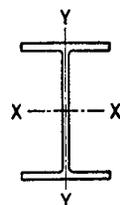

6.5 Standard Structural Sizes – Steel

Steel Sections. Tables 76–83 give the dimensions, weights, and properties of *rolled steel* structural sections, including wide-flang sections, American standard beams, channels, angles, tees, and zees. The values for the various structural forms, taken from the eighth edition, 1980, of *Steel Construction*, by the kind permission of the publisher, the American Institute of Steel Construction, give the section specification required in designing steel structures. The theory of design is covered in Section 4—Mechanics of Deformable Bodies.

Most of the sections can be supplied promptly steel mills. Owing to variations in the rolling practice of the different mills, their products are not identical, although their divergence from the values given in the tables is practically negligible. For standardization, only the lesser values are given, and therefore they are on the side of safety.

Further information on sections listed in the tables, together with information on other products and on the requirements for placing orders, may be gathered from mill catalogs.

Table 81 Properties and Dimensions of Tees

Tees are seldom used as structural framing members. When so used they are generally employed on short spans in flexure. This table lists a few selected sizes, the range of whose section moduli will cover all ordinary conditions. For sizes not listed, the catalogs of the respective rolling mills should be consulted.

Section Number	Weight per Foot (lb)	Area (in. ²)	Depth of Tee (in.)	Flange			Stem Thickness (in.)	Axis X-X				Axis Y-Y		
				Width (in.)	Average Thickness (in.)	Thickness (in.)		<i>l</i> (in. ⁴)	<i>S</i> (in. ³)	<i>r</i> (in.)	<i>y</i> (in.)	<i>l</i> (in. ⁴)	<i>S</i> (in. ³)	<i>r</i> (in.)

^a WF indicates structural tee cut from wide-flange section.

^b I indicates structural tee cut from standard beam section.

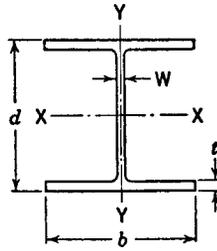

Table 82 Properties and Dimensions of Zees

Zees are seldom used as structural framing members. When so used they are generally employed on short spans in flexure. This table lists a few selected sizes, the range of whose section moduli will cover all ordinary conditions. For sizes not listed, the catalogs of the respective rolling mills should be consulted.

Schedule Nos. 5S, 10S, and 40S American National Standards Institute (ANSI)/American Society of Mechanical Engineers (ASME) B.36.19-1985, "Stainless Steel Pipe." ST = standard wall, XS = extra strong wall, XX = double extra strong wall are all taken from ANSI/ASME, B.36.10M-1985, "Welded and Seamless Wrought-steel Pipe." Wrought-iron pipe has slightly thicker walls, approximately 3%, but the same weight per foot, because of lower density. Decimal thicknesses for respective pipe sizes represent their nominal or average wall dimensions. Mill tolerances as high as 12½% are permitted.

Plain-end pipe is produced by a square cut. Pipe is also shipped from the mills threaded, with a threaded coupling on one end, or with the ends beveled for welding, or grooved or sized for patented couplings. Weights per foot for threaded and coupled pipe are slightly greater because of the weight of the coupling, but it is not available larger than 12 in., or lighter than Schedule 30 sizes 8 through 12 in., or Schedule 40 6 in. and smaller.

<i>Large Outside Diameter Pipe</i>												

Pipe 14 in. and larger is sold by actual outside step diameter and thickness.

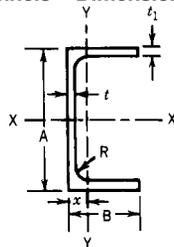

Sizes 14, 15, and 16 in. are available regularly in thicknesses varying by 1/16 in. from 1/4 to 1 in., inclusive.

All pipe is furnished random length unless otherwise ordered, viz: 12–22 ft with privilege of furnishing 5 % in 6–12-ft lengths. Pipe raiting is most economically detailed with slip joints and random lengths between couplings.

^a *Steel Construction*, 1980, A.I.S.C.

^a Users are encouraged to ascertain current availability of particular structural shapes through inquiries to their suppliers.

^b Areas listed are based on nominal dimensions.

^c Weights per foot are based on nominal dimensions and a density of 0.098 lb/in.³, which is the density of alloy 6061.

3	2 $\frac{11}{16}$	0.250	0.312	0.250	1.984	2.333
3	2 $\frac{11}{16}$	0.375	0.312	0.250	2.875	3.381
4	3 $\frac{1}{16}$	0.250	0.312	0.250	2.422	2.848
4 $\frac{1}{16}$	3 $\frac{1}{8}$	0.312	0.312	0.250	3.040	3.575
4 $\frac{1}{4}$	3 $\frac{3}{16}$	0.375	0.312	0.250	3.672	4.318
5	3 $\frac{1}{4}$	0.500	0.312	0.250	5.265	6.192
5 $\frac{1}{16}$	3 $\frac{5}{16}$	0.375	0.312	0.250	4.093	4.813

^a Users are encouraged to ascertain current availability of particular structural shapes through inquiries to their suppliers.

^b Areas listed are based on nominal dimensions.

^cWeights per foot are based on nominal dimensions and a density of 0.098 lb/in.³, which is the density of alloy 6061.

^aIn accordance with ANSI Standards B36.10 and B36.19.

^bBased on standard tolerances for pipe.

^cFor schedules 5 and 10 these values apply to mean outside diameters.

^dBased on nominal dimensions, plain ends, and a density of 0.098 lb/in.³, the density of 6061 alloy. For alloy 6063 multiply by 0.99, and for alloy 3003 multiply by 1.01.

^a To convert conductivity to maximum resistivity use Table 100.

^b Applicable up to 0.250 in.

^c Any test in a lot.

^d Average of all tests in a lot.

7 STANDARD SCREWS*

Standard Screw Threads The Unified and American Screw Threads included in Table 102 are taken from the publication of the American Standards Association, ASA B1.1—1949. The *coarse-thread series* is the former United States Standard Series. It is recommended for general use in engineering work where conditions do not require the use of a fine thread. The *fine-thread series* is the former “Regular Screw Thread Series” established by the Society of Automotive Engineers (SAE). The *fine-thread series* is recommended for general use in automotive and aircraft work and where special conditions require a fine thread. The *extra-fine-thread series* is the same as the former SAE fine series and the present SAE extra-fine series. It is used particularly in aircraft and aeronautical equipment where (a) thin-walled material is to be threaded; (b) thread depth of nuts clearing ferrules, coupling flanges, and so on, must be held to a minimum; and (c) a maximum practicable number of threads is required within a given thread length.

The method of designating a screw thread is by the use of the initial letters of the thread series, preceded by the nominal size (diameter in inches or the screw

number) and number of threads per inch, all in Arabic numerals, and followed by the classification designation, with or without the pitch diameter tolerances or limits of size. An example of an external thread designation and its meaning is as follows:

Example 1

1/4" — 20UNC — 2A

└─── Nominal size
└─── Number of threads per inch (n)
└─── Thread series
└─── Class of screw thread

A left-hand thread must be identified by the letters LH following the class designation. If no such designation is used, the thread is assumed to be right hand.

Classes of thread are distinguished from each other by the amounts of tolerance and allowance specified in ASA B1.1—1949.

Selection of Screws By definition a *screw* is a fastener that is intended to be torqued by the head. Screws are the most widely used method of assembly despite recent technical advances of adhesives, welding, and other joining techniques. Use of screws is essential in those applications that require ease of disassembly for normal maintenance and service. There is no real economy if savings made in factory installation create service problems later. There are many types of screws, and each variety will be treated separately. Material selection is generally common to all types of screws.

Material. Not all materials are suitable for the processes used in the manufacture of fasteners. Large-volume users or those with critical requirements can be very selective in their choice of materials. Low-volume users or those with noncritical applications would be

wise to permit a variety of materials in a general category in order to improve availability and lower cost. For example, it is usually desirable to specify low-carbon steel or 18-8-type stainless steel* rather than ask for a specific grade.

Low-carbon steel is widely used in the manufacture of fasteners where lowest cost is desirable and tensile strength requirements are ~50,000 psi. If corrosion is a problem, these fasteners can be plated either electrically or mechanically. Zinc or cadmium plating is used in most applications. Other finishes include nickel, chromium, copper, tin, and silver electroplating; electroless nickel and other immersion coatings; hot dip galvanizing; and phosphate coatings.

*Manufacturer may use UNS—S30200, S30300, S30400, S30500 (AISI type 302, 303, 304, or 305) depending upon quantity, diameter, and manufacturing process.

Medium-carbon steel, quenched, and tempered is widely used in applications requiring tensile strengths from 90,000 to 120,000 psi. Alloy steels are used in applications requiring tensile strengths from 115,000 to 180,000 psi, depending on the grade selected. Where better corrosion resistance is required, 300 series stainless steel can be specified. The 400 series stainless steel is used if it is necessary to have a corrosion-resistant material that can be hardened and tempered by heat treatment.

For superior corrosion resistance, materials such as brass, bronze, aluminum, or nickel are sometimes used in the manufacture of fasteners. If strength is no problem, plastics such as nylons are used in severe corrosion applications.

Drivability. When selecting a screw, thought must be given to the means of driving for assembly and disassembly as well as the head shape. Most screw heads provide a slot, a recess, or a hexagon shape as a means of driving. The slotted screw is the least preferred driving style and serves only when appearance must be combined with ease of disassembly with a common screwdriver. Only a limited amount of torque can be applied with a screwdriver. A slot can become inoperative after repeated disassembly destroys the edge of the wall that the blade of the screwdriver bears against. The hexagon head is preferred for the following reasons:

- Least likely to accidentally spin out (thereby marring the surface of the product)
- Lowest initial cost
- Adaptable to high-speed power drive
- Minimum worker fatigue

- Ease of assembly in difficult places
- Permits higher driving torque, especially in large sizes where strength is important
- Contains no recess to become clogged with dirt and interfere with driving
- Contains no recess to weaken the head

Unless frequent field disassembly is required, use of the unslotted hex head is preferred.

Appearance is the major disadvantage of the hex head, and this one factor is judged sufficient to eliminate it from consideration for the front or top of products.

The recessed head fastener is widely used and becomes the first choice for appearance applications. It usually costs more than a slot or a hexagon shape. There are many kinds of recesses. The Phillips and Phillips POZIDRIV are most widely used. To a lesser extent the Frearson, clutch-type, hexagonal, and fluted socket heads are used. For special applications, proprietary types of tamper-resistant heads can be selected (Fig. 1).

The recessed head has some of the same advantages as the hex head (see preceding list). It also has improved appearance. The Phillips POZIDRIV is slowly replacing the Phillips recess. The POZIDRIV recess can be readily identified by four radial lines centered between each recess slot. These slots are a slight modification of the conventional Phillips recess. This change improves the fit between the driver and the recess, thus minimizing the possibility of marring a surface from accidental spinout of the driver as well as increasing the life of the driver. The POZIDRIV design is recommended in high-production applications requiring high driving torques. The POZIDRIV

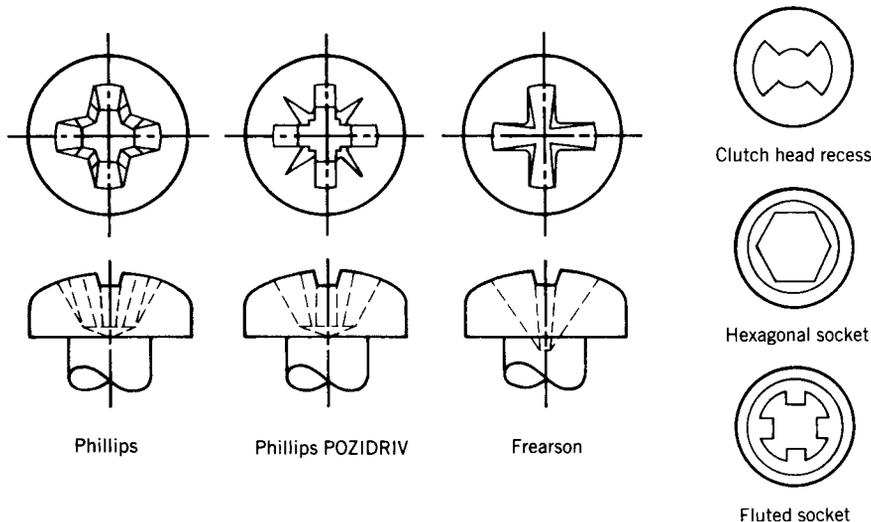

Fig. 1 Recessed head fasteners.

recess usually sells at a high-production applications requiring high driving torques. The POZIDRIV recess usually sells at a slightly higher price than the conventional Phillips recess, but some suppliers will furnish either at the same price. The savings resulting from longer tool life will usually justify the higher initial cost.

A conventional Phillips driver could be used to install or disassemble a POZIDRIV screw. However, a POZIDRIV driver should be used with a POZIDRIV screw in order to take advantage of the many features inherent in the new design. To avoid confusion, it should be clearly understood that a POZIDRIV driver cannot be used to install or remove a conventional Phillips head screw.

A Frearson recess is a somewhat different design than a Phillips recess and has the big advantage that one driving tool can be used for all sizes whereas a Phillips may require four driving tools in the range from no. 2 (0.086-in.) to 3/8 (0.375-in.) screw size. This must be balanced against the following disadvantages:

Limited availability.

Greater penetration of the recess means thinner walls between the bottom of the recess and the outer edge of the screw, which tends to weaken the head.

The sharp point of the driver can easily scratch or otherwise mar the surface of the product if it accidentally touches.

Although one driver can be used for all sizes, for optimum results, different size drivers are recommended for installing various screw sizes, thus minimizing the one real advantage of the Frearson recess.

The hexagon and futed socket head cap screws are only available in expensive high-strength alloy steel. Its unique small outside diameter or cylindrical head is useful on flanges counterbored holes, or other locations where clearances are restricted. Such special applications may justify the cost of a socket head cap screw. Appreciable savings can be made in other applications by substitution of a hexagon head screw.

Despite any claims to the contrary, the dimensional accuracy of hexagon socket head cap screws is no better than that of other cold-headed products, and there is no merit in close-thread tolerances, which are advocated by some manufacturers of these products. The high prices, therefore, should be justified solely on the basis of possible space savings in using the cylindrical head.

The futed socket is not as readily available and should only be considered in the very small sizes where a hexagon key tends to round out the socket. The futed socket offers spline design so that the key will neither slip nor be subject to excessive wear.

Many types of special recesses are tamper resistant. In most of these designs, the recess is an unusual shape

requiring a special tool for assembly and disassembly. A readily available driving tool such as a screwdriver or hexagon key would not fit the recess. The purpose of a tamper-resistant fastener is to prevent unauthorized removal of parts and equipment. Their protection is needed on any product located in public places to discourage vandalism and thievery. They may also be necessary on some consumer products as a safety measure to protect the amateur repairman from injury or to prevent him from causing serious damage to equipment. With product liability mania what it is today, the term "tamperproof" has all but disappeared. Now the fasteners are called "tamper resistant." They are the same as they were under their previous name, but the new term better reflects their true capabilities. Any skilled thief with ample time and proper tools can saw, drill, blast, or otherwise disassemble any tamper-resistant fastener. Therefore, these fasteners are intended only to discourage the casual thief or amateur tinkerer and make it more difficult for a skilled professional. Whatever the choice of fastener design, it is essential that hardened material be specified. No fastener is ever truly tamperproof, but hardened steel helps. Fasteners made of soft material can be disassembled easily by sawing a slot, hammering with a chisel, or drilling a hole and using an extraction bit.

Head Shapes The following information is equally applicable to all types of recesses as well as a slotted head. For simplification only slotted screws are shown.

The pan head is the most widely used and is intended to replace the round, binding, and truss heads in order to keep varieties to a minimum. It is preferred because it presents the best combination of appearance with adequate head height to minimize weakness due to depth of penetration of the recess (Fig. 2).

The round head was widely used in the past (Fig. 3). It has since been delisted as an American National Standard. Give preference to pan heads on all new designs. Figure 4 shows the superiority of the pan head: The high edge of the pan head at its periphery,

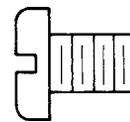

Fig. 2 Pan head.

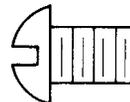

Fig. 3 Round head.

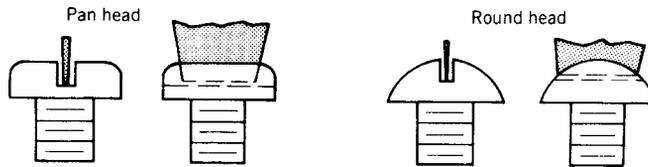

Fig. 4 Drive-slot engagement.

where driving action is most effective, provides superior driver-slot engagement and reduces the tendency to chew away the metal at the edge of the slot.

The fat head is used where a flush surface is required. The countersunk section aids in centering the screw (Fig. 5).

The oval head is similar to a flat head except that instead of a flush surface it presents a low silhouette that improves the appearance (Fig. 6).

The truss head is similar to the round head except that the head is shallower and has a larger diameter. It is used where extra bearing surface is required for extra holding power or where the clearance hole is oversized or the material is soft. It also presents a low silhouette that improves the appearance (Fig. 7).

The binding head is similar to the pan head and is commonly used for electrical connections where an undercut is usually specified to bind and prevent the fraying of stranded wire (Fig. 8).

The fillister head has the smallest diameter for a given shank size. It also has a deep slot that allows a higher torque to be applied during assembly. It is not as readily available or as widely used as some of the other head styles (Fig. 9).

Fig. 5 Flat head.

- (5) Trimmed hex head
- (6) Slotted trimmed hex head
- (7) Trimmed hex washer head
- (8) Slotted trimmed hex washer head

Fig. 10 Hex head.

The advantages of a hex head are listed in the discussion on drivability. This type head is available in eight variations (Fig. 10).

The indented design is lowest cost as the hex is completely cold upset in a counterbore die and possesses an identifying depression in the top surface of the head.

The trimmed design requires an extra operation to produce clean sharp corners with no indentation. Appearance is improved and there is no pocket on top to collect moisture.

The washer design has a larger bearing surface to spread the load over a wider area. The washer is an integral part of the head and also serves to protect the finish of the assembly from wrench disfigurement.

The slot is used to facilitate field service. It adds to the cost, weakens the head, and limits the amount of tightening torque that can be applied. A slot is unnecessary in high-production factory installation.

Any given location should standardize on one or possibly two of the eight variations.

Types of Screws

Machine Screws. Machine screws are meant to be assembled in tapped holes, either into a product or into a nut. The screw threads of a machine screw are readily available in American National Standard Unified Inch Coarse and Fine Thread series. They are generally considered for applications where the material to be joined is too hard, too weak, too brittle, or too thick to take a tapping screw. It is also used in applications where the assembly requires a fastener made of a material that cannot be hardened enough to make its own thread, such as brass or nylon machine screws. Applications requiring freedom from dust or particles of any kind cannot use thread-cutting screws and, therefore, must be joined by machine screws or a tapping screw which forms or rolls a thread.

There are many combinations of head styles, shapes, and materials.

Self-Tapping Screws. There are many different types of self-tapping screws commercially available. The following three types are capable of creating an internal thread by being twisted into a smooth hole:

1. Thread-forming screws
2. Thread-cutting screws
3. Thread-rolling screws

The following two types create their own opening before generating the thread:

4. Self-drilling and tapping screws
5. Self-extruding and tapping screws

1. Thread-Forming Screws. Thread-forming screws create an internal thread by forming or squeezing material. They rely on the pressure of the screw thread to force a mating thread into the workpiece. They are applicable in materials where large internal stresses are permissible or desirable to increase resistance to loosening. They are generally used to fasten sheet metal parts. They cannot be used to join brittle materials, such as plastics, because the stresses created in the workpiece can cause cracking. The following types of thread-forming screws are commonly used:

Types A and AB. Type AB screws have a spaced thread. This means that each thread is spaced further away from its adjacent thread than the popular machine screw series. They also have a gimlet point for ease in entering a predrilled hole. This type of screw is primarily intended to be used in sheet metal with a thickness from 0.015 in. (0.38 mm) to 0.05 in. (1.3 mm), resin-impregnated plywood, natural woods, and asbestos compositions.

Type AB screws were introduced several years ago to replace the type A screws. The type A screw is the same as the type AB except for a slightly wider spacing of the threads. Both are still available and can be used interchangeably. The big advantage of the type AB screw is that its threads are spaced exactly as the type B screws to be discussed later. In the interest of standardization it is recommended that type AB screws be used in place of either the type A or the type B series (Fig. 11).

Type B. Type B screws have the same spacing as type AB screws. Instead of a gimlet point, they have a blunt point with incomplete threads at the point. This point makes the type B more suitable for thicker metals and blind holes. The type B screws can be used in any of the applications listed under type AB. In addition the type B screw can be used in sheet metal up to a thickness of 0.200 in. (5 mm) and in nonferrous castings (Fig. 12).

Type C. Type C screws look like type B screws except that threads are spaced to be exactly the same as a machine screw thread and may be used to replace a machine screw in the field. They are recommended for general use in metal 0.030–0.100 in. (0.76–2.54 mm) thick. It should be recognized that in specific applications, involving long thread engagement or hard materials, this type of screw requires extreme driving torques.

2. Thread-Cutting Screws. Thread-cutting screws create an internal thread by actual removal of material from the internal hole. The design of the cavity to provide space for the chips and the design of the cutting edge differ with each type. They are used in place of the thread-forming type for applications

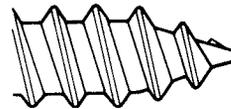

Fig. 11 Type AB.

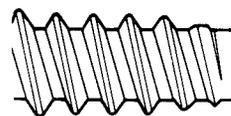

Fig. 12 Type B.

in materials where disruptive internal stresses are undesirable or where excessive driving torques are encountered. The following types of thread-cutting screws are commonly used:

Type BT (Formerly Known as Type 25). Type BT screws have a spaced thread and a blunt point similar to the type B screw. In addition they have one cutting edge and a wide chip cavity. These screws are primarily intended for use in very friable plastics such as urea compositions, asbestos, and other similar compositions. In these materials, a larger space between threads is required to produce a satisfactory joint because it reduces the buildup of internal stresses that fracture brittle plastic when a closer spaced thread is used. The wide cutting slot creates a large cutting edge and permits rapid deflection of the chips to produce clean mating threads. For best results all holes should be counterbored to prevent fracturing the plastic. Use of this type screw eliminates the need to use tapped metallic inserts in plastic materials (Fig. 13).

Type ABT. Type ABT screws are the same as type BT screws except that they have a gimlet point similar to a type AB screw. This design is not recognized as an American National Standard and should only be selected for large-volume applications (over 50,000 pieces of one size and type). It is primarily intended for use in plastic for the same reasons as listed for type BT screws (Fig. 14).

Type D (Formerly Known as Type 1). Type D screws have threads of machine screw diameter-pitch combinations approximating unifie form with a blunt point and tapered entering threads. In addition a slot is cut off center with one side on the center line. This radial side of the slot creates the sharp serrated cutting edge such as formed on a tap. The slot leaves a thinner section on one side of the screw that collapses and helps concentrate the pressure on the cutting edge. This screw is suitable for use in all thicknesses of metals (Fig. 15).

Type F. Type F screws are identical to type D except that instead of one slot there are several slots cut at a slight angle to the axis of the thread. This screw is

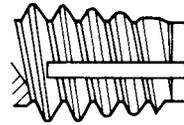

Fig. 15 Type D.

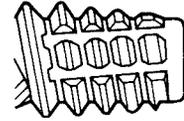

Fig. 16 Type F.

suitable for use in all thicknesses of metals and can be used interchangeably with a type D screw in many applications. However, the type F screw is superior to the type D screw for tapping into cast iron and permits the use of a smaller pilot hole (Fig. 16).

Type D or Type F. Because in many applications these two types can be used interchangeably with the concomitant advantages of simpler inventory and increased availability, a combined specification is often issued permitting the supplier to furnish either type.

Type T (Formerly Known as Type 23). Type T screws are similar to type D and type F except that they have an acute rake angle cutting edge. The cut in the end of the screw is designed to eliminate a pocket that confine the chips. The shape of the slot is such that the chips are forced ahead of the screw as it is driven. This screw is suitable for plastics and other soft materials when a standard machine screw series thread is desired. It is used in place of type D and type F when more chip room is required because of deep penetration (Fig. 17).

Type BF. Type BF screws are intended for use in plastics. The wide thread pitch reduces the buildup of internal stresses that fracture brittle plastics when a smaller thread pitch is used. The screw has a blunt point and tapered entering threads with several cutting edges and chip cavity (Fig. 18).

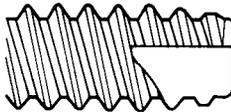

Fig. 13 Type BT.

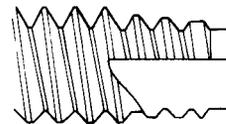

Fig. 17 Type T.

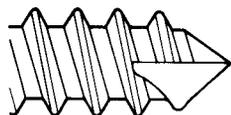

Fig. 14 Type ABT.

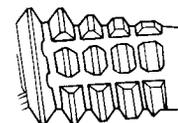

Fig. 18 Type BF.

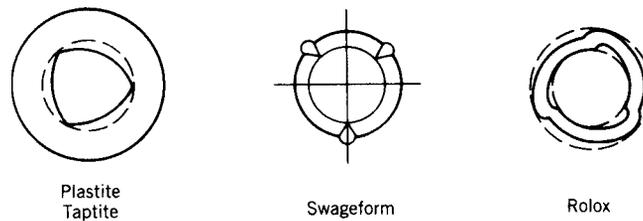

Fig. 19 Thread-rolling screws.

3. Thread-Rolling Screws. Thread-rolling screws (see Fig. 19) form an internal thread by flowing metal and thus do not cut through or disrupt the grain flow lines of materials as do thread-cutting screws. The screw compacts and work hardens the material, thereby forming strong, smoothly burnished internal threads. The screws have the threads of machine screw diameter-pitch combinations. This type screw is ideal for applications where chips can cause electrical shorting of equipment or jamming of delicate mechanism. Freedom from formation of chips eliminates the costly problem of cleaning the product of chips and burrs as would otherwise be required.

The ratio of driving torque to stripping torque is approximately 1 : 8 for a thread-rolling screw as contrasted to 1 : 3 for a conventional tapping screw. This higher ratio permits the driver torque release to be set well over the required driving torque and yet safely below the stripping torque. This increased ratio minimizes poor fastening due to stripped threads or inadequate seating of the screws.

Plastite is intended for use in filled or unfilled thermoplastics and some of the thermosetting plastics. The other three types are intended for use in metals. At present, there are no data to prove the superiority of one type over another.

4. Self-Drilling and Tapping Screws. The self-drilling and tapping screw (Fig. 20) drills its own hole and forms a mating thread, thus making a complete fastening in a single operation. Assembly labor is reduced by eliminating the need to predrill holes at assembly and by solving the problem of hole alignment. These screws must complete their metal-drilling function and fully penetrate the material before the screw thread can engage and begin its advancement. In order to meet this requirement, the unthreaded point length must be equal to or greater than the material thickness to be drilled. Therefore, there is a strict limitation on minimum and maximum material thickness that varies with screw size. There are many different styles and types of self-drilling and tapping screws to meet specific needs.

5. Self-Extruding Screws. Self-extruding screws provide their own extrusion as they are driven into an inexpensively produced punched hole. The resulting extrusion height is several times the base material thickness. This type screw is suitable for material in

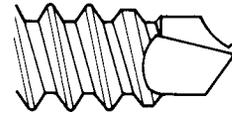

Fig. 20 Self-drilling and tapping screws.

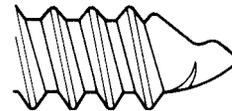

Fig. 21 Self-extruding screw.

thicknesses up to 0.048 in. (1.2 mm). By increasing the thread engagement, these screws increase the differential between driving and stripping torque and provide greater pull-out strength. Since they do not produce chips, they are excellent for grounding sheet metal for electrical connections (Fig. 21).

There is almost no limit to the variety of head styles, thread forms, and screw materials that are available commercially. The listing only shows representative examples. Users should attempt to keep varieties to a minimum by carefully selecting those variations that best meet the needs of their type of product.

Set Screws. Set screws are available in various combinations of head and point style as well as material and are used as locking, locating, and adjustment devices. The common head styles are slotted headless, square head, hexagonal socket, and fluted socket. The slotted headless has the lowest cost and can be used in a counterbored hole to provide a flush surface. The square head is applicable for location or adjustment of static parts where the projecting head is not objectionable. Its use should be avoided on all rotating parts. The hexagonal socket head can be used in a counterbored hole to provide a flush surface. It permits greater torque to be applied than with a slotted headless design. Fluted sockets are useful in very small

Table 104 Holding Power of Flat or Cup Point Set Screws

<i>d</i> (in.)	$\frac{1}{4}$	$\frac{5}{16}$	$\frac{3}{8}$	$\frac{7}{16}$	$\frac{1}{2}$	$\frac{9}{16}$	$\frac{5}{8}$	$\frac{3}{4}$	$\frac{7}{8}$	1	$1\frac{1}{8}$	$1\frac{1}{4}$

diameters, that is, no. 6 (0.138 in.) and under, where hexagon keys tend to round out the socket in hexagonal socket set screws. Set screws should not be used to transmit large amounts of torque, particularly under shock torsion loads. Increased torsion loads may be carried by two set screws located 120° apart.

The following points are available with the head styles discussed: The cup point (Table 104) is the standard stock point for all head shapes and is recommended for all general locking purposes. Flats are recommended on round shafts when close fits are used and it is desirable to avoid interference in disassembling parts because of burrs produced by action of the cup point or when the flats are desired to increase torque transmission. When flat are not used, it is recommended that the minimum shaft diameter be not less than four times the cup diameter since otherwise the whole cup may not be in contact with the shaft. The self-locking cup point has limited availability. It has counterclockwise knurls to prevent the screw from working loose even in poorly tapped holes (Fig. 22).

When oval points are used, the surface it contacts should be grooved or spotted to the same general contour as the point to assure good seating. It is used where frequent adjustment is necessary without excessive deformation of the part against which it bears (Fig. 23).

When flat points are used, it is customary to grind a flat on the shaft for better point contact. This point is preferred where wall thickness is thin and on top of plugs made of any soft material (Fig. 24).

When the cone point is used, it is recommended that the angle of countersink be as nearly as possible the angle of screw point for the best efficiency. Cone point

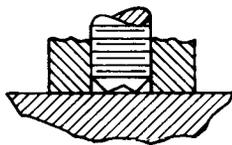

Fig. 22 Cup point.

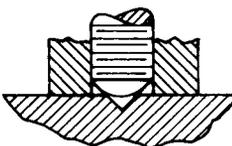

Fig. 23 Oval point.

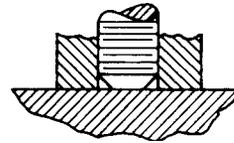

Fig. 24 Flat point.

Fig. 25 Cone point.

Fig. 26 Half-dog point.

set screws have some application as pivot points. It is used where permanent location of parts is required. Because of penetration, it has the highest axial and torsional holding power of any point (Fig. 25).

The half-dog point should be considered in lieu of full-dog points when the usable length of thread is less than the nominal diameter. It is also more readily obtained than the full-dog point. It can be used in place of dowel pins and where end of thread must be protected (Fig. 26).

Lag Screws. Lag screws (Table 105) are usually used in wood but also can be used in plastics and with expansion shields in masonry. A 60° gimlet point is the most readily available type. A 60° cone point, not covered in these drawings, is also available. Some suppliers refer to this item as a lag bolt (Fig. 27).

A lag screw is normally used in wood when it is inconvenient or objectionable to use a through bolt and nut. To facilitate the insertion of the screw especially in denser types of wood, it is advisable to use a lubricant on the threads. It is important to have a pilot hole of proper size and following are some recommended hole sizes for commonly used types of wood. Hole sizes for other types of wood should be in proportion

Table 105 Lag Screws

^a Pilot holes should be slightly larger than listed when lag screws of excessive lengths are to be used.

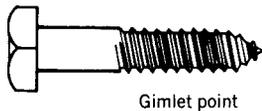

Fig. 27 Lag screws.

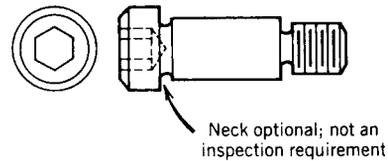

Fig. 28 Shoulder screw.

to the relative specific gravity of that wood to the ones listed in Table 106.

Shoulder Screws. These screws are also referred to as “stripper bolts.” They are used mainly as locators or retainers for spring strippers in punch and die operations and have found some application as fulcrums or pivots in machine designs that involve links, levers, or other oscillating parts. Consideration should be given to the alternative use of a sleeve bearing and a bolt on the basis of both cost and good design (Fig. 28).

Thumb Screws. Thumb screws have a flattened head designed for manual turning without a driver or a wrench. They are useful in applications requiring frequent disassembly or screw adjustment (Fig. 29).

Weld Screws. Weld screws come in many different head configurations all designed to provide one or more projections for welding the screw to a part.

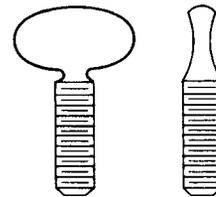

Fig. 29 Thumb screws.

Overhead projections are welded directly to the part. Underhead projections go through a pilot hole. The designs in Figs. 30 and 31 are widely used.

In projection welding of carbon steel screws, care should be observed in applications, since optimum weldability is obtained when the sum, for either parent metal or screw, of one-fourth the manganese content

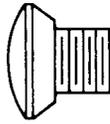

Fig. 30 Single-projection weld screw.

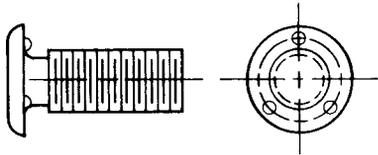

Fig. 31 Underhead weld screws.

plus the carbon content does not exceed 0.38. For good weldability with the annular ring type, the height of the weld projection should not exceed half the parent metal thickness as a rule of thumb.

Copper flash plating is provided for applications where cleanliness of the screw head is necessary in obtaining good welds.

Wood Screws. Wood screws are (Table 107) readily available in lengths from $\frac{1}{4}$ to 5 in. for steel and from $\frac{1}{4}$ to $3\frac{1}{2}$ in. for brass. Consideration should be given to the use of type AB thread-forming screws, which are lower in cost and more efficient than wood screws for use in wood. Wood screws are made with flat round, or oval heads.

The *resistance of wood screws to withdrawal* from side grain of seasoned wood is given by the formula $P = 2850G^2D$, where P is the allowable load on the screw (lb/in. penetration of the threaded portion), G is specific gravity of oven-dry wood, and D is the diameter of the screw (in.). Wood screws should not be designed to be loaded in withdrawal from the end grain.

The *allowable safe lateral resistance* of wood screws embedded seven diameters in the side grain

of seasoned wood is given by the formula $P = KD^2$, where P is the lateral resistance per screw (lb), D is the diameter (in.), and K is 4000 for oak (red and white), 3960 for Douglas fir (coast region) and southern pine, and 3240 for cypress (southern) and Douglas fir (inland region).

The following rules should be observed: (a) The size of the lead hole in soft (hard) woods should be about 70% (90%) of the core or root diameter of the screw; (b) lubricants such as soap may be used without great loss in holding power; (c) long, slender screws are preferable generally, but in hardwood too slender screws may reach the limit of their tensile strength; and (d) in the screws themselves, holding power is favored by thin sharp threads, rough unpolished surface, full diameter under the head, and shallow slots.

SEMS. The machine and tapping screws can be purchased with washers or lock washers as an integral part of the purchased screws. When thus joined together, the part is known as a SEMS unit. The washer is assembled on a headed screw blank before the threads are rolled. The inside diameter of the washer is of a size that will permit free rotation and yet prevent disassembly from the screw after the threads are rolled. If these screws and washers were purchased separately, there would be an initial cost savings over the preassembled units. However, these preassembled units reduce installation time because only one hand is needed to position them, leaving the other hand free to hold the driving tool. The time required to assemble a loose washer is eliminated. In addition, these assemblies act to minimize installation errors and inspection time because the washer is in place, correctly oriented. Also the use of a single unit, rather than two separate parts, simplifies bookkeeping, handling, inventory, and other related operations.

7.1 Nominal and Minimum Dressed Sizes of American Standard Lumber

Table 108 applies to boards, dimensional lumber, and timbers. The thicknesses apply to all widths and all widths to all thicknesses.

The names of Greek letters are found in Table 1, standard mathematical symbols in Table 2, and abbreviations for engineering terms in Table 3 in Section 4.5.

1 ARITHMETIC

1.1 Roman Numerals

Roman Notation. This uses seven letters and a bar; a letter with a bar placed over it represents a thousand times as much as it does without the bar. The letters and rules for combining them to represent numbers are as follows:

I	V	X	L	C	D	M	\bar{L}
1	5	10	50	100	500	1000	50,000

Rule 1 If no letter precedes a letter of greater value, add the numbers represented by the letters.

Example 1 XXX represents 30; VI represents 6.

Rule 2 If a letter precedes a letter of greater value, subtract the smaller from the greater; add the remainder or remainders thus obtained to the numbers represented by the other letters.

Example 2 IV represents 4; XL represents 40; CXLV represents 145.

Other illustrations:

IX	XIII	XIV	LV	XLII	XCVI	MDCI	\bar{IV}	CCXL
9	13	14	55	42	96	1601	4240	

1.2 Roots of Numbers

Roots can be found by use of Table 7, or logarithms, in Section 2.9.

To find an n th root by arithmetic, use a method indicated by the binomial theorem expansion of $(a + b)^n$:

$$\begin{aligned}
 (a + b)^n &= a^n + na^{n-1}b + \frac{n(n-1)}{2}a^{n-2}b^2 \\
 &\quad + \frac{n(n-1)(n-2)}{3 \cdot 2}a^{n-3}b^3 + \dots + b^n \\
 &= a^n + bD
 \end{aligned}$$

where $D = na^{n-1} + \frac{1}{2}n(n-1)a^{n-2}b + \dots + b^{n-1}$.

1. Point off the given number into periods of n figure each, starting at the decimal point and going both ways.
2. Find the largest n th power in the left-hand period and use its root as the first digit of the result. Subtract this n th power from the left-hand period and bring down the next period.
3. Use the quantity D , in which a is 10 times the first digit since the first digit occupies a higher place than the second, as the divisor to obtain the second digit b . As a trial divisor to estimate b , use the first term in D , since it is the largest. Multiply D by b , subtract, and bring down the next period.

4. To get the next digit use 10 times the first two digits as a and proceed as before.

Example 3

See the tabulation for Example 3 below.

1.3 Approximate Computation

Standard Notation. $N = a \cdot 10^b$, N is a given number; $1 \leq a < 10$, the figures in a being the *significant figures* in N ; b is an integer, positive or negative or zero.

Example 4 If $N = 2,953,000$, in which the first five figures are significant then $N = 2.9530 \times 10^6$.

A number is *rounded* to contain fewer significant figures by dropping figures from the right-hand side. If the figures dropped amount to more than $\frac{1}{2}$ in the last figure kept, this last figure is increased by 1. If the figures dropped amount to $\frac{1}{2}$, the last figure may or may not be increased.

Since the last significant figure used in making a measurement, an estimate, and so on, is not exact but is usually the nearer of two consecutive figures, an approximate number may represent any value in a range from $\frac{1}{2}$ less in its last significant figure to $\frac{1}{2}$ more. The *absolute error* in an approximate number may be as much as $\frac{1}{2}$ in the last significant figure.

Example 5 If $N = 2.9530 \times 10^6$ is an approximate number, then $2.95295 \times 10^6 \leq N \leq 2.95305 \times 10^6$.

The absolute error is between -0.00005×10^6 and 0.00005×10^6 .

The size of the absolute error depends on the location of the decimal point.

The *relative error* is the ratio of the absolute error to the number. Its size depends on the number of significant figures.

Example 6 The relative error in Example 5 is at most $0.00005 \times 10^6 / 2.9530 \times 10^6$, or about 1 in 60,000; the percentage error is at most $100 \times (0.00005 / 2.9530)$, or less than 0.002%.

In the result of a computation with approximate numbers, some figures on the right are doubtful and should be rounded off. It is always possible, by using the bounds of the ranges that approximate numbers represent, to compute exactly the bounds of the range in which the result lies and then round off the uncertain figures.

Example 7 Divide the approximate number 536 by the approximate number 217.4:

$$\begin{array}{r} \text{At least} \qquad \qquad \qquad \text{At most} \\ \frac{536}{217.4} = 2.47- \qquad \frac{535.5}{217.45} = 2.46+ \qquad \frac{536.5}{217.35} = 2.47- \end{array}$$

Tabulation for Example 3

1. Square root of 302.980652:

$$\begin{array}{r} 3'02.'98'06'52' \quad \boxed{17.406 +} \\ \underline{1} \\ 202 \\ \underline{189} \\ 344 \\ \underline{1398} \\ 1376 \\ \underline{220,652} \\ 208,836 \end{array}$$

2. Cube root of 1,58,252.632929:

$$\begin{array}{r} 158'252'.632'929 \quad \boxed{54.09} \\ 5^3 = 125 \\ \text{Trial divisor} = 3a^2 = 3 \times 50^2 = 7,500 \quad \boxed{33,252} \\ 3ab = 3 \times 50 \times 4 = 600 \\ b^2 = 4^2 = 16 \\ D = 3a^2 + 3ab + b^2 = \underline{8,116} \quad \boxed{32,464} \\ 3 \times 5400^2 = 8,7480,000 \quad \boxed{788,632,929} \\ 3 \times 5400 \times 9 = 145,800 \\ 9^2 = 81 \\ \underline{87,625,881} \quad \boxed{788,632,929} \end{array}$$

In the quotient the third figure may be in error. It is useless to carry the division further.

The following rules usually give the largest number of significant figures that it is reasonable to keep.

Addition and Subtraction. Keep as the last significant figure in the result the figure in the last full column. The absolute accuracy of the result is determined by the least absolutely accurate number.

Example 8

$$\begin{array}{r} 2.953xx \\ 0.8942x \\ \hline 0.06483 \\ 3.912xx \end{array}$$

Multiplication, Division, Powers, and Roots. Keep no more significant figures in the result than the fewest in any number involved. The relative accuracy of the result is determined by that of the least relatively accurate number. Shortcuts as shown in the examples may be used.

Example 9

1.
$$\begin{array}{r} 2953 \times 413 \\ \quad 2953 \\ \quad 413 \\ \hline 118 \overline{) 12} \\ \quad 3 \ 0 \\ \quad \quad 9 \\ \hline 122 \text{ xxx} = 1.22 \times 10^6 \end{array}$$

2.
$$\begin{array}{r} (1.22 \times 10^6) / 2953 \\ \quad 413 \\ \hline 2953 \overline{) 1,220,000} \\ \quad 11,812 \\ \hline 295 \overline{) 388} \\ \quad 295 \\ \hline 30 \overline{) 93} \\ \quad 90 \\ \hline \end{array}$$

In intermediate results keep one additional figure. If there is much difference in the relative accuracy, that is, the number of significant figures, of the numbers involved in a computation, round all of them to one more significant figure than the least accurate number has. This procedure may introduce a small error in the last figure kept in the result. A three-digit number beginning with 8 or 9 has about the same relative accuracy as a four-digit number beginning with 1.

Use of Tables. In using a table to find the value of a function corresponding to an approximate value of an argument, it is usually advisable to retain no more significant figures in the function than there are in the argument, although the accuracy of the function varies considerably, depending inversely on the slope of the curve representing the function. However, there is no need for many-place tables if the values of the argument are known only to a few significant figures

Example 10 $\frac{1}{57} = 0.019$; $\cos 61.3^\circ = 0.877$;
 $\log 3.74 = 0.573$.

To investigate the behavior of the error for any given function, the differential approximation is useful. If $y = f(x)$, then $dy = f'(x) dx$ approximates the absolute error, and $dy/y = f'(x) dx/f(x)$ the relative error.

For particular approximate values of the arguments, the bounds of the ranges of the functions can be found directly from a table with arguments given to one additional place.

1.4 Interpolation

Gregory-Newton Interpolation Formula. Let $f(x)$ be a tabulated function of the argument x , Δx the constant difference between values of x for which the function is tabulated, and p a proper fraction. To find $f(x + p\Delta x)$ use the formula

$$f(x + p \Delta x) = f(x) + p \Delta f + {}_p C_2 \Delta_2 f + {}_p C_3 \Delta_3 f + \dots$$

in which

$${}_p C_r = \frac{p(p-1)\dots(p-r+1)}{r!}$$

and $\Delta_r f = r$ th functional difference.

Binomial coefficient for interpolation:

p	${}_p C_2$	${}_p C_3$	${}_p C_4$	${}_p C_5$
0.1	-0.0450	0.0285	-0.0207	0.0161
0.2	-0.0800	0.0480	-0.0336	0.0255
0.3	-0.1050	0.0595	-0.0402	0.0297
0.4	-0.1200	0.0640	-0.0416	0.0300
0.5	-0.1250	0.0625	-0.0391	0.0273
0.6	-0.1200	0.0560	-0.0336	0.0228
0.7	-0.1050	0.0455	-0.0262	0.0173
0.8	-0.0800	0.0320	-0.0176	0.0113
0.9	-0.0450	0.0165	-0.0087	0.0054

In ordinary linear interpolation the first two terms of the formula are used.

Example 11 Find $\sqrt{15.4}$.

x	$f(x) = \sqrt{x}$	Δf	$\Delta_2 f$	$\Delta_3 f$
15	3.8730			
16	4.0000	0.1270		
17	4.1231	0.1231	-0.0039	0.0003
18	4.2426	0.1195	-0.0036	

$$\Delta x = 1 \quad p = 0.4$$

$$\begin{aligned} f(15 + 0.4 \times 1) &= 3.8730 + 0.4 \times 0.1270 + 0.1200 \\ &\quad \times 0.0039 + 0.0640 \times 0.0003 \\ &= 3.9243 \end{aligned}$$

2 ALGEBRA

2.1 Numbers

Classification

1. *Real (positive and negative)*.
 - (a) *Rational*, expressible as the quotient of two integers.
 - i. *Integers*, as $-1, 2, 53$.
 - ii. *Fractions*, as $\frac{3}{4}, -\frac{5}{2}$.
 - (b) *Irrational*, not expressible as the quotient of two integers, as $\sqrt{2}, \pi$.
2. *Imaginary*, a product of a real number and the *imaginary unit* $i (= \sqrt{-1})$. Electrical engineers use j to avoid confusion with i for current. Example: $\sqrt{-2} = \sqrt{2}i$.
3. *Complex*, a sum of a real number and an imaginary number, as $a + bi$ (a and b real), $-3 + 0.5i$. A real number may be regarded as a complex number in which $b = 0$ and an imaginary number as one in which $a = 0$.

The Absolute Value of:

1. A *real number* is the number itself if the number is positive and the number with its sign changed if it is negative, as, for example, $|3| = |-3| = 3$.
2. A *complex number* $a + bi$ is $\sqrt{a^2 + b^2}$, as, for example, $|-3 + 0.5i| = \sqrt{9 + \frac{1}{4}} = 3.04$.

2.2 Identities

Powers

1. $(-a)^n = a^n$ if n is even
2. $(-a)^n = -a^n$ if n is odd
3. $a^m \cdot a^n = a^{m+n}$
4. $a^m / a^n = a^{m-n}$

5. $(ab)^n = a^n b^n$
6. $(a/b)^n = a^n / b^n = (b/a)^{-n} = b^{-n} / a^{-n} = a^n b^{-n}$
7. $a^{-n} = (1/a)^n = \frac{1}{a^n}$
8. $(a^m)^n = a^{mn}$
9. $a^0 = 1; 0^n = 0; 0^0$ is meaningless

Roots

1. $\sqrt[n]{a} = a^{1/n}$
2. $(\sqrt[n]{a})^n = \sqrt[n]{a^n} = a$
3. $\sqrt[n]{ab} = \sqrt[n]{a} \sqrt[n]{b}$
4. $\sqrt[n]{a/b} = \sqrt[n]{a} / \sqrt[n]{b}$
5. $\sqrt[m]{a} \sqrt[n]{a} = a^{(1/m)+(1/n)} = \sqrt[mn]{a^{m+n}}$
6. $\sqrt[m]{a^n} = (\sqrt[n]{a})^m = a^{n/m}$
7. $\sqrt[m]{\sqrt[n]{a}} = \sqrt[mn]{a} = \sqrt[n]{\sqrt[m]{a}} = (a^{1/m})^{1/n} = a^{1/mn}$
8. $\sqrt{a} + \sqrt{b} = \sqrt{a + b + 2\sqrt{ab}}$

Products

1. $(a \pm b)^2 = a^2 \pm 2ab + b^2$
2. $(a + b)(a - b) = a^2 - b^2$.
3. $(a + b + c)^2 = a^2 + b^2 + c^2 + 2ab + 2ac + 2bc$
4. $(a \pm b)^3 = a^3 \pm 3a^2b + 3ab^2 \pm b^3$
5. $a^3 \pm b^3 = (a \pm b)(a^2 \mp ab + b^2)$

Quotients

1. $(a^n - b^n)/(a - b) = a^{n-1} + a^{n-2}b + a^{n-3}b^2 + \dots + ab^{n-2} + b^{n-1}$ if $a \neq b$
2. $(a^n + b^n)/(a + b) = a^{n-1} - a^{n-2}b + a^{n-3}b^2 - \dots - ab^{n-2} + b^{n-1}$ if n is odd
3. $(a^n - b^n)/(a + b) = a^{n-1} - a^{n-2}b + a^{n-3}b^2 - \dots + ab^{n-2} - b^{n-1}$ if n is even

Fractions

Signs:

$$\frac{a}{b} = \frac{-a}{-b} = \frac{-a}{b} = -\frac{a}{-b}$$

Addition and subtraction:

$$\begin{aligned} \frac{a}{c} \pm \frac{b}{d} &= \frac{ad \pm bc}{cd}, \frac{a}{c} \pm \frac{b}{c} = \frac{a \pm b}{c}, \frac{a}{c} \pm \frac{a}{d} \\ &= \frac{a(d \pm c)}{cd} \pm \frac{b}{d} \pm \frac{c}{df^2} \\ &= \frac{ae^2 fg + bdf^2 - ce^3 g}{de^3 f^2 g} \end{aligned}$$

Multiplication:

$$\frac{a}{b} \times \frac{c}{d} = \frac{ac}{bd}, \quad \frac{a}{\frac{c}{d}} = \frac{ac}{c}$$

Division:

$$\frac{a/b}{c/d} = \frac{a}{b} \times \frac{d}{c} = \frac{ad}{bc}, \quad \frac{a}{\frac{c}{b}} = \frac{a/c}{b/c}$$

Series

1. $1 + 2 + 3 + 4 + \dots + (n-1) + n = \frac{1}{2}n(n+1)$
2. $p + (p+1) + (p+2) + \dots + (q-1) + q = \frac{1}{2}(q+p)(q-p+1)$
3. $2 + 4 + 6 + 8 + \dots + (2n-2) + 2n = n(n+1)$
4. $1 + 3 + 5 + 7 + \dots + (2n-3) + (2n-1) = n^2$
5. $1^2 + 2^2 + 3^2 + 4^2 + \dots + (n-1)^2 + n^2 = \frac{1}{6}n(n+1)(2n+1)$
6. $1^3 + 2^3 + 3^3 + 4^3 + \dots + (n-1)^3 + n^3 = \frac{1}{4}n^2(n+1)^2$
7. $1^4 + 2^4 + 3^4 + 4^4 + \dots + (n-1)^4 + n^4 = \frac{1}{30}n(n+1)(2n+1)(3n^2+3n-1)$

2.3 Binomial Theorem

$$(a \pm b)^n = a^n \pm na^{n-1}b + \frac{n(n-1)}{1 \cdot 2}a^{n-2}b^2 \pm \frac{n(n-1)(n-2)}{1 \cdot 2 \cdot 3}a^{n-3}b^3 + \dots + (\pm 1)^r \frac{n(n-1) \dots (n-r+1)}{r!}a^{n-r}b^r + \dots$$

in which the last term shown is the $(r+1)$ th; $r!$, called *r factorial*, equals $1 \cdot 2 \cdot 3 \dots (r-1) \cdot r$; and $0! = 1$.

If n is a positive integer, the series is finite it has $n+1$ terms, the last being b^n ; and it holds for all values of a and b . If n is fractional or negative, the series is infinite it converges only for $|b| < |a|$ (see Section 9.4).

The coefficients $n, n(n-1)/2!, n(n-1)(n-2)/3!, \dots$ are called *binomial coefficients*. For brevity the coefficient $n(n-1) \dots (n-r+1)/r!$ of the $(r+1)$ th terms is written $\binom{n}{r}$ or ${}_nC_r$. If n is a positive integer,

the coefficients of the r th term from the beginning and the r th from the end are equal.

For any value of n and $-1 < x < 1$,

$$(1 \pm x)^n = 1 \pm nx + \frac{n(n-1)}{1 \cdot 2}x^2 \pm \frac{n(n-1)(n-2)}{1 \cdot 2 \cdot 3}x^3 + \frac{n(n-1)(n-2)(n-3)}{1 \cdot 2 \cdot 3 \cdot 4}x^4 \pm \dots$$

$$\frac{1}{1 \pm x} = (1 \pm x)^{-1} = 1 \mp x + x^2 \mp x^3 + x^4 \mp x^5 + \dots$$

$$\sqrt{1 \pm x} = (1 \pm x)^{1/2} = 1 \pm \frac{1}{2}x - \frac{1}{2 \cdot 4}x^2 \pm \frac{1 \cdot 3}{2 \cdot 4 \cdot 6}x^3 - \frac{1 \cdot 3 \cdot 5}{2 \cdot 4 \cdot 6 \cdot 8}x^4 \pm \frac{1 \cdot 3 \cdot 5 \cdot 7}{2 \cdot 4 \cdot 6 \cdot 8 \cdot 10}x^5 - \dots$$

$$\frac{1}{\sqrt{1 \pm x}} = (1 \pm x)^{-1/2} = 1 \mp \frac{1}{2}x + \frac{1 \cdot 3}{2 \cdot 4}x^2 \mp \frac{1 \cdot 3 \cdot 5}{2 \cdot 4 \cdot 6}x^3 + \dots$$

2.4 Approximate Formulas

(a) If $|x|$ and $|y|$ are small compared with 1:

1. $(1 \pm x)^2 = 1 \pm 2x$
2. $(1 \pm x)^{1/2} = 1 \pm \frac{1}{2}x$
3. $1/(1 \pm x) = 1 \mp x$
4. $(1+x)(1+y) = 1+x+y$
5. $(1+x)(1-y) = 1+x-y$
6. $e^x = 1+x + \frac{1}{2}x^2$
(where $e = 2.71828$)
7. $\log_e(1 \pm x) = \pm x - x^2/2 \pm x^3/3$

$$8. \log_e \left(\frac{1+x}{1-x} \right) = 2 \left(x + \frac{1}{3}x^3 + \frac{1}{5}x^5 \right)$$

(Last term often may be omitted.)

(b) If $|x|$ is small compared with a and $a > 0$:

$$9. a^x = 1 + x \log_e a + \frac{1}{2}x^2(\log_e a)^2. \quad (\text{Last term often may be omitted.})$$

(c) If a and b are nearly equal and both > 0 :

$$10. \sqrt{ab} = \frac{1}{2}(a+b)$$

(d) If b is small compared with a and both > 0 :

$$11. \sqrt{a^2 \pm b} = a \pm b/2a$$

$$12. \sqrt{a^2 \pm b} = a \pm b/3a^2$$

$$13. \sqrt{a^2 + b^2} = 0.960a + 0.398b. \quad \text{This is within 4\% of the true value if } a > b.$$

$$\text{A closer approximation is } \sqrt{a^2 + b^2} = 0.9938a + 0.0703b + 0.3567(b^2/a).$$

$$14. \sqrt{a^2 + b^2 + c^2} = 0.939a + 0.389b + 0.297c. \quad \text{This is within 6\% of the true value if } a > b > c. \text{ For instance, for the numbers 43, 42, and 41, the error is } < 5.2\%.$$

(e) If $|x|$ is less than $\pi/18$:

15. $\sin x = x - \frac{1}{6}x^3$
16. $\cos x = 1 - \frac{1}{2}x^2$
17. $\tan x = x + \frac{1}{3}x^3$

(Last term often may be omitted.)

(Note: If $x = 8^\circ = 8\pi/180 = 0.13963$, $\sin x = x - \frac{1}{6}x^3 = 0.13918$, which is one unit in error in the 5th decimal place. If the absolute value of the angle is less than 5° , the values of x and $\sin x$ do not differ more than one unit in the fourth decimal place.)

(f) If $|y|$ is less than $\pi/36$ and small compared with $|x|$:

- 18. $\sin(x \pm y) = \sin x \pm y \cos x$
- 19. $\cos(x \pm y) = \cos x \mp y \sin x$
- 20. $\tan(x \pm y) = \tan x \pm y/\cos^2 x$

(g) If $|n| > 1$:

- 21. $e^{1/n} = 1 + 1/(n - 0.5)$
- 22. $e^{-1/n} = 1 - 1/(n + 0.5)$

(h) As $n \rightarrow \infty$:

- 23. $\frac{1 + 2 + 3 + 4 + 5 \dots + n}{n^2} \rightarrow \frac{1}{2}$
- 24. $\frac{1 + 2^2 + 3^2 + 4^2 + \dots + n^2}{n^3} \rightarrow \frac{1}{3}$
- 25. $\frac{1 + 2^3 + 3^3 + 4^3 + \dots + n^3}{n^4} \rightarrow \frac{1}{4}$

2.5 Inequalities

Laws of Inequalities for Positive Quantities

(a) If $a > b$, then

$$\begin{array}{l} a + c > b + c \\ a - c > b - c \\ ac > bc \\ \frac{a}{c} > \frac{b}{c} \end{array} \qquad \begin{array}{l} b < a \\ c - a < c - b \\ -ca < -cb \\ \frac{c}{a} < \frac{c}{b} \end{array}$$

Corollary: If $a - c > b$, then $a > b + c$.

(b) If $a > b$ and $c > d$, then $a + c > b + d$; $ac > bd$; but $a - c$ may be greater than, equal to, or less than $b - d$; a/c may be greater than, equal to, or less than b/d .

2.6 Ratio and Proportion

Laws of Ratio and Proportion

(a) If $a/b = c/d$, then

$$\frac{a}{c} = \frac{b}{d} \qquad ad = bc$$

$$\frac{ma + nb}{pa + qb} = \frac{mc + nd}{pc + qd} \qquad \left(\frac{a}{b}\right)^n = \left(\frac{c}{d}\right)^n$$

If also $e/f = g/h$, then, $ae/bf = cg/dh$.

(b) If $a/b = c/d = e/f = \dots$, then

$$\frac{a}{b} = \frac{c}{d} = \frac{e}{f} = \dots = \frac{pa + qc + re + \dots}{pb + qd + rf + \dots}$$

Variation

If $y = kx$, y varies directly as x ; that is, y is directly proportional to x .

If $y = k/x$, y varies inversely as x ; that is, y is inversely proportional to x .

If $y = kxz$, y varies jointly as x and z .

If $y = k(x/z)$, y varies directly as x and inversely as z . The constant k is called the proportionality factor.

2.7 Progressions

Arithmetic Progression. This is a sequence in which the *difference* d of any two consecutive terms is a constant. If n = number of terms, a = first term, l = last term, s = sum of n terms, then $l = a + (n - 1)d$, and $s = (n/2)(a + l)$. The *arithmetic mean* A of two quantities m, n is the quantity that placed between them makes with them an arithmetic progression; $A = (m + n)/2$.

Example 12 Given the series $3 + 5 + 7 + \dots$ to 10 terms. Here $n = 10, a = 3, d = 2$; hence $l = 3 + (10 - 1) \times 2 = 21$ and $s = (10/2)(3 + 21) = 120$.

Geometric Progression. This is a sequence in which the *ratio* r of any two consecutive terms is a constant. If n = number of terms, a = first term, l = last term, s = sum of n terms, then $l = ar^{n-1}$, $s = (rl - a)/(r - 1) = a(1 - r^n)/(1 - r)$. The *geometric mean* G of two quantities m, n is the quantity that placed between them makes with them a geometric progression; $G = \sqrt{mn}$.

Example 13 Given the series $3 + 6 + 12 + \dots$ to six terms. Here $n = 6, a = 3, r = 2$; hence $l = 3 \times 2^{6-1} = 96$ and $s = (2 \times 96 - 3)/(2 - 1) = 3(1 - 2^6)/(1 - 2) = 189$.

If $|r| < 1$ then, as $n \rightarrow \infty, s \rightarrow a/(1 - r)$.

Example 14 Given the infinite series $\frac{1}{2} + \frac{1}{4} + \frac{1}{8} + \dots$. Here $a = \frac{1}{2}$ and $r = \frac{1}{2}$; hence $s \rightarrow (\frac{1}{2})/(1 - \frac{1}{2}) = 1$ as $n \rightarrow \infty$.

Harmonic Progression. This is a sequence in which the reciprocals of the terms form an arithmetic progression. The *harmonic mean* H of two quantities m, n is the quantity that placed between them makes with them a harmonic progression; $H = 2mn/(m + n)$.

The relation among the arithmetic, geometric, and harmonic means of two quantities is $G^2 = AH$.

2.8 Partial Fractions

A *proper* algebraic fraction is one in which the numerator is of lower degree than the denominator. An improper fraction can be changed to the sum of a polynomial and a proper fraction by dividing the numerator by the denominator.

A proper fraction can be resolved into *partial fractions*, the denominators of which are factors, prime to each other, of the denominator of the given fraction.

CASE 1: The denominator can be factored into real linear factors P, Q, R, \dots all different. Let

$$\frac{\text{Num}}{PQR\dots} = \frac{A}{P} + \frac{B}{Q} + \frac{C}{R} + \dots$$

Example 15

$$\frac{6x^2 - x + 1}{x^3 - x} = \frac{A}{x} + \frac{B}{x-1} + \frac{C}{x+1}$$

Clearing fractions,

$$6x^2 - x + 1 = A(x-1)(x+1) + Bx(x+1) + Cx(x-1) \quad (1)$$

(a) *Substitution method.* Letting $x = 0, A = -1; x = 1, B = 3; \text{ and } x = -1, C = 4$ yields

$$\frac{6x^2 - x + 1}{x^3 - x} = -\frac{1}{x} + \frac{3}{x-1} + \frac{4}{x+1}$$

(b) *Method of undetermined coefficients.* Rewriting Eq. (1),

$$6x^2 - x + 1 = (A + B + C)x^2 + (B - C)x - A$$

Equating coefficients of like powers of $x, A + B + C = 6, B - C = -1, -A = 1$. Solving this system of equations, $A = -1, B = 3, C = 4$.

CASE 2: The denominator can be factored into real linear factors, P, Q, \dots , one or more repeated. Let

$$\frac{\text{Num}}{p^2Q^3} = \frac{A}{P} + \frac{B}{p^2} + \frac{C}{Q} + \frac{D}{Q^2} + \frac{E}{Q^3} + \dots$$

Example 16

$$\frac{x+1}{x(x-1)^3} = \frac{A}{x} + \frac{B}{x-1} + \frac{C}{(x-1)^2} + \frac{D}{(x-1)^3}$$

Clearing fractions,

$$x+1 = A(x-1)^3 + Bx(x-1)^2 + Cx(x-1) + Dx$$

A and D can be found by substituting $x = 0$ and $x = 1$. After inserting these numerical values for A and D, B and C can be found by the method of undetermined coefficients

CASE 3: The denominator can be factored into quadratic factors, P, Q, \dots , all different, which cannot be factored into real linear factors. Let

$$\frac{\text{Num}}{PQ\dots} = \frac{Ax+B}{P} + \frac{Cx+D}{Q} + \dots$$

Example 17

$$\frac{3x^2 - 2}{(x^2 + x + 1)(x + 1)} = \frac{Ax + B}{x^2 + x + 1} + \frac{C}{x + 1}$$

Clearing fractions,

$$\begin{aligned} 3x^2 - 2 &= (Ax + B)(x + 1) + C(x^2 + x + 1) \\ &= (A + C)x^2 + (A + B + C)x + (B + C) \end{aligned}$$

Use the method of undetermined coefficient to find A, B, C .

CASE 4: The denominator can be factored into quadratic factors, P, Q, \dots , one or more repeated, which cannot be factored into real linear factors. Let

$$\begin{aligned} \frac{\text{Num}}{P^2Q^3\dots} &= \frac{Ax+B}{P} + \frac{Cx+D}{P^2} + \frac{Ex+F}{Q} \\ &+ \frac{Gx+H}{Q^2} + \frac{Ix+J}{Q^3} + \dots \end{aligned}$$

Example 18

$$\begin{aligned} \frac{5x^2 - 4x + 16}{(x-3)(x^2 - x + 1)^2} &= \frac{A}{x-3} + \frac{Bx+C}{x^2 - x + 1} \\ &+ \frac{Dx+E}{(x^2 - x + 1)^2} \end{aligned}$$

Clearing fractions,

$$\begin{aligned} 5x^2 - 4x + 16 &= A(x^2 - x + 1)^2 + (Bx + C)(x - 3) \\ &\times (x^2 - x + 1) + (Dx + E)(x - 3) \end{aligned}$$

Find A by substituting $x = 3$. Then use the method of undetermined coefficient to find B, C, D, E .

2.9 Logarithms

If $N = b^x$, then x is the *logarithm* of the number N to the *base* b . For computation, *common*, or Briggs, logarithms to the base 10 (abbreviated \log_{10} or \log) are used. For theoretical work involving calculus, *natural*, or Napierian, logarithms to the irrational base

$e = 2.71828 \dots$ (abbreviated \ln , \log_e , or \log) are used. The relation between logarithms of the two systems is

$$\log_e n = \frac{\log_{10} n}{\log_{10} e} = \frac{\log_{10} n}{0.4343} = 2.303 \log_{10} n$$

The integral part of a common logarithm, called the *characteristic*, may be positive, negative, or zero. The decimal part, called the *mantissa* and given in tables, is always positive.

To find the common logarithm of a number, first find the mantissa from Table 10 in Section 9.4, disregarding the decimal point of the number. Then from the location of the decimal point find the characteristic as follows. If the number is greater than 1, the characteristic is positive or zero. It is 1 less than the number of figures preceding the decimal point. For a number expressed in standard notation the characteristic is the exponent of 10.

Example 19 $\log 6.54 = 0.8156$, $\log 6540 = \log(6.54 \times 10^3) = 3.8156$.

If the number is less than 1, the characteristic is negative and is numerically 1 greater than the number of zeros immediately following the decimal point. To avoid having a negative integral part and a positive decimal part, the characteristic is written as a difference.

Example 20 $\log 0.654 = \log(6.54 \times 10^{-1}) = \bar{1}.8156 = 9.8156 - 10$, $\log 0.000654 = \log(6.54 \times 10^{-4}) = \bar{4}.8156 = 6.8156 - 10$.

To find a number whose logarithm is given, each of the preceding steps is reversed.

The cologarithm of a number is the logarithm of its reciprocal. Hence, $\text{colog} N = \log 1/N = \log 1 - \log N = -\log N$.

Use of Logarithms in Computation

- To multiply a and b $\log ab = \log a + \log b$
- To divide a by b $\log a/b = \log a - \log b$
- To raise a to the n th power $\log a^n = n \log a$
- To find the n th root of a $\log a^{1/n} = (1/n) \log a$

Example 21

1. $68.31 \times 0.2754 = 18.81$:

 $\log 68.31 = 1.8345$
 $\log 0.2754 = \frac{9.4400 - 10}{11.2745 - 10} = 1.2745 = \log 18.81$

2. $0.6841^{1.53} = 0.5582$:

 $\log 0.6831 = 9.8345 - 10$
 $1.53 \times (9.8345 - 10) = 15.0468 - 15.3$

To subtract 15.3 from 15.0468, add 10 to 15.0468 and subtract 10 from it:

$$\frac{25.0468 - 10}{15.3} = \frac{9.7468 - 10}{9.7468 - 10} = \log 0.5582$$

3. $\sqrt[5]{0.6831} = 0.9266$:

$$\log 0.6831 = 9.8345 - 10$$

$$\frac{1}{5}(49.8345 - 50) = 9.9669 - 10 = \log 0.9266$$

To solve a simple exponential equation of the form $a^x = b$, equate the logarithms of the two sides of the equation:

$$x \log a = \log b$$

from which

$$x = \frac{\log b}{\log a} \quad \text{and} \quad \log x = \log(\log b) - \log(\log a)$$

Example 22 $0.6831^x = 27.54$.

$$x = \frac{\log 27.54}{\log 0.6831} = \frac{1.4400}{9.8345 - 10} = \frac{1.4400}{-0.1655} = -8.701$$

2.10 Equations

The equation $f(x) = a_0x^n + a_1x^{n-1} + a_2x^{n-2} + \dots + a_n = 0$, a_i real, is a *polynomial equation of degree n* in one variable.

For $n = 1$, the equation $f(x) = ax + b = 0$ is *linear*. It has one root, $x_1 = -b/a$.

Quadratic Equation For $n = 2$, the equation $f(x) = ax^2 + bx + c = 0$ is *quadratic*. It has two roots, both real or both complex, given by the formulas

$$x_1, x_2 = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a} = \frac{2c}{-b \mp \sqrt{b^2 - 4ac}}$$

To avoid loss of precision if $\sqrt{b^2 - 4ac}$ and $|b|$ are nearly equal, use the form that does not involve the difference.

If the quantity $b^2 - 4ac$, called the *discriminant*, is greater than zero, the roots are real and unequal; if it equals zero, the roots are real and equal; if it is less than zero, the roots are complex.

Cubic Equation For $n = 3$, the equation $f(x) = a_0x^3 + a_1x^2 + a_2x + a_3 = 0$ is *cubic*. It has three roots, all real or one real and two complex.

Algebraic Solution. Write the equation in the form $ax^3 + 3bx^2 + 3cx + d = 0$. Let

$$q = ac - b^2 \quad \text{and} \quad r = \frac{1}{2}(3abc - a^2d) - b^3$$

Also let

$$s_1 = (r + \sqrt{q^3 + r^2})^{1/3} \quad \text{and}$$

$$s_2 = (r - \sqrt{q^3 + r^2})^{1/3}$$

Then the roots are

$$x_1 = \frac{(s_1 + s_2) - b}{a}$$

$$x_2 = \frac{-\frac{1}{2}(s_1 + s_2) + \frac{1}{2}\sqrt{-3}(s_1 - s_2) - b}{a}$$

$$x_3 = \frac{-\frac{1}{2}(s_1 + s_2) - \frac{1}{2}\sqrt{-3}(s_1 - s_2) - b}{a}$$

If $q^3 + r^2 > 0$, there are one real and two complex roots. If $q^3 + r^2 = 0$, there are three real roots of which at least two are equal. If $q^3 + r^2 < 0$, there are three real roots, but the numerical solution leads to finding the cube roots of complex quantities. In such a case the trigonometric solution is employed.

Example 23 Given the equation $x^3 + 12x^2 + 45x + 54 = 0$. Here $a = 1, b = 4, c = 15, d = 54$. Let $q = 15 - 16 = -1; r = \frac{1}{2}(180 - 54) - 64 = 1; q^3 + r^2 = -1 + 1 = 0, s_1 = s_2 = (-1)^{1/2} = -1; s_1 + s_2 = -2; s_1 - s_2 = 0$. Hence the roots are $x_1 = (-2 - 4) = -6; x_2 = x_3 = [-\frac{1}{2}(-2) - 4] = -3$.

Trigonometric Solution. Write the equation in the form $ax^3 + 3bx^2 + 3cx + d = 0$. Let $q = ac - b^2$ and $r = \frac{1}{2}(3abc - a^2d) - b^3$ (as in algebraic solution). Then the roots are

$$x_1 = \frac{y_1 - b}{a} \quad x_2 = \frac{y_2 - b}{a} \quad x_3 = \frac{y_3 - b}{a}$$

where $y_1, y_2,$ and y_3 have the following values (upper of alternative signs being used when r is positive and the lower when r is negative):

CASE 1: If q is negative and $q^3 + r^2 \leq 0$:

$$y_1 = \pm 2\sqrt{-q} \cos \left(\frac{1}{3} \cos^{-1} \frac{\pm r}{\sqrt{-q^3}} \right)$$

$$y_2 = \pm 2\sqrt{-q} \cos \left(\frac{1}{3} \cos^{-1} \frac{\pm r}{\sqrt{-q^3}} + \frac{2\pi}{3} \right)$$

$$y_3 = \pm 2\sqrt{-q} \cos \left(\frac{1}{3} \cos^{-1} \frac{\pm r}{\sqrt{-q^3}} + \frac{4\pi}{3} \right)$$

CASE 2: If q is negative and $q^3 + r^2 \geq 0$:

$$y_1 = \pm 2\sqrt{-q} \cosh \left(\frac{1}{3} \cosh^{-1} \frac{\pm r}{\sqrt{-q^3}} \right)$$

$$y_2 = \mp \sqrt{-q} \cosh \left(\frac{1}{3} \cosh^{-1} \frac{\pm r}{\sqrt{-q^3}} \right)$$

$$+ i\sqrt{-3q} \sinh \left(\frac{1}{3} \cosh^{-1} \frac{\pm r}{\sqrt{-q^3}} \right)$$

$$y_3 = \mp \sqrt{-q} \cosh \left(\frac{1}{3} \cosh^{-1} \frac{\pm r}{\sqrt{-q^3}} \right)$$

$$- i\sqrt{-3q} \sinh \left(\frac{1}{3} \cosh^{-1} \frac{\pm r}{\sqrt{-q^3}} \right)$$

CASE 3: If q is positive:

$$y_1 = \pm 2\sqrt{q} \sinh \left(\frac{1}{3} \sinh^{-1} \frac{\pm r}{\sqrt{q^3}} \right)$$

$$y_2 = \mp \sqrt{q} \sinh \left(\frac{1}{3} \sinh^{-1} \frac{\pm r}{\sqrt{q^3}} \right)$$

$$+ i\sqrt{3q} \cosh \left(\frac{1}{3} \sinh^{-1} \frac{\pm r}{\sqrt{q^3}} \right)$$

$$y_3 = \mp \sqrt{q} \sinh \left(\frac{1}{3} \sinh^{-1} \frac{\pm r}{\sqrt{q^3}} \right)$$

$$- i\sqrt{3q} \cosh \left(\frac{1}{3} \sinh^{-1} \frac{\pm r}{\sqrt{q^3}} \right)$$

Example 24 Given the equation $x^3 + 6x^2 - 9x - 54 = 0$.

Here $a = 1, b = 2, c = -3, d = -54; q = -3 - 4 = -7; r = \frac{1}{2}(-18 + 54) - 8 = 10; q^3 + r^2 = -343 + 100 = -243$. Note that q is negative; $q^3 + r^2 < 0; r$ is positive. Therefore use Case 1 with upper signs:

$$y_1 = 2\sqrt{7} \cos \left(\frac{1}{3} \cos^{-1} \frac{10}{\sqrt{343}} \right) = 2\sqrt{7} \cos 19.1^\circ = 5$$

Hence, one root is $x_1 = 5 - 2 = 3$. The other roots can be similarly determined.

Quartic Equation For $n = 4$, the equation $f(x) = a_0x^4 + a_1x^3 + a_2x^2 + a_3x + a_4 = 0$ is *quartic*. It has four roots, all real, all complex, or two real and two complex.

To solve, first divide the equation by a_0 to put it in the form $x^4 + ax^3 + bx^2 + cx + d = 0$. Find any real root y_1 of the cubic equation:

$$8y^3 - 4by^2 + 2(ac - 4d)y - [c^2 + d(a^2 - 4b)] = 0$$

Then the four roots of the quartic equation are given by the roots of the two quadratic equations:

$$x^2 + \left(\frac{1}{2}a + \sqrt{\frac{1}{4}a^2 + 2y_1 - b}\right)x + (y_1 + \sqrt{y_1^2 - d}) = 0$$

$$x^2 + \left(\frac{1}{2}a - \sqrt{\frac{1}{4}a^2 + 2y_1 - b}\right)x + (y_1 - \sqrt{y_1^2 - d}) = 0$$

***n*th-Degree Equation**

Properties of $f(x) = a_0x^n + a_1x^{n-1} + \dots + a_n = 0$.
Assume a_n 's are real.

- Remainder Theorem.** If $f(x)$ is divided by $x - r$ until a remainder independent of x is obtained, this remainder is equal to $f(r)$, the value of $f(x)$ for $x = r$.
- Factor Theorem.** If and only if $x - r$ is a factor of $f(x)$, then $f(r) = 0$.
- The equation $f(x) = 0$ has n roots, not necessarily distinct. Complex roots occur in conjugate pairs, $a + bi$ and $a - bi$. If n is odd, there is at least one real root.
- The sum of the roots is $-a_1/a_0$, the sum of the products of the roots taken two at a time is a_2/a_0 , the sum of the products of the roots taken three at a time is $-a_3/a_0$, and so on. The product of all the roots is $(-1)^n a_n/a_0$.
- If the a_i are integers and p/q is a rational root of $f(x) = 0$ reduced to its lowest terms, then p is a divisor of a_n and q of a_0 . If a_0 is 1, the rational roots are integers.

- If x is replaced by (a) y/m , (b) $-y$, (c) $y + h$, the roots of the resulting equation $\phi(y) = 0$ are (a) m times, (b) the negatives of, (c) less by h than the corresponding roots of $f(x) = 0$.
- Descartes' Rule of Signs.** A variation of sign occurs in $f(x) = 0$ if two consecutive terms have unlike signs. The number of positive roots is either equal to the number of variations of sign or is less by a positive even integer. For negative roots apply the rule to $f(-x) = 0$.
- If, for two real numbers a and b , $f(a)$ and $f(b)$ have opposite signs, there is an odd number of roots between a and b .
- If k is the exponent of the first term with a negative coefficient and G the greatest of the absolute values of the negative coefficients, then an upper bound of the real roots is $1 + \sqrt[k]{G/a_0}$.
- Sturm's Theorem.** Let the equation $f(x) = 0$ have no multiple roots. With $f_0 = f(x)$ and $f_1 = f'(x)$, form the sequence $f_0, f_1, f_2, \dots, f_n$ as follows:

$$f_0 = q_1 f_1 - f_2 \quad f_1 = q_2 f_2 - f_3$$

$$f_2 = q_3 f_3 - f_4, \dots, f_{n-2} = q_{n-1} f_{n-1} - f_n$$

At any step, a function f_i may be multiplied by a positive number to avoid fractions. Let a and b be real numbers, $a < b$ such that $f(a) \neq 0, f(b) \neq 0$, and let $V(a)$ be the number of variations of sign in the nonzero members of the sequence $f_0(a), f_1(a), \dots, f_n$. Then the number of real roots between a and b is $V(a) - V(b)$.

If $f(x) = 0$ has multiple roots, the sequence terminates with the function $f_m, m < n$, when $f_{m-1} = q_m f_m$. For this sequence, $V(a) - V(b)$ is the number of distinct real roots between a and b .

Example 25 See the tabulation for Example 25 below.

Tabulation for Example 25

- Locate the real roots of $x^3 - 7x - 7 = 0$.

$x =$	-2	-1	0	1	2	3	4	$3x - \frac{9}{2}$	x	
$f_0 = x^3 - 7x - 7$	-	-	-	-	-	-	+	$2x + 3$	$3x^2 - 7$	$x^3 - 7x - 7$
$f_1 = 3x^2 - 7$	+	-	-	-	+	+	+		$6x^2 - 17$	$3x^3 - 21x - 21$
$f_2 = 2x + 3$	-	+	+	+	+	+	+		$6x^2 + 9x$	$3x^2 - 7x$
$f_3 = 1$	+	+	+	+	+	+	+		$-9x - 14$	$-14x - 21$
$V(x) =$	3	1	1	1	1	1	1		$-9x - \frac{27}{2}$	$2x + 3 = f^2$
									$-\frac{1}{2}$	
									$1 = f_3$	

$$V(-2) - V(-1) = 2$$

$$-2 < r_1 r_2 < -1$$

$$V(3) - V(4) = 1$$

$$3 < r_3 < 4$$

Tabulation for Example 25 (continued)

2. Locate the real roots of $4x^3 - 3x - 1 = 0$.

$x =$	-1	0	1	2	$2x - 1x$		
$f_0 = 4x^3 - 3x - 1$	-	-	0	+	$2x + 1$	$4x^2 - 1$	$4x^3 - 3x - 1$
$f_1 = 3(4x^2 - 1)$	+	-		+		$4x^2 + 2x$	$4x^3 - x$
$f_2 = 2x + 3$	-	+		+		$-2x - 1$	$-2x - 1$
$V(x) =$	2	1	0			$-2x - 1$	$2x - 1 = f_2$

$$V(-1) - V(0) = 2 \quad V(3) - V(4) = 1$$

$$-1 < r_1 < 0 \quad 0 < r_2 < 2$$

Then r_1 can be found to be a double root.

Synthetic Division. To divide a polynomial $f(x)$ by $x - a$, proceed as in Example 25. Divide $f(x) = 4x^3 - 7x + 1$ by $x + 2$. Arrange the coefficients in order of descending powers of x , supplying zeros for missing powers. Place $a (= -2)$ to the left. Bring down the first coefficient, multiply it by a , and add the product to the next coefficient. Multiply the sum by a , add the product to the next coefficient, and continue thus:

$$\begin{array}{r|rrrr}
 -2 & 4 & 0 & -7 & +1 \\
 & -8 & -16 & -18 & \\
 \hline
 & 4 & -8 & +9 & -17
 \end{array}$$

The last number is the remainder. It is the value of the polynomial $f(x) = 4x^3 - 7x + 1$ for $x = -2$, or $f(-2) = -17$. The other numbers in the last line are the coefficients of the quotient $4x^2 - 8x + 9$, a polynomial of one degree less than the dividend.

Rational Roots. Possible integral and fractional roots can be found by property 5 and tested by synthetic division. If a rational root r is found, then the remaining roots are roots of $q(x) \equiv f(x)/(x - r) = 0$.

Irrational Roots.

Horner's Method This consists of diminishing a root repeatedly toward zero and adding together the amounts by which it is diminished. This sum approximates the original root. The method is explained by an example.

A root of $x^3 + 4x - 7 = 0$ is located between the successive integers 1 and 2, graphically or by synthetic division, using property 8. First, the roots are diminished by 1 (property 6c) to give an equation $f(y + 1) \equiv \phi(y) = 0$, which has a root between 0 and 1. The method of obtaining the coefficients of $\phi(y)$ by use of successive synthetic divisions is illustrated. The remainders are the required coefficients. The root between 0 and 1 of $\phi(y) = 0$ is then located between successive tenths. Since its value is small, the last two terms set equal to 0 suffice to estimate that it is between 0.2 and 0.3. Next, diminish the roots by 0.2 to obtain

an equation with a root between 0 and 0.1. To check that the root was between 0.2 and 0.3, note that the first remainder, which is the value of $\phi(0.2)$, remains negative when $\phi(y)$ is divided by $y - 0.2$, and that the remainder would be found to be positive if $\phi(y)$ were divided by $y - 0.3$. Repeat the process, using the last two terms to estimate that the root of the new equation is between 0.05 and 0.06, and then diminish by 0.05. At the next stage it is frequently possible to estimate two more figures by using the last two terms.

$$\begin{array}{r|rrrr}
 1+0 & +4 & - & 7 & |1 \\
 +1 & +1 & + & 5 & \\
 \hline
 1+1 & +5 & - & 2 & \\
 +1 & +2 & & & \\
 \hline
 1+2 & +7 & & & \\
 +1 & & & & \\
 \hline
 1+3 & + & 7 & - & 2 & |0.2 \\
 +0.2 & + & 0.64 & + & 1.528 & \\
 \hline
 1+3.2 & + & 7.64 & - & 0.472 & \\
 +0.2 & + & 0.68 & - & & \\
 \hline
 1+3.4 & + & 8.32 & & & \\
 +0.2 & & & & & \\
 \hline
 1+3.6 & + & 8.32 & - & 0.472 & |0.05 \\
 +0.05 & + & 0.1825 & + & 0.425125 & \\
 \hline
 1+3.65 & + & 8.5025 & - & 0.046875 & \\
 +0.05 & + & 0.185 & & & \\
 \hline
 1+3.70 & + & 8.6875 & & & \\
 +0.05 & & & & & \\
 \hline
 1+3.75 & & & & &
 \end{array}$$

$$8.6875x - 0.046875 = 0$$

$$x = 0.0054$$

The root is 1.2554.

To find a *negative* irrational root $-r$ by Horner's method, replace x in $f(x) = 0$ by $-y$, find the positive root r of $\phi(y) = f(-y) = 0$, and change its sign.

Newton's Method This can be used to find a root of either an algebraic or a transcendental equation. The

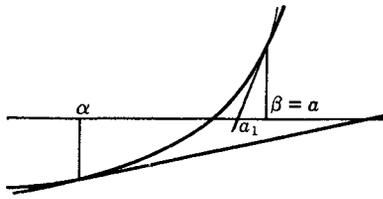

Fig. 1

root is first located graphically between α and β , $f(\alpha)$ and $f(\beta)$ having unlike signs (Fig. 1). Assume that there is no maximum, minimum, or inflection point in the interval (α, β) , that is, that neither $f'(x)$ nor $f''(x)$ equals zero for any point in (α, β) . Take as a first approximation a the endpoint α or β for which $f(x)$ and $f''(x)$ have the same sign, that is, if the curve is concave up, take the endpoint at which $f(x)$ is positive, and, if concave down, the endpoint at which $f(x)$ is negative. The point $a_1 = a - f(a)/f'(a)$, at which the tangent to the curve at $[a, f(a)]$ intersects the x axis, is between a and the root. Then, by using a_1 instead of a , a still better approximation a_2 is obtained, and so forth. If the endpoint for which $f(x)$ and $f''(x)$ have opposite signs were used, it could happen that the approximation obtained would be better than a_1 , but it might be much worse since the tangent would not cross the x axis between the endpoint used and the root (Fig. 1).

Example 26 Find the real root of $x^3 + 4x - 7 = 0$.

$$f(x) = x^3 + 4x - 7$$

$$f'(x) = 3x^2 + 4$$

$$f''(x) = 6x$$

Graphically (Fig. 2), $\alpha = 1.2$, $\beta = 1.3$. Since $f(1.2) = -0.472$ and $f(1.3) = 0.397$, and $f''(x)$ is positive in the interval, then $a = 1.3$.

$$a_1 = a - \frac{f(a)}{f'(a)} = 1.3 - \frac{0.397}{9.07} = 1.3 - 0.044 = 1.256$$

$$a_2 = 1.256 - \frac{0.005385}{8.7326} = 1.256 - 0.00062 = 1.25538$$

If Newton's method of using the tangent is not applicable, either because of the presence of a maximum, minimum, or inflection point or because of difficulty in finding $f'(x)$, the interpolation method using the chord joining $[\alpha, f(\alpha)]$ and $[\beta, f(\beta)]$ can be used. The chord crosses the x axis at $a = \alpha - f(\alpha)(\beta - \alpha)/[f(\beta) - f(\alpha)]$, a better approximation than either α or β . Note that this formula differs from Newton's only in having the difference quotient, which is the slope of the chord, in place of the derivative, which is the slope of the tangent. To get a still better approximation, repeat the procedure, using as one endpoint a

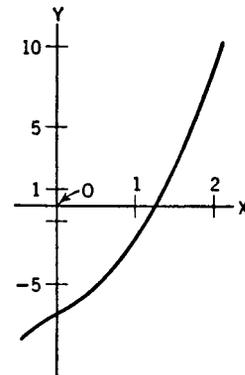

Fig. 2

and as the other either α or β , chosen so that $f(x)$ has opposite signs at the endpoints of the new interval.

Graphical Method of Solution This can be used to solve any kind of equation if it gives sufficient accuracy. To solve the equation $f(x) = 0$, graph the function $y = f(x)$. The x coordinates of the points at which the graph intersects the x axis are roots of $f(x) = 0$. Another method is to set $f(x)$ equal to any convenient difference $f_1(x) - f_2(x)$ and graph the functions $y = f_1(x)$ and $y = f_2(x)$ on the same axes. The x coordinates of the points of intersection of the two graphs are real roots of $f(x) = 0$. Also, see section 2.12.

Graeffe's Method for Real and Complex Roots

Let x_1, x_2, \dots, x_n be the roots of the equation $a_0x^n + a_1x^{n-1} + \dots + a_n = 0$, arranged in descending order of absolute values. Form a sequence of equations such that the roots of each are the negatives of the squares of the roots of the preceding equation. Using the negatives of the squares gives more uniform formulas.

Let A_i be a coefficient of the equation being formed, and a_i a coefficient of the preceding equation:

$$A_0 = a_0 = 1$$

$$A_1 = a_1^2 - 2a_0a_2 = a_1^2 - 2a_2$$

$$A_2 = a_2^2 - 2a_1a_3 + 2a_4$$

$$A_3 = a_3^2 - 2a_2a_4 + 2a_1a_5 - 2a_6$$

⋮

$$A_{n-1} = a_{n-1}^2 - 2a_{n-2}a_n$$

$$A_n = a_n^2$$

Each coefficient is the sum of the square of the preceding and twice the product of all pairs of equidistant coefficient in the preceding equation, taken with alternately minus and plus signs. Missing coefficient

are zero. The process is ended when further steps do not affect the nonfluctuating coefficients to the accuracy desired in the roots.

As the successive equations are formed, various cases arise depending on the behavior of the coefficients. Among them are:

CASE 1: Each coefficient approaches the square of the preceding. The roots are real and unequal in absolute value. Let A_i be a coefficient of the equation whose roots are $-x_1^p, -x_2^p, \dots, -x_n^p$. Then, approximately, $x_1 = \pm \sqrt[p]{A_1}, x_2 = \pm \sqrt[p]{A_2/A_1}, \dots, x_n = \pm \sqrt[p]{A_n/A_{n-1}}$. The signs of the roots are determined by substitution in the original equation. It is usually sufficient to find successive integers between which a root is located.

Example 27 $f(x) = x^3 - 2x^2 - 5x + 4 = 0$. See the tabulation for Example 27 below.

Using synthetic substitution,

$$\begin{array}{r|rrrr} 3 & 1 & -2 & -5 & +4 \\ & & +3 & +3 & -6 \\ \hline & 1 & +1 & -2 & -2 \end{array} \quad \begin{array}{r|rrrr} 4 & 1 & -2 & -5 & +4 \\ & & +4 & +8 & +12 \\ \hline & 1 & +2 & -3 & -16 \end{array}$$

we have $f(3) = -2, f(4) = 16$. Therefore there is a root between 3 and 4, and $x_1 = 3.177$.

$$\begin{aligned} \log x_2 &= \frac{1}{16} (\log 2.136 \times 10^{12} - \log 1.080 \times 10^8) \\ &= \frac{1}{16} (12.3296 - 8.0334) \end{aligned}$$

$$= \frac{1}{16} \times 4.2962 = 0.2685$$

$$x_2 = \pm 1.856$$

Using synthetic substitution, $f(-2) = -2, f(-1) = 6$. Therefore $x_2 = -1.856$.

$$\begin{aligned} \log x_3 &= \frac{1}{16} (\log 4.295 \times 10^9 - \log 2.136 \times 10^{12}) \\ &= \frac{1}{16} (9.6330 - 12.3296) \\ &= \frac{1}{16} (157.3034 - 160) = 9.8315 - 10 \\ x_3 &= \pm 0.678 \end{aligned}$$

Since $x_1 + x_2 + x_3 = 2, x_3 = 0.678$.

CASE 2: A coefficient fluctuates in sign. There is a pair of complex roots. If the sign of A_i fluctuates then $x_i = u + iv$ and $x_{i+1} = u - iv$ are complex. Let $r^2 = u^2 + v^2$. Then $r^2 = \sqrt[p]{A_{i+1}/A_{i-1}}, 2u = -a_1 - (\text{sum of real roots}), v = \sqrt{r^2 - u^2}$.

Example 28 $f(x) = x^4 - 2x^3 - 4x^2 + 5x - 7 = 0$. See the tabulation for Example 28 on next page.

If, for a fourth-degree equation, alternate coefficients, that is, the second and fourth, fluctuate in sign, all four roots are complex. Let the roots be $u_1 \pm iv_1, u_2 \pm iv_2$. Then $r_1^2 = \sqrt[p]{A_2}, r_2^2 = \sqrt[p]{A_4/A_2}, 2(u_1 + u_2) = -a_1, 2(r_2^2 u_1 + r_1^2 u_2) = -a_3$.

Tabulation for Example 27

	x^3	x^2	x	x^0
1st	1	-2	-5	4
	1	4	25	16
		10	16

	1	1.0000×10^4	1.758×10^6	1.428×10^6	5.765×10^6
		-0.2652×10^4	0.239×10^6	-6.367×10^6	
			0.005×10^6		
8th	1	7.348×10^3	2.002×10^6	-4.939×10^6	5.765×10^6
	1	5.399×10^7	4.008×10^{12}	2.439×10^{13}	3.324×10^{13}
		-0.400×10^7	0.073×10^{12}	-2.308×10^{13}	
16th	1	4.999×10^7	4.081×10^{12}	1.31×10^{12}	3.324×10^{13}
	1	2.499×10^{15}	1.665×10^{25}	0.017×10^{26}	1.105×10^{27}
		-0.001×10^{15}		-2.713×10^{26}	
32nd	1	2.498×10^{15}	1.665×10^{25}	-2.696×10^{26}	1.105×10^{27}

Since the sign of A_3 fluctuates x_3 and x_4 are complex.

$$x_1 = \pm \sqrt[32]{2.498 \times 10^{15}} = \pm 3.028$$

$$\frac{\log(2.498 \times 10^{15})}{32} = \frac{15.3976}{32} = 0.4812$$

$$f(3) = - \quad f(4) = +$$

$$x_1 = 3.028$$

$$x_2 = \pm \sqrt[32]{\frac{1.665 \times 10^{25}}{2.498 \times 10^{15}}} = \pm 2.028$$

$$f(-3) = + \quad f(-2) = -$$

$$\frac{25.2214}{15.3976} = 1.640$$

$$\frac{9.8238}{32} = 0.3070$$

$$x_2 = -2.028$$

$$r^2 = \sqrt[32]{\frac{1.105 \times 10^{27}}{1.665 \times 10^{25}}} = 1.140$$

$$u = \frac{2 - (3.028 - 2.028)}{2} = 0.500$$

$$\frac{27.0434}{25.2214} = 1.072$$

$$\frac{1.8220}{32} = 0.05694$$

$$v = \sqrt{1.140 - 0.250} = \sqrt{0.890} = 0.943$$

$$x_3, x_4 = 0.5 \pm 0.943i$$

Tabulation for Example 29

	x^4	x^3	x^2	x	x^0
1st	1	-3	-1	4	14
	1	9	1	16	196
		2	24	28	
			28		
2nd	1	11	53	44	196
	1	121	2809	1936	38416
		-106	-968	-20776	
		392			
4th	1	15	2.233×10^3	-1.884×10^4	3.842×10^4
	1	0.225×10^3	4.986×10^6	3.549×10^8	1.476×10^9
		-4.466×10^3	0.565×10^6	-1.716×10^8	
		0.077×10^6			
8th	1	-4.241×10^3	5.628×10^6	1.833×10^8	1.476×10^9
	1	1.799×10^7	3.1674×10^{13}	3.360×10^{16}	2.178×10^{18}
		-1.126×10^7	0.1555×10^{13}	-1.661×10^{16}	
		0.0003×10^{13}			
16th	1	0.675×10^7	3.323×10^{13}	1.699×10^{16}	2.178×10^{18}

Since A_1 and A_3 fluctuate in sign, there are four complex roots.

$$r_1^2 = \sqrt[16]{3.323 \times 10^{13}} = 7.000$$

$$\frac{\log(3.323 \times 10^{13})}{16} = \frac{13.5215}{16} = 0.8451$$

$$r_2^2 = \sqrt[16]{\frac{2.178 \times 10^{18}}{3.323 \times 10^{13}}} = 2.000$$

$$\frac{18.3380}{16} = 1.1461$$

$$\frac{13.5215}{4.8165} = 2.8075$$

$$2(u_1 + u_2) = 3$$

$$2(2u_1 + 7u_2) = -4$$

$$u_2 = -1 \quad u_1 = 2.5$$

$$v_2 = \sqrt{r_2^2 - u_2^2} = \sqrt{2 - 1} = 1$$

$$v_1 = \sqrt{r_1^2 - u_1^2} = \sqrt{7 - 6.25} = \sqrt{0.75} = 0.866$$

$$x_1, x_2 = 2.5 \pm 0.866i$$

$$x_3, x_4 = -1 \pm i$$

Example 29 $f(x) = x^4 - 3x^3 - x^2 + 4x + 14 = 0$.
See the tabulation for Example 29 above.

value. If A_i approaches one-half the square of the preceding coefficient, then $|x_i| = |x_{i+1}| = \sqrt[2p]{A_{i+1}/A_{i-1}}$.

CASE 3: A coefficient approaches one-half the square of the preceding. There is a double real root or there are two real roots of equal absolute

Example 30 $f(x) = x^3 + 2.20x^2 - 2.95x + 0.80 = 0$.
See the tabulation for Example 30 below.

Tabulation for Example 30

	x^3	x^2	x	x^0
1st	1	2.20	-2.95	0.80
	1	4.84	8.703	0.64
		5.90	-3.52	
2nd	1	10.74	5.183	0.64

	1	1.1025×10^4	1.719×10^2	0.1678
		-0.0026×10^4	-0.860×10^2	
8th	1	1.100×10^4	0.859×10^2	0.1678

Tabulation for Example 30

Since A_2 approaches one-half the square of the preceding coefficient, $|x_2| = |x_3|$.

$$\begin{array}{rcl}
 x_1 = \pm \sqrt[8]{1.100 \times 10^4} = \pm 3.20 & f(-4) = - & f(-3) = + \\
 \frac{\log(1.100 \times 10^4)}{8} = \frac{4.0414}{8} = 0.5052 & f(0.5) = 0 & f(-0.5) \neq 0 \\
 |x_2| = |x_3| = \sqrt[16]{\frac{0.1678}{1.100 \times 10^4}} = 0.50 & x_1 = -3.20 & \\
 \frac{9.2248 - 10}{4.0414} = \frac{155.1834 - 160}{16} = 9.6990 - 10 & x_2 = x_3 = 0.50 &
 \end{array}$$

For a more extensive treatment of Graeffe’s method, see mathworld.wolfram.com/GraeffesMethod.html (August 2008) and math.fullerton.edu/mathews/n2003/GraeffesMethodMod/html (August 2008).

2.11 Matrices and Determinants

Definitions

1. A *matrix* is a system of mn quantities, called *elements*, arranged in a rectangular array of m rows and n columns:

$$A = \begin{pmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} & \cdots & a_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ a_{m1} & a_{m2} & \cdots & a_{mn} \end{pmatrix} = \left\| \begin{array}{cccc} a_{11} & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} & \cdots & a_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ a_{m1} & a_{m2} & \cdots & a_{mn} \end{array} \right\|$$

$$= (a_{ij}) = \|a_{ij}\|$$

$$i = 1, \dots, m \quad j = 1, \dots, n$$

2. If $m = n$, then A is a *square matrix* of *order* n .

3. Two matrices are *equal* if and *only if* they have the same number of rows and of columns and corresponding elements are equal.

4. Two matrices are *transposes* (sometimes called *conjugates*) of each other if either is obtained from the other by interchanging rows and columns.

5. The *complex conjugate* of a matrix (a_{ij}) with complex elements is the matrix (\bar{a}_{ij}) . See Section 13.1.

6. A matrix is *symmetric* if it is equal to its transpose, that is, if $a_{ij} = a_{ji}$, $i, j = 1, \dots, n$.

7. A matrix is *skew symmetric*, or *antisymmetric*, if $a_{ij} = -a_{ji}$, $i, j = 1, \dots, n$. The diagonal elements $a_{ii} = 0$.

8. A matrix all of whose elements are zero is a *zero matrix*.

9. If the nondiagonal elements $a_{ij}, i \neq j$, of a square matrix A are all zero, then A is a *diagonal matrix*. If, furthermore, the diagonal elements are all equal, the matrix is a *scalar matrix*; if they are all 1, it is an *identity* or *unit matrix*, denoted by I .

10. The *determinant* $|A|$ of a square matrix (a_{ij}) , $i, j = 1, \dots, n$, is the sum of the $n!$ products $a_{1r_1} a_{2r_2} \cdots a_{nr_n}$, in which r_1, r_2, \dots, r_n is a permutation of $1, 2, \dots, n$, and the sign of each product is plus or minus according as the permutation is obtained from $1, 2, \dots, n$ by an even or an odd number of interchanges of two numbers.

Symbols used are

$$|A| = \begin{vmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} & \cdots & a_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ a_{n1} & a_{n2} & \cdots & a_{nn} \end{vmatrix} = |a_{ij}| \quad i, j = 1, \dots, n$$

11. A square matrix (a_{ij}) is *singular* if its determinant $|a_{ij}|$ is zero.

12. The determinants of the square submatrices of any matrix A , obtained by striking out certain rows or columns or both, are called the *determinants* or *minors* of A . A matrix is of *rank* r if it has at least one r -rowed determinant that is not zero while all its determinants of order higher than r are zero. The *nullity* d of a square matrix of order n is $d = n - r$. The zero matrix is of rank 0.

13. The minor D_{ij} of the element a_{ij} of a square matrix is the determinant of the submatrix obtained by striking out the row and column in which a_{ij} lies. The *cofactor* A_{ij} of the element a_{ij} is $(-1)^{i+j} D_{ij}$. A *principal minor* is the minor obtained by striking out the same rows as columns.

14. The *inverse* of the square matrix A is

$$A^{-1} = \begin{pmatrix} \frac{A_{11}}{|A|} & \cdots & \frac{A_{n1}}{|A|} \\ \vdots & \ddots & \vdots \\ \frac{A_{1n}}{|A|} & \cdots & \frac{A_{nn}}{|A|} \end{pmatrix}$$

$$AA^{-1} = A^{-A} = I$$

15. The *adjoint* of A is

$$\text{adj } A = \begin{pmatrix} A_{11} & \cdots & A_{n1} \\ \vdots & \ddots & \vdots \\ A_{1n} & \cdots & A_{nn} \end{pmatrix}$$

16. *Elementary transformations* of a matrix are:

- The interchange of two rows or of two columns
- The addition to the elements of a row (or column) of any constant multiple of the corresponding elements of another row (or column)
- The multiplication of each element of a row (or column) by any nonzero constant

17. Two $m \times n$ matrices A and B are *equivalent* if it is possible to pass from one to the other by a finite number of elementary transformations.

- The matrices A and B are equivalent if and only if there exist two nonsingular square matrices E and F , having m and n rows, respectively, such that $EAF = B$.
- The matrices A and B are equivalent if and only if they have the same rank.

Matrix Operations

Addition and Subtraction. The sum or difference of two matrices (a_{ij}) and (b_{ij}) is the matrix $(a_{ij} \pm b_{ij})$, $i = 1, \dots, m$, $j = 1, \dots, n$.

Scalar Multiplication. The product of the scalar k and the matrix (a_{ij}) is the matrix (ka_{ij}) .

Matrix Multiplication. The product (p_{ik}) , $i = 1, \dots, m$, $k = 1, \dots, q$, of two matrices (a_{ij}) , $i = 1, \dots, m$, $j = 1, \dots, n$, and (b_{jk}) , $j = 1, \dots, n$, $k = 1, \dots, q$, is the matrix whose elements are

$$p_{ik} = \sum_{j=1}^n a_{ij}b_{jk} = a_{i1}b_{1k} + a_{i2}b_{2k} + \cdots + a_{in}b_{nk}$$

The element in the i th row and k th column of the product is the sum of the n products of the n elements of the i th row of (a_{ij}) by the corresponding n elements of the k th column of (b_{jk}) .

Example 31

$$\begin{pmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{pmatrix} \begin{pmatrix} b_{11} & b_{12} & b_{13} \\ b_{21} & b_{22} & b_{23} \end{pmatrix} \\ = \begin{pmatrix} a_{11}b_{11} + a_{12}b_{21} & a_{11}b_{12} + a_{12}b_{22} & a_{11}b_{13} + a_{12}b_{23} \\ a_{21}b_{11} + a_{22}b_{21} & a_{21}b_{12} + a_{22}b_{22} & a_{21}b_{13} + a_{22}b_{23} \end{pmatrix}$$

All the laws of ordinary algebra hold for the addition and subtraction of matrices and for scalar multiplication.

Multiplication of matrices is not in general commutative, but it is associative and distributive.

If the product of two or more matrices is zero, it does not follow that one of the factors is zero. The factors are *divisors of zero*.

Example 32

$$\begin{pmatrix} a & 0 \\ b & 0 \end{pmatrix} \begin{pmatrix} 0 & 0 \\ c & d \end{pmatrix} = \begin{pmatrix} 0 & 0 \\ 0 & 0 \end{pmatrix}$$

Linear Dependence

1. The quantities l_1, l_2, \dots, l_n are *linearly dependent* if there exist constants c_1, c_2, \dots, c_n , not all zero, such that

$$c_1l_1 + c_2l_2 + \cdots + c_nl_n = 0$$

If no such constants exist, the quantities are *linearly independent*.

2. The linear functions

$$l_i = a_{i1}x_1 + a_{i2}x_2 + \cdots + a_{in}x_n \quad i = 1, 2, \dots, m$$

are linearly dependent if and only if the matrix of the coefficient is of rank $r < m$. Exactly r of the l_i form a linearly independent set.

3. For $m > n$, any set of m linear functions are linearly dependent.

Consistency of Equations

1. The system of homogeneous linear equations

$$a_{i1}x_1 + a_{i2}x_2 + \cdots + a_{in}x_n = 0 \quad i = 1, 2, \dots, m$$

has solutions not all zero if the rank r of the matrix (a_{ij}) is less than n .

If $m < n$, there always exist solutions not all zero. If $m = n$, there exist solutions not all zero if $|a_{ij}| \neq 0$.

If r of the equations are so selected that their matrix is of rank r , they determine uniquely r of the variables as homogeneous linear functions of the remaining $n - r$ variables. A solution of the system is obtained by assigning arbitrary values to the $n - r$ variables and finding the corresponding values of the r variables.

2. The system of linear equations

$$a_{i1}x_1 + a_{i2}x_2 + \cdots + a_{in}x_n = k_i \quad i = 1, 2, \dots, m$$

is consistent if and only if the *augmented* matrix derived from (a_{ij}) by annexing the column k_1, \dots, k_m has the same rank r as (a_{ij}) .

As in the case of a system of homogeneous linear equations, r of the variables can be expressed in terms of the remaining $n - r$ variables.

Linear Transformations

1. If a linear transformation

$$x'_i = a_{i1}x_1 + a_{i2}x_2 + \dots + a_{in}x_n \quad i = 1, 2, \dots, n$$

with matrix (a_{ij}) transforms the variables x_i into the variables x'_i and a linear transformation

$$x''_i = b'_{i1}x_1 + b'_{i2}x_2 + \dots + b'_{in}x_n \quad i = 1, 2, \dots, n$$

with matrix (b_{ij}) transforms the variables x'_i into the variables x''_i , then the linear transformation with matrix $(b_{ij})(a_{ij})$ transforms the variables x_i into the variables x''_i directly.

2. A real *orthogonal* transformation is a linear transformation of the variables x_i into the variables x'_i such that

$$\sum_{i=1}^n x_i^2 = \sum_{i=1}^n x'^2_i$$

A transformation is orthogonal if and only if the transpose of its matrix is the inverse of its matrix.

3. A *unitary* transformation is a linear transformation of the variables x_i into the variables x'_i such that

$$\sum_{i=1}^n x_i \bar{x}_i = \sum_{i=1}^n x'_i \bar{x}'_i$$

A transformation is unitary if and only if the transpose of the conjugate of its matrix is the inverse of its matrix.

Quadratic Forms A *quadratic form* in n variables is

$$\sum_{i,j=1}^n a_{ij}x_i x_j = a_{11}x_1^2 + a_{12}x_1 x_2 + \dots + a_{1n}x_1 x_n$$

$$+ a_{21}x_2 x_1 + a_{22}x_2^2 + \dots + a_{2n}x_2 x_n + a_{n1}x_n x_1 + a_{n2}x_n x_2 + \dots + a_{nn}x_n^2$$

in which $a_{ji} = a_{ij}$. The symmetric matrix (a_{ij}) of the coefficients is the matrix of the quadratic form and the rank of (a_{ij}) is the rank of the quadratic form.

A real quadratic form of rank r can be reduced by a real nonsingular linear transformation to the *normal form*

$$x_1^2 + \dots + x_p^2 - x_{p+1}^2 - \dots - x_r^2$$

in which the *index* p is uniquely determined.

If $p = r$, a quadratic form is *positive*, and if $p = 0$, it is *negative*. If, furthermore, $r = n$, both are *definite*. A quadratic form is positive definite if and only if the determinant and all the principal minors of its matrix are positive.

A method of reducing a quadratic form to its normal form is illustrated.

Example 33 See the tabulation for Example 33 below.

The transformation

$$x' = 3x + 2y - z \quad y' = -\frac{16}{3}y + \frac{8}{3}z \quad z' = z$$

reduces q to $\frac{1}{3}x'^2 - \frac{3}{16}y'^2$.

The transformation

$$x'' = \sqrt{3}x' \quad y'' = \frac{4}{\sqrt{3}}y' \quad z'' = z'$$

further reduces q to the normal form $x''^2 - y''^2$ of rank 2 and index 1.

Expressing x, y, z in terms of x'', y'', z'' , the real nonsingular linear transformation that reduces q to the normal form is

Tabulation for Example 33

$$q = 3x^2 - 4y^2 - z^2 + 4xy - 2xz + 4yz$$

$$q = \left\{ \begin{array}{l} 3x^2 + 2xy - xz \\ +2xy - 4y^2 + 2yz \\ -xz + 2yz - z^2 \end{array} \right\} = \frac{1}{3}(3x + 2y - z)^2 + q_1, \text{ in which the quantity in parentheses is obtained by factoring } x \text{ out of the first row}$$

$$= \frac{1}{3}(9x^2 + 4y^2 + z^2 + 12xy - 6xz - 4yz) + q_1$$

$$q_1 = -\frac{4}{3}y_1^2 - \frac{1}{3}z^2 + \frac{4}{3}yz - 4y^2 + 4yz - z^2$$

$$= \left\{ \begin{array}{l} -\frac{16}{3}y^2 + \frac{8}{3}yz \\ +\frac{8}{3}yz - \frac{4}{3}z^2 \end{array} \right\} = -\frac{3}{16}\left(-\frac{16}{3}y + \frac{8}{3}z\right)^2 + q_2$$

$$q_2 = 0$$

$$x = \frac{\sqrt{3}}{3}x'' + \frac{1}{2\sqrt{3}}y''$$

$$y = -\frac{\sqrt{3}}{4}y'' + \frac{1}{2}z''$$

$$z = z''$$

Hermitian Forms A *Hermitian form* in n variables is

$$\sum_{i,j=1}^n a_{ij}x_i\bar{x}_j \quad a_{ji} = \bar{a}_{ij}$$

The matrix (a_{ij}) is a *Hermitian matrix*. Its transpose is equal to its conjugate. The rank of (a_{ij}) is the rank of the Hermitian form.

A Hermitian form of rank r can be reduced by a nonsingular linear transformation to the normal form

$$x_1\bar{x}_1 + \dots + x_p\bar{x}_p - x_{p+1}\bar{x}_{p+1} - \dots - x_r\bar{x}_r$$

in which the index p is uniquely determined.

If $p = r$, the Hermitian form is positive, and, if $p = 0$, it is negative. If, furthermore, $r = n$, both are definit

Determinants Second- and third-order determinants are formed from their square symbols by taking diagonal products, down from left to right being positive and up negative:

$$\begin{vmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{vmatrix} = a_{11}a_{22} - a_{21}a_{12}$$

$$\begin{vmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{vmatrix} = a_{11}a_{22}a_{33} + a_{12}a_{23}a_{31} + a_{13}a_{32}a_{21} - a_{31}a_{22}a_{13} - a_{32}a_{23}a_{11} - a_{33}a_{12}a_{21}$$

Third- and higher order determinants are formed by selecting any row or column and taking the sum of the products of each element and its cofactor. This process is continued until second- or third-order cofactors are reached:

$$\begin{vmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{vmatrix} = a_{11} \begin{vmatrix} a_{22} & a_{23} \\ a_{32} & a_{33} \end{vmatrix} - a_{21} \begin{vmatrix} a_{12} & a_{13} \\ a_{32} & a_{33} \end{vmatrix} + a_{31} \begin{vmatrix} a_{12} & a_{13} \\ a_{22} & a_{23} \end{vmatrix}$$

The determinant of a matrix A is:

1. Zero if two rows or two columns of A have proportional elements
2. Unchanged if:
 - a. The rows and columns of A are interchanged
 - b. To each element of a row or column of A is added a constant multiple of the corresponding element of another row or column
3. Changed in sign if two rows or two columns of A are interchanged
4. Multiplied by c if each element of any row or column of A is multiplied by c
5. The sum of the determinants of two matrices B and C if A , B , and C have all the same elements except that in one row or column each element of A is the sum of the corresponding elements of B and C

Example 34 See the tabulation for Example 34 below.

Tabulation for Example 34

$$\begin{vmatrix} 2 & 9 & 9 & 4 \\ 2 & -3 & 12 & 8 \\ 4 & 8 & 3 & -5 \\ 1 & 2 & 6 & 4 \end{vmatrix} = \begin{vmatrix} 2 & 5 & 9 & 4 \\ 2 & -7 & 12 & 8 \\ 4 & 0 & 3 & -5 \\ 1 & 0 & 6 & 4 \end{vmatrix} = 3 \begin{vmatrix} 2 & 5 & 3 & 4 \\ 2 & -7 & 4 & 8 \\ 4 & 0 & 1 & -5 \\ 1 & 0 & 2 & 4 \end{vmatrix}$$

Multiply 1st column by -2 and add to 2nd

Factor 3 out of 3rd column

$$= 3 \times (-5) \begin{vmatrix} 2 & 4 & 8 \\ 4 & 1 & -5 \\ 1 & 2 & 4 \end{vmatrix} + 3 \times (-7) \begin{vmatrix} 2 & 3 & 4 \\ 4 & 1 & -5 \\ 1 & 2 & 4 \end{vmatrix} = 0 \quad -21 \begin{vmatrix} 1 & 1 & 0 \\ 4 & 1 & -5 \\ 1 & 2 & 4 \end{vmatrix}$$

Expand according to 2nd column

1st and 3rd rows are proportional

Subtract 3rd row from 1st

$$= -21 \begin{vmatrix} 1 & -5 \\ 2 & 4 \end{vmatrix} - (-21) \begin{vmatrix} 4 & -5 \\ 1 & 4 \end{vmatrix} = -21[(4 + 10) - (16 + 5)] = +147$$

Expand according to 1st row

2.12 Systems of Equations

Linear Systems (also see Section 11.6)

Homogeneous. $a_{i1}x_1 + \dots + a_{in}x_n = 0, i = 1, \dots, m$. Let $r = \text{rank of } (a_{ij})$.

For $m = n$:

$r = n, |a_{ij}| \neq 0$; one solution, $x_1 = \dots = x_n = 0$.

$r < n, |a_{ij}| = 0$; infinit number of solutions.

Nonhomogeneous. $a_{i1}x_1 + \dots + a_{in}x_n = k_i, i = 1, \dots, m$.

Let $a = (a_{ij})$, an $m \times n$ matrix.

$$k = \text{augmented matrix} = \begin{pmatrix} a_{11} & \dots & a_{1n} & k_1 \\ \vdots & \ddots & \vdots & \vdots \\ a_{m1} & \dots & a_{mn} & k_m \end{pmatrix},$$

an $m \times (n + 1)$ matrix.

$r_a = \text{rank of } a$.

$r_k = \text{rank of } k$.

For $m = n$:

$r_a = r_k$; consistent.

(a) $r_a = r_k = n, |a_{ij}| \neq 0$; independent. One solution.

(b) $r_a = r_k < n, |a_{ij}| = 0$; dependent. Infinit number of solutions.

$r_a < r_k$; inconsistent. No solution.

Methods of Solution *Elimination* is a practical method of solution for a system of two or three linear equations in as many variables.

Example 35

1. By addition and subtraction, solve

$$2x + y + 3z = 9 \quad (2)$$

$$x - 2y + z = -2 \quad (3)$$

$$3x + 2y + 2z = 7 \quad (4)$$

$$(3) + (4) \quad \text{gives} \quad 4x + 3z = 5 \quad (5)$$

$$2 \times (2) + (3) \quad \text{gives} \quad 5x + 7z = 16 \quad (6)$$

$$5 \times (5) - 4 \times (6) \quad \text{gives} \quad -13z = -39 \quad \text{or}$$

$$z = 3$$

Putting $z = 3$ in (5) or (6) gives $x = -1$. Then from (2), (3), or (4), $y = 2$.

2. By substitution, solve

$$\begin{cases} x + 2y - z = 5 & (7) \\ x - y = 2 & (8) \\ 2x + z = 1 & (9) \end{cases}$$

From (8), $y = x - 2$, and from (9), $z = -2x + 1$. Substituting for y and z in (7), $x - 2x - 4 + 2x - 1 = 5$, from which $x = 2$. Then $y = 2 - 2 = 0, z = -4 + 1 = -3$.

Determinants can be used to solve a system of n nonhomogeneous linear equations in n variables for which $|a_{ij}| \neq 0$. To solve for x_j , form a fraction the denominator of which is the determinant $|a_{ij}|$ and the numerator the determinant obtained from $|a_{ij}|$ by replacing its j th column by the constants k_i .

Example 36 Solve

$$2x + y + 3z = 9$$

$$x - 2y + z = -2$$

$$3x + 2y + 2z = 7$$

$$x = \frac{\begin{vmatrix} 9 & 1 & 3 \\ -2 & -2 & 1 \\ 7 & 2 & 2 \end{vmatrix}}{\begin{vmatrix} 2 & 1 & 3 \\ 1 & -2 & 1 \\ 3 & 2 & 2 \end{vmatrix}} = \frac{\begin{vmatrix} 9 & 1 & 3 \\ -2 & -2 & 1 \\ 5 & 0 & 3 \end{vmatrix}}{\begin{vmatrix} 2 & 1 & 3 \\ 1 & -2 & 1 \\ 4 & 0 & 3 \end{vmatrix}} = \frac{\begin{vmatrix} 9 & 1 & 3 \\ 16 & 0 & 7 \\ 5 & 0 & 3 \end{vmatrix}}{\begin{vmatrix} 2 & 1 & 3 \\ 5 & 0 & 7 \\ 4 & 0 & 3 \end{vmatrix}} = \frac{-48 - 35}{-15 - 28} = -1$$

Miscellaneous Systems To be solvable a system of equations must have as many independent equations as variables. A system of two polynomial equations of degrees m and n has mn solutions, real or complex. For systems in general no statement can be made regarding the number of solutions.

Graphical Method of Solution. This is a general method for systems of two equations in two variables. It consists of graphing both equations on the same axes and reading the pairs of coordinates of the points of intersection of the graphs as solutions of the system. This method gives real solutions only.

Example 37 Solve

$$y = \sin x \quad x^2 + y^2 = 2$$

Solution from the graph (Fig. 3) gives $x = 1.1, y = 0.9$. From symmetry, $x = -1.1, y = -0.9$, is also a solution.

Method of Elimination of Variables. This is a general method that can be applied to systems composed of any kinds of equations, algebraic or transcendental. However, except in fairly simple cases, practical diffculties are frequently encountered.

Example 38 Solve

$$y = \sin x \quad x^2 + y^2 = 2$$

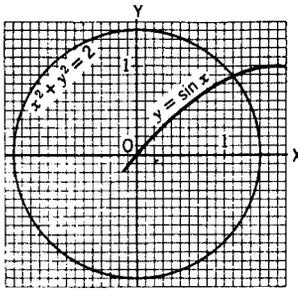

Fig. 3

Squaring both sides of the first equation and subtracting it from the second to eliminate y , $x^2 = 2 - \sin^2 x$. This equation can be solved by Newton's method. Extraneous solutions introduced by squaring can be eliminated by reference to the graph.

There are numerous devices for eliminating variables in special systems. For example, to solve the system of *two general quadratics*

$$a_1x^2 + b_1xy + c_1y^2 + d_1x + e_1y + f_1 = 0 \quad (10)$$

$$a_2x^2 + b_2xy + c_2y^2 + d_2x + e_2y + f_2 = 0 \quad (11)$$

eliminate x^2 by multiplying (10) by a_2 and (11) by a_1 and subtracting, solve the resulting equation for x , substitute this expression in either of the given equations, and clear fractions. The resulting fourth-degree equation in y can be solved by Horner's method. In a similar manner y could have been eliminated instead of x .

2.13 Permutations and Combinations

Fundamental Principle. If in a sequence of s events the first event can occur in n_1 ways, the second in n_2 , ..., the s th in n_s , then the number of different ways in which the sequence can occur is $n_1n_2 \dots n_s$.

A *permutation* of n objects taken r at a time is an arrangement of any r objects selected from the n objects. The number of permutations of n objects taken r at a time is

$${}_n P_r = n(n-1)(n-2) \dots (n-r+1) = \frac{n!}{(n-r)!}$$

In particular, ${}_n P_1 = n$, ${}_n P_n = n!$. Cyclic permutations are

$${}_n P_r^c = \frac{n!}{r(n-r)!} \quad {}_n P_n^c = (n-1)!$$

If the n objects are divided into s sets each containing n_i objects that are alike, the distinguishable permutations are

$$n = n_1 + n_2 + \dots + n_s \quad {}_n P_n = \frac{n!}{n_1!n_2! \dots n_s!}$$

A *combination* of n objects taken r at a time is an unarranged selection of any r of the n objects. The number of combinations of n objects taken r at a time is

$${}_n C_r = \frac{{}_n P_r}{r!} = \frac{n!}{r!(n-r)!} = {}_n C_{n-r}$$

In particular, ${}_n C_1 = n$, ${}_n C_n = 1$. Combinations taken any number at a time, ${}_n C_1 + {}_n C_2 + \dots + {}_n C_n = 2^n - 1$.

2.14 Probability

If, in a set M of m events that are mutually exclusive and equally likely, one event will occur, and if in the set M there is a subset N of n events ($n \leq m$), then the *a priori probability* p that the event that will occur is one of the subset N is n/m . The probability q that the event that will occur does not belong to N is $1 - n/m$.

Example 39 If the probability of drawing one of the 4 aces from a deck of 52 cards is to be found, then $m = 52$, $n = 4$, and $p = \frac{4}{52} = \frac{1}{13}$. The probability of drawing a card that is not an ace is $q = 1 - \frac{1}{13} = \frac{12}{13}$.

If, out of a large number r of observations in which a given event might or might not occur, the event has occurred s times, then a useful approximate value of the *experimental*, or *a posteriori*, probability of the occurrence of the event under the same conditions is s/r .

Example 40 From the American Experience Mortality Table, out of 100,000 persons living at age 10 years 749 died within a year. Here $r = 100,000$, $s = 749$, and the probability that a person of age 10 will die within a year is $749/100,000$.

If p is the probability of receiving an amount A , then the *expectation* is pA .

Addition Rule (either or). The probability that any one of several mutually exclusive events will occur is the sum of their separate probabilities.

Example 41 The probability of drawing an ace from a deck of cards is $\frac{1}{13}$, and the probability of drawing a king is the same. Then the probability of drawing either an ace or a king is $\frac{1}{13} + \frac{1}{13} = \frac{2}{13}$.

Multiplication Rule (both and). (a) The probability that two (or more) independent events will both (or all) occur is the product of their separate probabilities.

(b) If p_1 is the probability that an event will occur, and if, after it has occurred, p_2 is the probability that another event will occur, then the probability that both will occur in the given order is p_1p_2 . This rule can be extended to more than two events.

Example 42 (a) The probability of drawing an ace from a deck of cards is $\frac{1}{13}$, and the probability of drawing a king from another deck is $\frac{1}{13}$. Then the probability that an ace will be drawn from the first deck and a king from the second is $\frac{1}{13} \cdot \frac{1}{13} = \frac{1}{169}$. (b) After an ace has been drawn from a deck of cards, the probability of drawing a king is $\frac{4}{51}$. If two cards are drawn in succession without the first being replaced, the probability that the first is an ace and the second a king is $\frac{1}{13} \cdot \frac{4}{51} = \frac{4}{663}$.

Repeated Trials. If p is the probability that an event will occur in a single trial, then the probability that it will occur exactly s times in r trials is the *binomial*, or *Bernoulli*, distribution function

$${}_r C_s p^s (1 - p)^{r-s}$$

The probability that it will occur at least s times is

$$p^r + {}_r C_{r-1} p^{r-1} (1 - p) + {}_r C_{r-2} p^{r-2} (1 - p)^2 + \dots + {}_r C_s p^s (1 - p)^{r-s}$$

Example 43 If five cards are drawn, one from each of five decks, the probability that exactly three will be aces is ${}_5 C_3 (\frac{1}{13})^3 (\frac{12}{13})^2$. The probability that at least three will be aces is $(\frac{1}{13})^5 + {}_5 C_4 (\frac{1}{13})^4 (\frac{12}{13}) + {}_5 C_3 (\frac{1}{13})^3 (\frac{12}{13})^2$.

3 SET ALGEBRA

3.1 Sets

A *set* is a collection of objects called *elements* that are distinguished by a particular characteristic. Examples are a set of engineers, a set of integers, a set of points. Element e belongs to set \mathcal{S} is written $e \in \mathcal{S}$. If not, $e \notin \mathcal{S}$. A set can be denoted by including the listed elements, or merely by a typical element, in curly brackets: $\{2, 4, 6\}$; $\{e_1, e_2\}$, $\{e\}$. A set with no elements is called the *null set* and is denoted by \emptyset . A set with one element e_1 is denoted by $\{e_1\}$; and to

avoid a paradox in logic, these two ideas must be kept distinct.

Two sets \mathcal{A}, \mathcal{B} may be compared as follows. If every element of set \mathcal{A} is also an element of \mathcal{B} , then \mathcal{A} is contained in \mathcal{B} . This is written $\mathcal{A} \subset \mathcal{B}$ and is read " \mathcal{A} is contained in \mathcal{B} " or " \mathcal{A} is a *subset* of \mathcal{B} ." If, in addition, $\mathcal{B} \subset \mathcal{A}$, then their relation is written $\mathcal{A} = \mathcal{B}$. On the other hand, if \mathcal{A} has at least one element not contained in \mathcal{B} but $\mathcal{B} \subset \mathcal{A}$, \mathcal{B} is a *proper subset* of \mathcal{A} . If \mathcal{S} can contain all the elements of \mathcal{A} , this can be stressed by writing $\mathcal{A} \subseteq \mathcal{S}$. Evidently $\emptyset \subset \mathcal{S}$ for every set \mathcal{S} .

If S , called the *space*, is the largest set concerned in a particular discussion, all the other sets are subsets of S . Thus set $\mathcal{A} \subset S$. The *complement* of \mathcal{A} , \mathcal{A}^c , with respect to space S is the set of elements in S that are not elements of \mathcal{A} .

Binary Operations for Sets. The *union*, $\mathcal{A} \cup \mathcal{B}$, of sets \mathcal{A} and \mathcal{B} is the set of elements in \mathcal{A} or \mathcal{B} or in both. Note that union differs from the idea of sum since in the union the common elements are counted only once. The *intersection*, $\mathcal{A} \cap \mathcal{B}$, of sets \mathcal{A} and \mathcal{B} is the set of elements in both \mathcal{A} and \mathcal{B} . See the tabulation below.

Let $\mathcal{A}, \mathcal{B}, \mathcal{C}$ have their elements in space S .

Boolean algebra has as one representation the following:

UNICITY. Unique union $\mathcal{A} \cup \mathcal{B} \subset S$. Unique intersection $\mathcal{A} \cap \mathcal{B} \subset S$.

COMMUTATIVITY. $\mathcal{A} \cup \mathcal{B} = \mathcal{B} \cup \mathcal{A}$, $\mathcal{A} \cap \mathcal{B} = \mathcal{B} \cap \mathcal{A}$.

ASSOCIATIVITY. $\mathcal{A} \cup (\mathcal{B} \cup \mathcal{C}) = (\mathcal{A} \cup \mathcal{B}) \cup \mathcal{C}$, $\mathcal{A} \cap (\mathcal{B} \cap \mathcal{C}) = (\mathcal{A} \cap \mathcal{B}) \cap \mathcal{C}$.

DISTRIBUTIVITY. $\mathcal{A} \cup (\mathcal{B} \cap \mathcal{C}) = (\mathcal{A} \cup \mathcal{B}) \cap (\mathcal{A} \cup \mathcal{C})$, $\mathcal{A} \cap (\mathcal{B} \cup \mathcal{C}) = (\mathcal{A} \cap \mathcal{B}) \cup (\mathcal{A} \cap \mathcal{C})$.

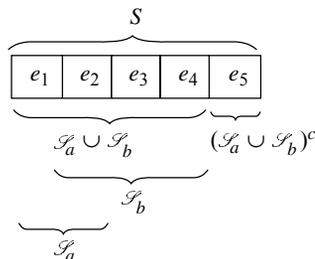

IDEMPOTENCY. $\mathcal{A} \cup \mathcal{A} = \mathcal{A}$, $\mathcal{A} \cap \mathcal{A} = \mathcal{A}$.

SPACE. $\mathcal{A} \cup S = S$, $\mathcal{A} \cap S = \mathcal{A}$.

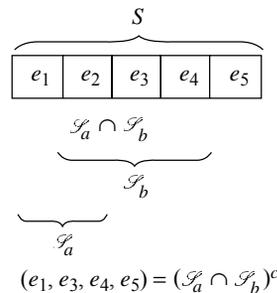

NULL SET. $\mathcal{A} \cup \emptyset = \mathcal{A}$, $\mathcal{A} \cap \emptyset = \emptyset$.

SUBSET. $\emptyset \subset \mathcal{A} \subset S$, $\mathcal{A} \subset (\mathcal{A} \cup \mathcal{B})$, $(\mathcal{A} \cap \mathcal{B}) \subset \mathcal{A}$, $\mathcal{A} \subset \mathcal{B} \Rightarrow \mathcal{A} \cup \mathcal{B} = \mathcal{B}$, and $\mathcal{A} \cap \mathcal{B} = \mathcal{A}$.

Tabulation for Binary Operations for Sets

Union

Intersection

COMPLEMENT. To $\mathcal{S}_a \subset S$ there corresponds unique $\mathcal{S}_a^c \subset S$; $\mathcal{S}_a \cup \mathcal{S}_a^c = S$, $\mathcal{S}_a \cap \mathcal{S}_a^c = \emptyset$.

DE MORGAN'S RELATIONS. $(\mathcal{S}_a \cup \mathcal{S}_b)^c = \mathcal{S}_a^c \cap \mathcal{S}_b^c$, $(\mathcal{S}_a \cap \mathcal{S}_b)^c = \mathcal{S}_a^c \cup \mathcal{S}_b^c$.

INVARIANT under the *duality transformation*, $\cup \leftrightarrow \cap$, $\subset \leftrightarrow \supset$, $S \leftrightarrow \emptyset$, are all the preceding relations.

3.2 Groups

A *group* is a system composed of a *set of elements* $\{a\}$ and a *rule of combination* of any two of them to form a product, such that:

1. The *product* of any ordered pair of elements and the square of each element are elements of the set.
2. The *associative* law holds.
3. The set contains an *identity* element I such that $Ia = aI = a$ for any element a of the set.
4. For any element a of the set there is in the set an *inverse* a^{-1} such that $aa^{-1} = a^{-1}a = I$.
5. If, in addition, the *commutative* law holds, the group is *commutative*, or *Abelian*.

The *order* of a group is the number n of elements in the group.

3.3 Rings, Integral Domains, and Fields

Rings. Space S consists of a set of elements e_1, e_2, e_3, \dots . These elements are compared for *equality* and *order* and combined by the operations of *addition* and *multiplication*. These terms are partially define by the following sets of assumptions.

Equality is a term from logic and means that if two expressions have this relation, then one may be substituted for the other.

Assumptions of equality E_1 . Unicity: either $e_1 = e_2$ or $e_1 \neq e_2$. E_2 . Reflexivity $E_1 = e_1$, E_3 . Symmetry: $e_1 = e_2 \Rightarrow e_2 = e_1$. E_4 . Transitivity: $e_1 = e_2, e_2 = e_3 \Rightarrow e_1 = e_3$.

Assumptions of addition A_1 . Closure: $e_1 + e_2 \in S$. A_2 : $e_1 = e_2 \Rightarrow e_1 + e_3 = e_2 + e_3$ and $e_3 + e_1 = e_3 + e_2$. (Invariance under addition.) A_3 . Associativity: $e_1 + (e_2 + e_3) = (e_1 + e_2) + e_3$. A_4 . Identity element: There exists an element $z \in S$ such that $e_1 + z = e_1, z + e_1 = e_1$. A_5 . Commutativity: $e_1 + e_2 = e_2 + e_1$.

Theorem 1: z is unique.

Negative. To each $e \in S$, there corresponds an $e' \in S$ such that $e + e' = z$; e' is called the negative of e and written $-e$.

Theorem 2: e' or $-e$ is unique. Theorem 3: $-(-e) = e$. Theorem 4: $-z = z$. Theorem 5: Equation $x + e_1 = e_2$ has the solution $x = e_2 - e_1$. Theorem 6: $e_1 + e_3 = e_1 \Rightarrow e_3 = z$.

Assumptions of multiplication M_1 . Closure: $e_1 \cdot e_2 \in S$. M_2 . $e_1 = e_2 \Rightarrow e_1 \cdot e_3 = e_2 \cdot e_3$ and $e_3 \cdot e_1 = e_3 \cdot e_2$. (Invariance under multiplication.) M_3 . Associativity: $e_1(e_2 \cdot e_3) = (e_1 \cdot e_2)e_3$. M_4 . Identity element:

There exists an element $u \in S$ such that $e_1 \cdot u = e_1, u \cdot e_1 = e_1$. M_5 . Commutativity: $e_1 \cdot e_2 = e_2 \cdot e_1$.

Theorem 7: u is unique.

Reciprocal. To each element $e \in S$ except z there corresponds an $e'' \in S$ such that $e \cdot e'' = u$; e'' is called the reciprocal of e and written e^{-1} .

Theorem 8: e'' or e^{-1} is unique.

M_7 . Distributivity: $e_1(e_2 + e_3) = e_1 \cdot e_2 + e_1 \cdot e_3$.

Theorem 9: $e \cdot z = z$. Theorem 10: $e_1(-e_2) = -(e_1 \cdot e_2) = (-e_1)e_2$. Theorem 11: $(-e_1)(-e_2) = e_1 \cdot e_2$. Theorem 12: If S contains an element besides z , then it is $u \neq z$. Theorem 13: $e_1 \cdot e_2 = z \Rightarrow$ either $e_1 = z$ or $e_2 = z$.

A *ring* is a space S having at least two elements for which assumptions E_1 to E_4 , A_1 to A_6 , M_1 to M_5 , and M_7 hold. An example is a residue system modulo 4.

Integral Domain. An *integral domain* is a ring for which, as an assumption, Theorem 13 holds. An example is the set of all integers.

Field. A *field* is an integral domain for which M_6 holds. An example of a field is the set of algebraic numbers.

Assumptions of (linear) order O_1 . (Contains E_1 .) If $e_1, e_2 \in S$, then either $e_1 < e_2, e_1 = e_2$, or $e_2 < e_1$. O_2 . $e_1 < e_2 \Rightarrow e_1 + e_3 < e_2 + e_3$. (Invariance under addition.) O_3 . Transitivity: $e_1 < e_2, e_2 < e_3 \Rightarrow e_1 < e_3$.

Negative. If $e_1 < z$, then e_1 is called negative.

Positive. If $z < e_2$, then e_2 is called positive.

O_4 . $z < e_2z < e_3 \Rightarrow z < e_2 \cdot e_3$.

An *ordered integral domain* is an integral domain for which O_1 to O_4 hold. An example is the set of all integers.

An *ordered field* is an ordered integral domain for which M_6 holds. An example is the set of all rational numbers.

If an additional order assumption, O_5 , known as the Dedekind assumption—see a book on real analysis—is included, then the space S for which assumptions E_1 to E_4 , A_1 to A_6 , M_1 to M_7 , and O_1 to O_5 hold is called the real number space. An example is the set of real numbers. Here z is denoted 0, and u is denoted 1. Another example is the set of points on the real line.

4 STATISTICS AND PROBABILITY

4.1 Frequency Distributions of One Variable

Definitions A *frequency distribution* of statistical data consisting of N values of a variable x is a tabulation by intervals, called *classes*, showing the number f_i , called the *frequency* or *weight*, in each class; $N = \sum f_i$.

The midvalue x_i of a class is the *class mark*.

For equal classes, the *class interval* is $c = x_{i+1} - x_i$.

The *cumulative frequency*, cum f , at any class is the sum of the frequencies of all classes up to and including the given class.

Graphs

Frequency Polygon. Plot the points (x_i, f_i) and draw a broken line through them.

Histogram. Draw a set of rectangles using as bases intervals representing the classes marked off on a straight line and using altitudes proportional to the frequencies.

Frequency Curve. Draw a continuous curve approximating a frequency polygon or such that the region under the curve approximates a histogram. As the class interval c is taken smaller and the total frequency N larger, the approximation becomes better.

Ogive. This is a graph of cumulative frequencies.

Averages

Arithmetic Mean

$$AM = \bar{x} = \frac{1}{N} \sum_{i=1}^k f_i x_i$$

in which $N = \sum_{i=1}^k f_i$.

Geometric Mean

$$GM = (x_1^{f_1} \cdot x_2^{f_2} \cdots x_k^{f_k})^{1/N}$$

$$\log GM = \frac{1}{N} \sum_{i=1}^k f_i \log x_i$$

Harmonic Mean

$$HM = \frac{N}{\sum_{i=1}^k (f_i/x_i)}$$

Root-Mean-Square

$$rms = \sqrt{\frac{\sum_{i=1}^k f_i x_i^2}{N}}$$

Median. (a) For continuously varying data, the value of x for which $\text{cum } f = N/2$; (b) for discrete data, the value of x such that there is an equal number of values larger and smaller; for N odd, $N = 2k - 1$, the median is x_k ; for N even, $N = 2k$, the median may be taken as $\frac{1}{2}(x_k + x_{k+1})$.

Mode. The value of x that occurs most frequently.

Moments

1. About x_0 . In x units

$$v_r = \frac{1}{N} \sum_{i=1}^k f_i (x_i - x_0)^r \quad r = 0, 1, \dots$$

If $x_0 = 0, v_1 = \bar{x}$, which is the *arithmetic mean*. In u units

$$v_r = \frac{1}{N} \sum_{i=1}^k f_i u_i^r \quad r = 0, 1, \dots \quad u = \frac{x - x_0}{c}$$

$c =$ class interval

2. About the *mean*. In x units

$$\mu_r = \frac{1}{N} \sum_{i=1}^k f_i (x_i - \bar{x})^r \quad r = 0, 1, \dots$$

$\bar{x} = v_1$ in x units

In u units

$$\mu_r = \frac{1}{N} \sum_{i=1}^k f_i (u_i - \bar{u})^r \quad r = 0, 1, \dots$$

$\bar{u} = v_1$ in u units

In either x or u units, the μ 's as functions of the v 's are

$$\mu_0 = 1$$

$$\mu_1 = 0$$

$$\mu_2 = v_2 - v_1^2$$

$$\mu_3 = v_3 - 3v_1v_2 + 2v_1^3$$

$$\mu_4 = v_4 - 4v_1v_3 + 6v_1^2v_2 - 3v_1^4$$

$$\mu_r (\text{in } x \text{ units}) = c^r \mu_r (\text{in } u \text{ units}) \quad r = 0, 1, \dots$$

In x units, μ_2 is the *variance*; $\sqrt{\mu_2}$ is the *standard deviation* σ . Both are used as measures of dispersion. To compute σ ,

$$\sigma = c \sqrt{\frac{\sum_{i=1}^k f_i u_i^2}{N} - \bar{u}^2}$$

Probable error = 0.6745σ .

3. In *standard* (deviation) units,

$$\alpha_1 = 0 \quad \alpha_2 = 1$$

$$\alpha_3 = \frac{\mu_3}{\sigma^3} \quad (\text{a measure of skewness})$$

$$\alpha_4 = \frac{\mu_4}{\sigma^4} \quad (\text{a measure of kurtosis})$$

The *moment-generating function*, or arbitrary-range inverse real Laplace transform, is

$$M(\theta) = \int_a^b e^{\theta x} f(x) dx$$

The r th moment is

$$\mu_r = \left. \frac{d^r M}{d\theta^r} \right|_{\theta=0} \quad r = 0, 1, 2, \dots$$

M Tiles The r th *quartile* Q_r is the value of x for which $\text{cum } f/N = r/4$. The r th *percentile* P_r is the value of x for which $\text{cum } f/N = r/100$. For $r = 10s$, $P_r = D_s$, the s th *decile*.

Other Measures of Shape

Dispersion

1. *Range* of x , the difference between the largest and the smallest values of x .
2. *Mean deviation*, $(1/N) \sum_{i=1}^k f_i |x_i - \bar{x}|$.
3. *Semi-interquartile range*, or *quartile deviation*,

$$Q = \frac{1}{2} |Q_3 - Q_1|$$

Skewness. *Quartile coefficient of skewness*, $(Q_3 - 2Q_2 + Q_1)/Q$.

Statistical Hypotheses A hypothesis concerning one or more statistical distribution parameters is a *statistical hypothesis*. A *test* of such a hypothesis is a procedure leading to a decision to accept or reject the hypothesis. The *significance level* is the probability value below which a hypothesis is rejected.

A *type 1 error* is made if the hypothesis is correct but the test rejects the hypothesis. A *type 2 error* is made if the hypothesis is false but the test accepts the hypothesis.

If the variable x has a distribution function $f(x; \theta)$, with parameter θ , then the *likelihood* function, that is, distribution function of a random sample of size n , is $P(\theta) = f(x_1; \theta) f(x_2; \theta) \cdots f(x_n; \theta)$. The use of $P_{\max}(\theta)$ in the estimation of population parameters is the *method of maximum likelihood*. It often consists of solving $dP/d\theta = 0$ for θ .

Random Sampling A set x_1, x_2, \dots, x_n of values of x with distribution function $f(x)$ is a *sample of size n* drawn from the population described by $f(x)$. If repeated samples of size n drawn from the population have the x_r 's independently distributed in the probability sense and each x_r has the same distribution as the population, then the sampling is *random*.

Normal and Nonnormal Distributions The normal distribution function in analytic and tabular form is found in Section 4.5. A linear combination of independent normal variables is normally distributed.

The *Poisson distribution*, $P(x) = e^{-m} m^x / x!$, is the limit approached by the binomial distribution (Section) if the probability p that an event will occur in a single trial approaches zero and the number of trials r

becomes infinite in such a way that $rp = m$ remains constant.

If m is the mean of a nonnormal distribution of x , σ the standard deviation, and if the moment-generating function exists, then the variable $(\bar{x} - m)n^{1/2}/\sigma$, in which \bar{x} is the mean of a sample of size n , has a distribution that approaches the normal distribution as $n \rightarrow \infty$.

Nonparametric methods are those that do not involve the estimation of parameters of a distribution function. Tchebycheff's inequality (Section) provides nonparametric tests for the validity of hypotheses. It leads to the *law of large numbers*. Let p be the probability of an event occurring in one trial and p_n the ratio of the number of occurrences in n trials to the number n . The probability that $|p_n - p| > \varepsilon$ is $\leq pq/n\varepsilon$; this can be made arbitrarily small, however small ε is, by taking n large enough. The ratio p_n converges *stochastically* to the probability p .

Two numbers L_1, L_2 between which a large fraction of a population is expected to lie are *tolerance limits*. If z is the fraction of the population of a variable with a continuous distribution that lies between the extreme values of a random sample of size n from this population, then the distribution of z is $f(z) = n(n-1)z^{n-2}(1-z)$.

Statistical Control of Production Processes

A chart on which percentage defective in a sample is graphed as a function of output time can be used for control of an industrial process. Horizontal lines are drawn through the mean m and the controls $m \pm 3\sigma/n^{1/2}$. The behavior of the graph with respect to these control lines is used as an error signal in a feedback system that controls the process. If the graph goes out of the band bounded by the control lines, the process is stopped until the trouble is located and removed.

4.2 Correlation

To discover whether there is a simple relation between two variables, corresponding pairs of values are used as coordinates to plot the points of a *scatter diagram*. The simplest relation exists if the scatter diagram can be approximated more or less closely by a straight line.

Least-Square Straight Line. This line, which minimizes the sum of the squares of the y deviations of the points, is

$$\hat{y} - \bar{y} = M(x - \bar{x})$$

in which

$$M = \frac{\Sigma(x - \bar{x})y}{\Sigma(x - \bar{x})^2}$$

(x, y) is a plotted point, and (x, \hat{y}) is a point on this *line of regression* of y on x . The *correlation coefficient*

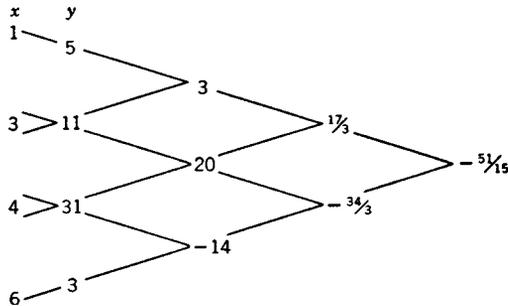

$$r = \pm \left[1 - \frac{\Sigma(y - \hat{y})^2}{\Sigma(y - \bar{y})^2} \right]^{1/2}$$

is a measure of the usefulness of the regression line. If $r = 0$, the line is useless; if $r = \pm 1$, the line gives a perfect estimate. The percentage of the variance of y that has been accounted for by y 's relation to x is equal to r^2 .

Polynomial of Degree $n-1$. This can be passed through n points (x_i, y_i) . The method of doing this by *divided differences* is as follows:

Example 44 Find the polynomial through $(1, 5)$, $(3, 11)$, $(4, 31)$, $(6, 3)$.

Using the first three values of x , assume the polynomial to be of the form $y = a_1 + a_2(x - 1) + a_3(x - 1)(x - 3) + a_4(x - 1)(x - 3)(x - 4)$. The a_i are the last four numbers in the top diagonal of the following:

To form the graphic, put the given (x_i, y_i) in the first two columns. To find a number in any other column, divide the difference of the two numbers just above and below it immediately to the left by the difference of the x 's in the two diagonals through it. The polynomial is $y = 5 + 3(x - 1) + \frac{17}{3}(x - 1)(x - 3) - \frac{51}{15}(x - 1)(x - 3)(x - 4)$.

Power Formula. $y = ax^n$ fit well if the points (x_i, y_i) lie approximately on a straight line when plotted on logarithmic (log scales on both horizontal and vertical axes) graph paper. To find a and n use two of the points (x_1, y_1) and (x_2, y_2) , preferably far apart:

$$n = \frac{\log y_2 - \log y_1}{\log x_2 - \log x_1}$$

$$\log a = \log y_1 - n \log x_1$$

Exponential Formula. $y = ae^{nx}$ fit well if the points (x_i, y_i) lie approximately on a straight line when plotted on semilogarithmic (log scale on vertical axis) graph paper. To find a and n use two of the points (x_1, y_1) and (x_2, y_2) , preferably far apart:

$$n = \frac{\ln y_1 - \ln y_2}{x_1 - x_2} = 2.3026 \frac{\log y_1 - \log y_2}{x_1 - x_2}$$

$$\ln a = \ln y_1 - nx_1 \quad \text{or} \quad \log a = \log y_1 - 0.4343nx_1$$

4.3 Statistical Estimation by Small Samples

A statistic is an *unbiased estimate* of a population parameter if its expected value is equal to the population parameter.

In the problem of estimating a population parameter, such as the mean or variance, the interval within which c percent of the sample parameter values lies is the *c percent confidence interval* for the parameter.

The χ^2 distribution function for ν degrees of freedom is

$$f(\chi^2) = \frac{1}{2^{\nu/2}\Gamma(\nu/2)}(\chi^2)^{(\nu-2)/2}e^{-\chi^2/2}$$

and its moment-generating function is

$$M(\phi) = (1 - 2\theta)^{-\nu/2}$$

The sum of the squares of n random sample values of x has a χ^2 distribution with n degrees of freedom if x has a normal distribution with zero mean and unit variance.

The *binomial index of dispersion* is

$$\chi^2 = \sum_{r=1}^k \frac{(x_r - \bar{x})^2}{\bar{x}(1 - \bar{x}/n)}$$

For p small and n large, this reduces to the *Poisson index of dispersion* $\sum_{r=1}^k (x_r - \bar{x})^2/\bar{x}$.

These indices are used to test the hypothesis that k sample frequencies x_r came from the same binomial or Poisson population, respectively.

Student's t distribution for the variable $t = uv^{1/2}/v$ is

$$f(t) = c \left(1 + \frac{t^2}{v}\right)^{-(v+1)/2}$$

ν degrees of freedom, c constant, if u has a normal distribution with zero mean and unit variance and v^2 has a χ^2 distribution with ν degrees of freedom.

The *F distribution* for the variable $F = (u/v_1)/(v/v_2)$ is

$$f(F) = \frac{cF^{(v_1-2)/2}}{(v_2 + v_1F)^{(v_1+v_2)/2}}$$

ν_1 and ν_2 degrees of freedom, c constant, if u and v have independent χ^2 distributions with ν_1 and ν_2 degrees of freedom, respectively.

Analysis of Variance *Experimental error* is the variation in the basic variable remaining after the effects of controlled variables have been removed (Section 4.5). The *analysis of variance* means the resolution of the basic sum of squares into the component that measures the part of the variation being tested and the component that measures the experimental error.

4.4 Statistical Design of Experiments

To get *valid* conclusions from an experiment, there is need for proper control of the other variables besides those being investigated and also for sufficiently large and random samples.

Sampling Inspection. To make an inspection *efficient*, the cost and usually the amount of sampling should be minimized.

It is a common practice in industry for a consumer to accept or reject a lot on the basis of a sample drawn from the lot. There is a maximum fraction of defectives that the consumer will tolerate. This is the *lot tolerance fraction defective* p_t . A random sample of n pieces is selected from a lot of N pieces. The maximum allowable number of defective pieces in an acceptable sample is c . *Single sampling* means: (a) Inspect a sample of n pieces. (b) Accept the lot if the number of defective pieces is c or less; otherwise inspect the remainder of the lot. (c) Replace all defective pieces found by nondefective ones.

The *consumer's risk*, that is, the probability that a consumer will accept a lot of quality lower than p_t , is

$$P_c = \sum_{x=0}^c \frac{\binom{Np_t}{x} \binom{N-Np_t}{n-x}}{\binom{N}{n}} \quad (12)$$

If a producer has standardized quality at a fractional value \bar{p} , the *process average fraction defective*, then the *producer's risk*, that is, the probability that a lot will be erroneously rejected, is

$$P_p = 1 - \sum_{x=0}^c \frac{\binom{N\bar{p}}{x} \binom{N-N\bar{p}}{n-x}}{\binom{N}{n}} \quad (13)$$

These two risks correspond to errors of type 2 and type 1, respectively.

The average number of pieces inspected per lot for single sampling is $I = n + (N - n)P_p$. The amount of inspection and ordinarily the cost are minimized by finding the pair of values of n and c that satisfy (a) above for an assigned value of P_c and minimize I .

Sequential Analysis. An improvement on the fixed-size sampling methods already described results in greater efficiency if the inspection can be conducted on an accumulation-of-information basis. Such sequential methods operate on successive terms of a sequence of observations as they are received. They involve two steps: (a) to accept or reject the hypothesis under test and (b) to continue taking additional observations if the hypothesis is rejected.

For a more extensive treatment of the elementary theory of statistics, see *Applied Statistics and Probability for Engineers* by D. C. Montgomery and G. C. Runger (Wiley, Hoboken, New Jersey, 2007).

4.5 Precision of Measurements

Observations and Errors The *error of an observation* is $e_i = m_i - m$, $i = 1, 2, \dots, n$, where the m_i are the observed values, the e_i the errors, and m the mean value, that is, the arithmetic mean of a very large number (theoretically infinite) of observations.

In a large number of measurements *random errors* are as often negative as positive and have little effect on the arithmetic mean. All other errors are classed as *systematic*. If due to the same cause, they affect the mean in the same sense and give it a definite bias.

Best Estimate and Measured Value. If all systematic errors have been eliminated, it is possible to consider the sample of individual repeated measurements of a quantity with a view to securing the "best" estimate of the mean value m and assessing the degree of reproducibility that has been obtained. The final result will then be expressed in the form $E \pm L$, where E is the best estimate of m and L the characteristic limit of variation associated with a certain risk. Not merely E but the entire result $E \pm L$ is the value measured.

Arithmetic Mean. If a large number of measurements have been made to determine directly the mean m of a certain quantity, all measurements having been made with equal skill and care, the best estimate of m from a sample of n is the arithmetic mean \bar{m} of the measurements in the sample,

$$\bar{m} = \frac{1}{n} \sum_{i=1}^n m_i$$

Standard deviation is the *root-mean-square* of the deviations e_i of a set of observations from the mean,

$$\sigma = \left(\frac{1}{n} \sum_{i=1}^n e_i^2 \right)^{1/2}$$

Since neither the mean m nor the errors of observation e_i are ordinarily known, the deviations from the arithmetic mean, or the *residuals*, $x_i = m_i - \bar{m}$, $i = 1, 2, \dots, n$, will be referred to as errors.

Likewise, for σ the unbiased value

$$\begin{aligned} \sigma &= (n-1)^{-1/2} \left[\sum_{i=1}^n (m_i - \bar{m})^2 \right]^{1/2} \\ &= (n-1)^{1/2} \left(\sum_{i=1}^n e_i^2 \right)^{1/2} \end{aligned}$$

will be used, in which n is replaced by $n - 1$ since one degree of freedom is lost by using \bar{m} instead of m , \bar{m} being related to the m_i .

Normal Distribution

Relative Frequency of Errors. The Gauss–Laplace, or normal, distribution of frequency of errors is (Fig. 4)

$$y = \frac{1}{\sigma\sqrt{2\pi}} e^{-x^2/2\sigma^2}$$

or

$$y = \frac{1}{\sqrt{\pi}} h e^{-h^2 x^2}$$

where $2h^2\sigma^2 = 1$, or $h = 1/(\sqrt{2}\sigma)$, and y represents the proportionate number of errors of value x . The area under the curve is unity. The dotted curve is also an error distribution curve with a greater value of the precision index h , which measures the concentration of observations about their mean.

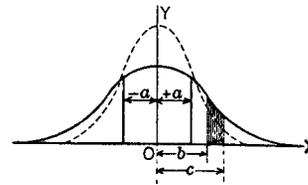

Fig. 4

Probability. The fraction of the total number of errors whose values lie between $x = -a$ and $x = a$ is

$$P = \frac{h}{\sqrt{\pi}} \int_{-a}^{+a} e^{-h^2 x^2} dx = \frac{2}{\sqrt{\pi}} \int_0^{ha} e^{-h^2 x^2} d(hx)$$

that is, P is the probability of an error x having a value between $-a$ and a (see Table 1). Similarly, the shaded area represents the probability of errors between b and c .

Table 1 Values of $P = \frac{2}{\sqrt{\pi}} \int_0^{ha} e^{-h^2 x^2} d(hx)$

^a $ha = 0.47694(a/r) = (1/\sqrt{2})(a/\sigma)$.

Probable Error. Results of measurements are sometimes expressed in the form $E \pm r$, where r is the *probable error* of a single observation and is defined as the number that the actual error may with equal probability be greater or less than. From (14)

$$\frac{2}{\sqrt{\pi}} \int_0^{hr} e^{-h^2x^2} d(hx) = 0.50$$

and

$$hr = 0.47694$$

or

$$r = 0.4769 \times \sqrt{2}\sigma = 0.6745\sigma$$

Similarly, 5% of the errors x are greater than 2σ and less than 1% are greater than 3σ .

For rapid comparisons the following approximate formula due to Peters is useful:

$$r \approx 0.8453[n(n-1)]^{-1/2} \sum_{i=1}^n |x_i|$$

The *standard deviation of the arithmetic mean*, $\sigma_{\bar{m}}$, as calculated from data, is related to the standard deviation σ by the formula

$$\sigma_{\bar{m}} = n^{-1/2}\sigma = [n(n-1)]^{-1/2} \left(\sum_{i=1}^n x_i^2 \right)^{1/2}$$

From this formula and Tables 1 and 2 the limits corresponding to given risks can be determined as indicated previously. It is evident that the stability of the mean increases with n , that is, the effect of the erratic behavior of single cases decreases with increase of n .

The *probable error of the arithmetic mean* as calculated from data, $r_{\bar{m}}$, is then given by

$$r_{\bar{m}} = 0.6745[n(n-1)]^{-1/2} \left(\sum_{i=1}^n x_i^2 \right)^{1/2}$$

and Peters's formula for the approximate value is

$$r_{\bar{m}} \approx 0.8453[n^2(n-1)]^{-1/2} \sum_{i=1}^n |x_i|$$

Example 45. The following are 10 measurements, m_i , of the length of a baseline. The values of the residuals, x_i , and their squares are given: $m = 455.35$, 455.35, 455.20, 455.05, 455.75, 455.40, 455.10, 455.30, 455.50, 455.30.

Arithmetic mean $\bar{m} = 455.330$.

x_i : 0.02, 0.02, -0.13, -0.28, 0.42, 0.07, -0.23, -0.03, -0.17, -0.03.

x_i^2 : 0.0004, 0.0004, 0.0169, 0.0784, 0.1764, 0.0049, 0.0529, 0.0009, 0.0289, 0.0009.

Hence

$$\sum_{i=1}^{10} x_i^2 = 0.3610 \quad \text{and} \quad \sum_{i=1}^{10} |x_i| = 1.40$$

So by the standard formulas, $r = 0.6745(9)^{-1/2} (0.3610)^{1/2} = 0.13$, $r_{\bar{m}} = (10)^{-1/2}r = 0.042$. By the approximate formulas, $r \approx 0.8453(90)^{-1/2}(1.40) = 0.12$, $r_{\bar{m}} \approx 0.039$.

For the best estimate of the baseline, the result is 455.330 with probable error ± 0.042 (using result given by the standard formula), usually written 455.330 ± 0.042 . In any considerable number of observations it should be the case, as it is here, that half of the residuals are less than the probable error.

Rounded Numbers. It can be shown that the standard deviation σ of a *rounded number* (Section 1.3) due to rounding is $\sigma = 0.2887 w$, where w is a unit in the last place retained. Consequently, the probable error of a rounded number due to rounding is

$$r = 0.6745 \times 0.2887 w = 0.1947 w$$

Weighted Observations. Sometimes, notwithstanding the care with which observations are taken, there are reasons for believing that certain observations are better than others. In such cases the observations are given different weights, that is, are counted a different number of times, the weights or numbers expressing their relative practical worth. If there are n weighted observations m_i with weights p_i , these being made directly on the same quantity, then the best estimate of the mean value m of the quantity is the *weighted arithmetic mean* \bar{m} of the sample,

$$\bar{m} \equiv \frac{\sum_{i=1}^n p_i m_i}{\sum_{i=1}^n p_i}$$

For the set of weighted observations we have

$$r = 0.6745(n-1)^{-1/2} \left(\sum_{i=1}^n p_i x_i^2 \right)^{1/2}$$

as the probable error of an observation of unit weight and

$$r_{\bar{m}} = 0.6745 \left[(n-1) \sum_{i=1}^n p_i \right]^{-1/2} \left(\sum_{i=1}^n p_i x_i^2 \right)^{1/2}$$

Tabulation for Example 46

p_i	5	4	1	4	3	4
m_i	178.26	176.30	181.06	177.95	176.20	180.85
$p_i m_i$	891.30	705.20	181.06	711.80	528.60	723.40
x_i	0.10	1.86	2.90	0.21	1.96	2.69
x_i^2	0.010	3.460	8.410	0.441	3.842	7.230
$p_i x_i^2$	0.05	13.84	8.41	0.18	11.53	28.94

as the probable error of the arithmetic mean of weighted items, in which

$$x_i \equiv \frac{m_i - \sum_{i=1}^n p_i m_i}{\sum_{i=1}^n p_i}$$

Example 46. Let six observations on the same quantity be made with weights p_i , the sum of these weights being 21 (see the tabulation above). The sum of the weighted observations, $\sum_{i=1}^6 p_i m_i$, is 3741.36. The best estimate of the value of m for the observed quantity is $\bar{m} = 3741.36/21 = 178.16$. Subtracting this from each m_i gives the residuals x_i . The sum of the weighted squares of the residuals, $\sum_{i=1}^6 p_i x_i^2$, is 62.95. Then the preceding formulas give the probable error of an observation of weight unity as $r = 2.39$ and the probable error of the weighted mean as $r_{\bar{m}} = 0.52$. The final result then is 178.16 ± 0.52 .

Probable Error in a Result Calculated from Means of Several Observed Quantities.

Let Z be a sum of n means of observed independent quantities, each taken with a plus or a minus sign. Then, if $r_j, j = 1, 2, \dots, n$, are the probable errors in these means, the probable error in Z is $(\sum_{j=1}^n r_j^2)^{1/2}$.

Let $Z = Az$, where z is the mean of an observed quantity with probable error r and A an exact number. Then the probable error in Z is Ar .

Let Z be any differentiable function of the means of independently observed quantities z_j with probable errors r_j . Then the probable error in Z is $[\sum_{j=1}^m (\partial Z / \partial z_j)^2 r_j^2]^{1/2}$. For example, if $Z = z_1 z_2$, the probable error in Z is $(z_1^2 r_2^2 + z_2^2 r_1^2)^{1/2}$.

Conditions of Applicability. The theory underlying the foregoing development depends on the following assumptions: (a) The sample consists of a large number of observations. (b) The observations have

been made with equal care and skill so that (i) there are approximately an equal number of readings above and below the mean (except in the case of weighted items), (ii) the individual deviations from the mean are small in most cases, and (iii) the number of deviations diminishes rapidly as their size increases.

The extent to which the observed data satisfy these assumptions is a measure of the extent to which we are justified in using the Gauss error distribution curve, which is consistent with the statement that \bar{m} is the best estimate of the mean value m and which leads to the factor 0.6745 used in computing probable error. Even if we were not justified in assuming the Gaussian distribution of errors, the arithmetic mean still remains the best estimate we have for m . Therefore, there is little difficulty in this regard, especially since "errors" appear to follow the Gaussian distribution as closely as any other we know. Our difficulties enter in connection with the factor 0.6745 and the accuracy of the σ , as estimated from the data.

If the number of observations n in a sample is small, the estimate of the standard deviation of the possible infinite of observations with mean m is itself subject to considerable error. For example, for $n = 3$ the standard error of the standard deviation is as large as the standard deviation itself, and hence the probable error calculated from $r = 0.6745\sigma$ would not be very reliable. Table 3 will illustrate this. The second and third columns give the probability that the probable error of a single observation should be out 20 and 50%, respectively.

From Table 3 it is clear that with 10 observations the odds are only 3 : 2 that the calculated probable error is within 20% of the correct value and about 30 : 1 that it is within 50% of the correct value. Of course, the probable error of the mean will be correspondingly out.

The use of Table 2.3 is quite legitimate for $100 < n$, and for $30 < n < 100$ the table may be used provided σ is multiplied by $(n - 3)^{-1/2}$. For $n < 30$, a rough estimate can be obtained from the fact that the percentage of cases lying outside the range, $m \pm k\sigma$, is $< 100k^{-2}$ for $1 < k$. A striking property of this inequality due to Tchebycheff is that it is *nonparametric*,

which means independent of the nature of the distribution assumed.

5 GEOMETRY

5.1 Geometric Concepts

Plane Angles A degree ($^{\circ}$) is $\frac{1}{360}$ of a revolution (or *perigon*) and is divided into 60 units called *minutes* ($'$) that in turn are divided into 60 units called *seconds* ($''$).

A *radian* is a *central angle* that intercepts a *circular arc* equal to its *radius*. One radian, therefore, equals $360/2\pi$ degrees, or 57.295779513° , and $1^{\circ} = 0.017453293$ radian.

An angle of 90° is a *right angle*, and the lines that form it are *perpendicular*. An angle less than a right angle is *acute*. An angle greater than a right angle but less than 180° is *obtuse*. If the sum of two angles equals 90° , they are *complementary* to each other, and if their sum is 180° , *supplementary* to each other.

Polygons A *polygon*, or *plane rectilinear figure*, is a closed broken line.

A *triangle* is a polygon of three sides. It is *isosceles* if two sides (and their opposite angles) are equal; it is *equilateral* if all three sides (and all three angles) are equal.

A *quadrilateral* is a polygon of four sides. This classification includes the *trapezium*, having no two sides parallel; the *trapezoid*, having two opposite sides parallel (*isosceles trapezoid* if the nonparallel sides are equal); and the *parallelogram*, having both pairs of opposite sides parallel and equal. The parallelogram includes the *rhomboid*, having no right angles and, in general, adjacent sides not equal; the *rhombus*, having no right angles but all sides equal; the *rectangle*, having only right angles and, in general, adjacent sides not equal; and the *square*, having only right angles and all sides equal.

Similar polygons have their respective angles equal and their corresponding sides proportional.

A *regular polygon* has all sides equal and all angles equal. An equilateral triangle and a square are regular polygons.

Other polygons classify according to number of sides are (5) *pentagon*, (6) *hexagon*, (7) *heptagon*, (8) *octagon*, (9) *enneagon*, or *nonagon*, (10) *decagon*, and (12) *dodecagon*. Two regular polygons of the same number of sides are *similar*.

Properties of Triangles

General Triangle. The sum of the angles equals 180° . $\angle XAB$ (Fig. 5) is an *exterior angle* of $\triangle ABC$

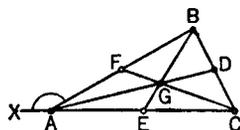

Fig. 5

and equals the sum of the opposite *interior angles* (i.e., $\angle XAB = \angle B + \angle C$). A *median* of a triangle is a line joining a vertex to the midpoint of the opposite side. The three medians meet at the *center of gravity*, G , and G trisects each median (e.g., $AG = \frac{2}{3}AD$). *Bisectors of angles* of a triangle (Fig. 6) meet in a point M equidistant from all sides. M is the center of the *inscribed circle* (tangent to all sides), or the *incenter* of the triangle. An angle bisector divides the opposite side into segments proportional to the adjacent sides of the angle (e.g. $AK/KC = AB/BC$). An *altitude* of a triangle is a perpendicular from a vertex to the opposite side. The three altitudes meet in a point called the *orthocenter*. The *perpendicular bisectors* of the sides of a triangle (Fig. 7) meet in a point O equidistant from all vertices. O is the center of the *circumscribed circle* (passing through all vertices), or the *circumcenter* of the triangle. The longest side of a triangle is opposite the largest angle, and vice versa. The line joining the midpoints of two sides of a triangle is parallel to the third side and half its length. If two triangles are mutually equiangular, they are similar, and their corresponding sides are proportional.

Orthogonal Projection. In Figs. 8 and 9, AE is the orthogonal projection of AB on AC , BE being perpendicular to AC . The square of the side opposite an acute angle equals the sum of the squares of the other two sides diminished by twice the product of one of those sides by the orthogonal projection of the other side upon it. In Fig. 8, $a^2 = b^2 + c^2 - 2b \cdot AE$. The

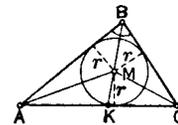

Fig. 6

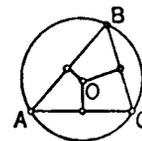

Fig. 7

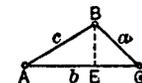

Fig. 8

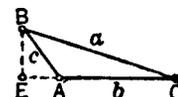

Fig. 9

square of the side opposite an obtuse angle equals the sum of the squares of the other two sides increased by twice the product of one of those sides by the orthogonal projection of the other side upon it. In Fig. 9, $a^2 = b^2 + c^2 + 2b \cdot AE$.

Right Triangle. In Fig. 10, let h be the altitude drawn from the vertex of right angle C to the hypotenuse c . Then $\angle A + \angle B = 90^\circ$; $c^2 = a^2 + b^2$; $h^2 = mn$; $b^2 = cm$; $a^2 = cn$; median from $C = c/2$.

Isosceles Triangle. Two sides are equal and their opposite angles are equal. If a straight line from the vertex at which the equal sides meet bisects the base, it also bisects the angle at the vertex and is perpendicular to the base.

Circles A *circle* is a closed plane curve, all the points of which are equidistant from a *center* point. A *chord* is a straight line joining two points on a curve, that is, joining the extremities of an *arc*. A *segment* of a circle is the part of its plane included between a concave arc and its chord. An angle *intercepts* an arc cut off by its sides; the arc *subtends* the angle. A *central angle* of a circle is one whose vertex is at the center and whose sides are two radii. A *sector* of a circle is the part of its plane that is included between an arc and two radii drawn to its extremities. A *secant* of a circle is a straight line intersecting it in two points. Parallel secants (or tangents) intercept equal arcs. A tangent line meets a circle in only one point and is perpendicular to the radius to that point. If a radius is perpendicular to a chord, it bisects both the chord and the arc intercepted by the chord. If two circles are tangent to each other, the line of centers passes through the point of contact; if the circles intersect, the line of centers bisects the common chord at right angles. In Fig. 11, the product of linear segments AC and AE equals the product of linear segments AB and AF . In Fig. 12, the product of the whole secant AB and its external segment AE equals the product of the whole

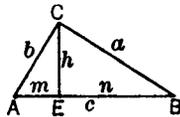

Fig. 10

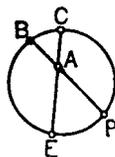

Fig. 11

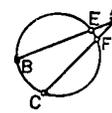

Fig. 12

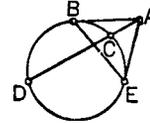

Fig. 13

secant AC and its external segment AF . In Fig. 13, the product of the whole secant AD and its external segment AC equals the square of tangent AB (or AE). Also $\angle ABE = \angle AEB$.

Angle Measurement. Considering the arc of a circle to be expressed in terms of the central angle that it subtends, the arc may be said to contain a certain number of degrees and hence be used to express the measurement of other angles related to the circle. On this basis, an entire circle equals 360° . The *inscribed angle* formed by two chords intersecting on a circle equals half the arc intercepted by it. Thus, in Fig. 14, $\angle BAC = \frac{1}{2}$ arc BC . An angle inscribed in a semicircle is a right angle. The angle formed by a tangent to a circle and a chord having one extremity at the point of contact equals half the arc intercepted by the chord. In Fig. 14, $\angle BAT = \frac{1}{2}$ arc BCA . The angle formed by two chords intersecting within a circle equals half the sum of the intercepted arcs. In Fig. 11, $\angle BAC$ (or $\angle EAF$) = $\frac{1}{2}$ (arc $BC +$ arc EF). The angle formed by two secants, or two tangents, or a secant and a tangent, intersecting outside a circle, equals half the difference of the intercepted arcs. In Fig. 12, $\angle BAC = \frac{1}{2}$ (arc $BC -$ arc EF). In Fig. 13, $\angle BAE = \frac{1}{2}$ (arc $BDE -$ arc BCE), and $\angle BAD = \frac{1}{2}$ (arc $BD -$ arc BC).

Coaxial Systems

Types

1. A set of nonintersecting circles having collinear centers and orthogonal to a given circle with

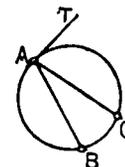

Fig. 14

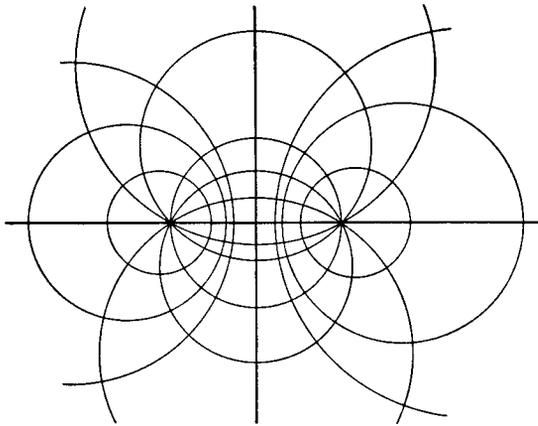

Fig. 15

center also collinear. The endpoints of the diameter of the given circle on the line of centers are the limiting points of the system (Fig. 15, centers on horizontal line).

2. A set of circles through two given points (Fig. 15, centers on vertical line).
3. A set of circles with a common point of tangency.
4. A set of concentric circles.
5. A set of concurrent lines.
6. A set of parallel lines.

Conjugate Systems. Two coaxial systems whose members are mutually orthogonal are *conjugate*. A conjugate pair may consist of (a) a system of type 1 and one of type 2, with the limiting points of one the common points of the other (Fig. 15); (b) two systems of type 3; (c) a system of type 4 and one of type 5; (d) two systems of type 6.

Inversion If the point O is the center of a circle c of radius r , if P and P' are collinear with O , and if $OP \cdot OP' = r^2$, then P and P' are *inverse* to each other with respect to the circle c (Fig. 16). The point O is the *center of inversion*.

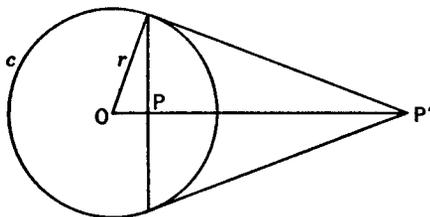

Fig. 16

The inverse of a circle not passing through the center of inversion is a circle, the inverse of a circle through the center is a straight line not through the center, and the inverse of a straight line through the center is itself.

Two intersecting curves invert into curves intersecting at the same angle.

Nonplanar Angles A *dihedral angle* is the opening between two intersecting planes. In Fig. 17, $P-BD-Q$ is a dihedral angle of which the two planes are the *faces* and their line of intersection DB is the *edge*. A *plane angle* that measures a dihedral angle is an angle formed by two lines, one in each face, drawn perpendicular to the edge at the same point (as $\angle ABC$). A *right dihedral angle* is one whose plane angle is a right angle. Through a given line oblique or parallel to a given plane, one and only one plane can be passed perpendicular to the given plane. The line of intersection CD (Fig. 18) is the *orthogonal projection* of line AB upon plane P . The *angle between a line and a plane* is the angle that the line (produced if necessary) makes with its orthogonal projection on the plane. This angle is the least angle that the line makes with any line in the plane.

A *polyhedral angle* is the opening of three or more planes that meet in a common point. In Fig. 19, $O-ABCDE$ is a polyhedral angle of which the intersections of the planes, as OA , OB , and so on, are the edges; the portions of the planes lying between the edges are the *faces*; and the common point O is the *vertex*. Angles formed by adjacent edges, as angles AOB , BOC , and so on, are *face angles*. A polyhedral angle

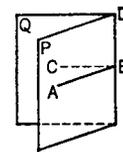

Fig. 17

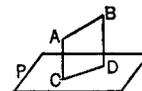

Fig. 18

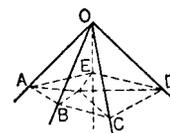

Fig. 19

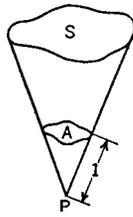

Fig. 20

is called a *trihedral angle* if it has three faces; a *tetrahedral angle* if it has four faces; and so on.

A *solid angle* measures the opening between surfaces, either planar or nonplanar, which meet in a common point. The polyhedral angle is a special case. In Fig. 20 the solid angle at any point P , subtended by any surface S , is equal numerically to the portion A of the surface of a sphere of unit radius that is cut out by a conical surface with vertex at P and having the boundary of S for base. The *unit solid angle* is the *steradian* and equals the central solid angle that intercepts a spherical area (of any shape) equal to the radius squared. The total solid angle about a point equals 4π steradians.

A *spherical angle* is the opening between two arcs of great circles drawn on a sphere from the same point (vertex) and is measured by the plane angle formed by tangents to its sides at its vertex. If the planes of the great circles are perpendicular, the angle is a *right spherical angle*.

Polyhedrons A *polyhedron* is a convex closed surface consisting of parts of four or more planes, called its faces; its faces intersect in straight lines, called its edges; its edges at points, called its vertices.

A *prism* is a polyhedron of which two faces (the *bases*) are congruent polygons in parallel planes and the other (*lateral*) faces are parallelograms whose planes intersect in the *lateral edges*. Prisms are *triangular*, *rectangular*, *quadrangular*, and so on, according as their bases are triangles, rectangles, quadrilaterals, and so on. A *right prism* has its lateral edges perpendicular to its bases. A prism whose bases are parallelograms is a *parallelepiped*; if in addition the edges are perpendicular to the bases, it is a *right parallelepiped*. A *rectangular parallelepiped* is a right parallelepiped whose bases are rectangles. A *cube* is a parallelepiped whose six faces are squares. A *truncated prism* is that part of a prism included between a base and a section made by a plane oblique to the base. A *right section* of a prism is a section made by a plane that cuts all the lateral edges perpendicularly.

A *prismatoid* is a polyhedron of which two faces (the bases) are polygons in parallel planes and the other (*lateral*) faces are triangles or trapezoids with one side common with one base and the opposite vertex or side common with the other base.

A *pyramid* is a polyhedron of which one face (the base) is a polygon and the other (*lateral*) faces are triangles meeting in a common point called the vertex of the pyramid and intersecting one another in its lateral edges. Pyramids are triangular, quadrangular, and so on, according as their bases are triangles, quadrilaterals, and so on. A *regular pyramid* (or *right pyramid*) has for its base a regular polygon whose center coincides with the foot of the perpendicular dropped from the vertex to the base. A *frustum of a pyramid* is the portion of a pyramid included between its base and a section parallel to the base. If the section is not parallel to the base, a *truncated pyramid* results.

A *regular polyhedron* has all faces formed of congruent regular polygons and all polyhedral angles equal. The only regular polyhedrons possible are the five types discussed in the mensuration table (Table 4).

A *tetrahedron* is a polyhedron of four faces. It may be described also as a triangular pyramid, and any one of its four triangular faces may be considered as the base. The four perpendiculars erected at circumcenters of the four faces meet in a point equidistant from all vertices, which is the center of the circumscribed sphere. The four *medians*, joining each vertex with the center of gravity of the opposite face, meet in a point, which is the *center of gravity* of the tetrahedron. This point is three-fourths of the distance from each vertex along a median. The four altitudes meet in a point, called the *orthocenter* of the tetrahedron. The six planes bisecting the six dihedral angles meet in a point equidistant from all faces, this being the center of the inscribed sphere.

Solids Having Curved Surfaces A *cylinder* is a solid bounded by two parallel plane surfaces (the bases) and a cylindrical lateral surface. A *cylindrical surface* is a surface generated by the movement of a straight line (the *generatrix*) which constantly is parallel to a fixed straight line and touches a fixed curve (the *directrix*) not in the plane of the fixed straight line. The generatrix in any position is an *element* of the cylindrical surface. A *circular cylinder* is one having circular bases. A *right cylinder* is one whose elements are perpendicular to its bases. A *truncated cylinder* is the part of a cylinder included between a base and a section made by a plane oblique to the base. A *right section* of a cylinder is a section made by a plane which cuts all the elements perpendicularly.

A *cone* is a solid bounded by a conic lateral surface and a plane (the base) that cuts all the elements of the conic surface. A *conic surface* is a surface generated by the movement of a straight line (the generatrix) that constantly touches a fixed plane curve (the directrix) and passes through a fixed point (the vertex) not in the plane of the fixed curve. The generatrix in any position is an *element* of the conic surface. A *circular cone* is one having a circular base. A *right cone* is a circular cone whose center of the base coincides with the foot of the perpendicular dropped from the vertex to the base. A *frustum of a cone* is the portion of a

Table 4 Mensuration Formulas

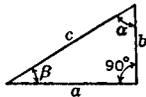

Approximate Decimal Equivalents (for reference)

$\pi = 3.1416$	$\frac{1}{\pi} = 0.318$	$\sqrt{2} = 1.414$

1a. Plane Rectilinear Figures

Notation. Lines, a, b, c, \dots ; angles, $\alpha, \beta, \gamma, \dots$; altitude (perpendicular height), h ; side, l ; diagonals, d, d_1, \dots ; perimeter, p ; radius of inscribed circle, r ; radius of circumscribed circle, R ; area, A .

1. Right triangle

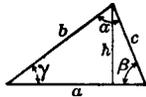

(One angle 90°)

$$p = a + b + c; c^2 = a^2 + b^2;$$

$$A = \frac{1}{2}ab = \frac{1}{2}a^2 \tan \beta = \frac{1}{4}c^2 \sin 2\beta = c \frac{1}{4}c^2 \sin 2\alpha.$$

For additional formulas, see *general triangle* below and also trigonometry.

2. General triangle (and equilateral triangle)

For general triangle:

$$p = a + b + c. \text{ Let } s = \frac{1}{2}(a + b + c).$$

$$r = \frac{\sqrt{s(s-a)(s-b)(s-c)}}{s}; R = \frac{a}{2 \sin \alpha} = \frac{abc}{4rs};$$

$$A = \frac{ah}{2} = \frac{ab}{2} \sin \gamma = \frac{b^2 \sin \gamma \sin \alpha}{2 \sin \beta} = rs = \frac{abc}{4R}.$$

$$\text{Length of median to side } c = \frac{1}{2}\sqrt{2(a^2 + b^2) - c^2}.$$

$$\text{Length of bisector of angle } \gamma = \frac{\sqrt{ab[(a+b)^2 - c^2]}}{a+b}.$$

For equilateral triangle ($a = b = c = l$ and $\alpha = \beta = \gamma = 60^\circ$):

(Equal sides and equal angles)

$$p = 3l, r = \frac{l}{2\sqrt{3}}; R = \frac{l}{\sqrt{3}} = 2r;$$

$$h = \frac{l\sqrt{3}}{2}; l = \frac{2h}{\sqrt{3}}; A = \frac{l^2\sqrt{3}}{4}.$$

For additional formulas, see trigonometry.

3. Rectangle (and square)

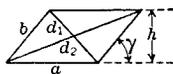

$$p = 2(a + b); d = \sqrt{a^2 + b^2}; A = ab.$$

For square ($a = b = l$):

$$p = 4l; d = l\sqrt{2}; l = \frac{d}{\sqrt{2}}; A = l^2 = \frac{d^2}{2}.$$

4. General parallelogram (and rhombus)

For general parallelogram (rhomboid):

(Opposite sides parallel)

$$p = 2(a + b); d_1 = \sqrt{a^2 + b^2 - 2ab \cos \gamma};$$

$$d_2 = \sqrt{a^2 + b^2 + 2ab \cos \gamma}; d_1^2 + d_2^2 = 2(a^2 + b^2);$$

$$A = ah = ab \sin \gamma.$$

Table 4 (Continued)

1a. Plane Rectilinear Figures (Continued)

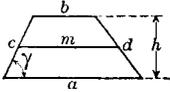

For rhombus ($a = b = l$):

(Opposite sides parallel and all sides equal)

$$p = 4l; d_1 = 2l \sin \frac{1}{2}\gamma; d_2 = 2l \cos \frac{1}{2}\gamma; d_1^2 + d_2^2 = 4l^2;$$

$$d_1 d_2 = 2l^2 \sin \gamma; A = lh = l^2 \sin \gamma = \frac{1}{2}(d_1 d_2).$$

5. General trapezoid (and isosceles trapezoid)

Let midline bisecting nonparallel sides = m . Then $m = \frac{1}{2}(a + b)$.

For general trapezoid:

(Only one pair of opposite sides parallel)

$$p = a + b + c + d; A = \frac{1}{2}(a + b)h = mh.$$

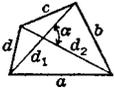

For isosceles trapezoid ($d = c$):

(Nonparallel sides equal)

$$A = \frac{1}{2}(a + b)h = mh = \frac{1}{2}(a + b)c \sin \gamma$$

$$= (a - c \cos \gamma)c \sin \gamma = (b + c \cos \gamma)c \sin \gamma.$$

6. General quadrilateral (trapezium)

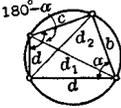

(No sides parallel)

$$p = a + b + c + d.$$

$$A = \frac{1}{2}d_1 d_2 \sin \alpha = \text{sum of areas of the two triangles formed by either diagonal and the four sides.}$$

7. Quadrilateral inscribed in circle

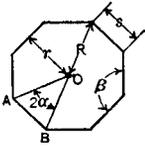

(Sum of opposite angles = 180°)

$$ac + bd = d_1 d_2.$$

$$\text{Let } s = \frac{1}{2}(a + b + c + d) = \frac{1}{2}p \text{ and } \alpha = \text{angle between sides } a \text{ and } b.$$

$$A = \sqrt{(s - a)(s - b)(s - c)(s - d)} = \frac{1}{2}(ab + cd) \sin \alpha.$$

8. Regular polygon (and general polygon)

For regular polygon:

(Equal sides and equal angles)

Let n = number of sides.

$$\text{Central angle} = 2\alpha = \frac{2\pi}{n} \text{ radians;}$$

$$\text{Vertex angle} = \beta = \frac{n - 2}{n}\pi \text{ radians.}$$

$$p = ns; s = 2r \tan \alpha = 2R \sin \alpha;$$

$$r = \frac{1}{2}s \cot \alpha; R = \frac{1}{2}s \csc \alpha;$$

$$A = \frac{1}{2}nsr = nr^2 \tan \alpha = \frac{1}{2}nR^2 \sin 2\alpha = \frac{1}{4}ns^2 \cot \alpha = \text{sum of areas of the } n \text{ equal triangles such as } \triangle OAB.$$

For general polygon:

 A = sum of areas of constituent triangles into which it can be divided.

Table 4 (Continued)

1b. Plane Curvilinear Figures

Notation. Lines, a, b, \dots ; radius, r ; diameter, d ; perimeter, p ; circumference, c ; central angle n radians, θ ; arc, s ; chord of arc s , l ; chord of half arc $s/2$, l' ; rise, h ; area, A .

9. Circle (and circular arc)

For circle:

$$d = 2r; c = 2\pi r = \pi d; A = \pi r^2 = \frac{\pi d^2}{4} = \frac{c^2}{4\pi}.$$

For circular arc:

Let arc $PAQ = s$; and chord $PA = l'$. Then, $s = r\theta = \frac{1}{2}d\theta$; $s = \frac{1}{3}(8l' - l)$.

(The latter equation is Huygen's approximate formula. For θ small; error is very small; for $\theta = 120^\circ$, error is about 0.25%; for $\theta = 180^\circ$, error is less than 1.25%.)

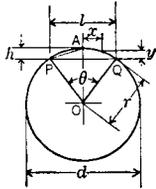

$$l = 2r \sin \frac{1}{2}\theta; l = 2\sqrt{2hr - h^2} \text{ (approximate formula)}$$

$$r = \frac{s}{\theta} = \frac{l}{2 \sin(\theta/2)}; r = \frac{4h^2 + l'^2}{8h} \text{ (approximate formula)}$$

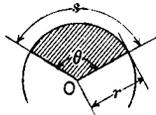

$$h = r \mp \sqrt{r^2 - \frac{1}{4}l'^2} \text{ (- if } \theta \leq 180^\circ \text{ + if } \theta \geq 180^\circ) = r(1 - \cos \frac{1}{2}\theta)$$

$$= r \operatorname{versin} \frac{1}{2}\theta = 2r \sin^2 \frac{1}{4}\theta = \frac{1}{2}l \tan \frac{1}{4}\theta = r + y - \sqrt{r^2 - x^2}.$$

$$\text{Side ordinate } y = h - r + \sqrt{r^2 - x^2}.$$

10. Circular sector (and semicircle)

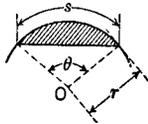

For circular sector:

$$A = \frac{1}{2}\theta r^2 = \frac{1}{2}sr.$$

For semicircle:

$$A = \frac{1}{2}\pi r^2.$$

11. Circular segment

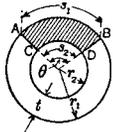

$$A = \frac{1}{2}r^2(\theta - \sin \theta)$$

$$= \frac{1}{2}[sr \mp l(r - h)](- \text{if } h \leq r; + \text{if } h \geq r).$$

$$A = \frac{2lh}{3} \text{ or } \frac{h}{15}(8l' + 6l). \text{ (Approximate formulas. For } h \text{ small compared with } r,$$

error is very small; for $h = \frac{1}{4}r$, first formula errs about 3.5% and second less than 1.0%.)

12. Annulus

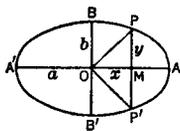

(Region between two concentric circles)

$$A = \pi(r_1^2 - r_2^2) = \pi(r_1 + r_2)(r_1 - r_2);$$

$$A \text{ of sector } ABCD = \frac{1}{2}\theta(r_1^2 - r_2^2) = \frac{1}{2}\theta(r_1 + r_2)(r_1 - r_2)$$

$$= \frac{1}{2}t(s_1 + s_2).$$

13. Ellipse

$$p = \pi(a + b) \left(1 + \frac{R^2}{4} + \frac{R^4}{64} + \frac{R^4}{256} + \dots \right) \text{ where } R = \frac{a - b}{a + b}.$$

$$p = \pi(a + b) \frac{64 - 3R^4}{64 - 16R^2} \text{ (approximate formula).}$$

$$A = \pi ab; A \text{ of quadrant } AOB = \frac{1}{4}\pi ab;$$

$$A \text{ of sector } AOP = \frac{ab}{2} \cos^{-1} \frac{x}{a}; A \text{ of sector } POB = \frac{ab}{2} \sin^{-1} \frac{x}{a};$$

Table 4 (Continued)

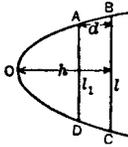

1b. Plane Curvilinear Figures (Continued)

A of section $BPP'B' = xy + ab \sin^{-1} \frac{x}{a}$;

A of segment $PAP'P = -xy + ab \cos^{-1} \frac{x}{a}$.

For additional formulas, see analytic geometry.

14. Parabola

Arc $BOC = s = \frac{1}{2} \sqrt{l^2 + 16h^2} + \frac{l^2}{8h} \log_e \frac{4h + \sqrt{l^2 + 16h^2}}{l}$.

Let $R = \frac{h}{l}$. Then:

$s = l \left(1 + \frac{8R^2}{3} - \frac{32R^4}{5} + \dots \right)$ (approximate formula).

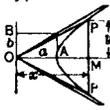

$d = \frac{h}{l^2} (l^2 - l_1^2)$; $l_1 = l \sqrt{\frac{h-d}{h}}$; $h = \frac{dl^2}{l^2 - l_1^2}$;

A of segment $BOC = \frac{2hl}{3}$;

A of section $ABCD = \frac{2}{3} d \left(\frac{l^3 - l_1^3}{l^2 - l_1^2} \right)$.

For additional formulas, see analytic geometry.

15. Hyperbola

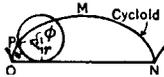

A of figure $OPAP'O = ab \log_e \left(\frac{x}{a} + \frac{y}{b} \right) = ab \cosh^{-1} \frac{x}{a}$;

A of segment $PAP' = xy - ab \log_e \left(\frac{x}{a} + \frac{y}{b} \right) = xy - ab \cosh^{-1} \frac{x}{a}$.

For additional formulas, see analytic geometry.

16. Cycloid

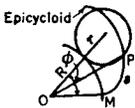

Arc $OP = s = 4r(1 - \cos \frac{1}{2}\phi)$; arc $OMN = 8r$;

A under curve $OMN = 3\pi r^2$.

For additional formulas, see analytic geometry.

17. Epicycloid

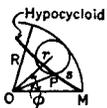

Arc $MP = s = \frac{4r}{R} (R + r) \left(1 - \cos \frac{R\phi}{2r} \right)$;

Area $MOP = A = \frac{r}{2R} (R + r)(R + 2r) \left(\frac{R\phi}{r} - \sin \frac{R\phi}{r} \right)$.

For additional formulas, see analytic geometry.

18. Hypocycloid

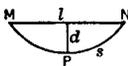

Arc $MP = s = \frac{4r}{R} (R - r) \left(1 - \cos \frac{R\phi}{2r} \right)$;

Area $MOP = A = \frac{r}{2R} (R - r)(R - 2r) \left(\frac{R\phi}{r} - \sin \frac{R\phi}{r} \right)$.

For additional formulas, see analytic geometry.

19. Catenary

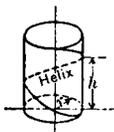

If d is small compared with l :

Arc $MPN = s = l \left[1 + \frac{2}{3} \left(\frac{2d}{l} \right)^2 \right]$ (approximately).

For additional formulas, see analytic geometry:

20. Helix (a skew curve)

Let length of helix = s ; radius of coil (= radius of cylinder in figure) = r ;
distance advanced in one revolution = pitch = h ; and number of revolutions = n . Then:

$s = n\sqrt{(2\pi r)^2 + h^2}$.

Durand's rule	<p>Simpson's rule (n must be even) $A = \frac{1}{3} w[(y_0 + y_n) + 4(y_1 + y_3 + \dots + y_{n-1}) + 2(y_2 + y_4 + \dots + y_{n-2})]$;</p>
Simpson's rule (n must be even)	<p>Weddle's rule (for 6 strips only) $A = \frac{3w}{10} [5(y_1 + y_5) + 6y_3 + y_0 + y_2 + y_4 + y_6]$.</p>
Weddle's rule (for 6 strips only)	<p>Areas of irregular regions can often be determined more quickly by such methods as plotting on squared paper and counting the squares; graphical coordinate representation (see analytic geometry); or use of a planimeter.</p>
1c. Solids Having Plane Surfaces	
<p><i>Notation.</i> Lines, a, b, c, \dots; altitude (perpendicular height), h; slant height, s; perimeter of base, p_h or p_B; perimeter of a right section, p_r; area of base, A_b or A_B; area of a right section, A_r; total area of lateral surfaces, A_l; total area of all surfaces, A_t; volume, V.</p>	
23. Wedge (and right triangular prism)	<p>For wedge: (Narrow-side rectangular); $V = \frac{1}{6}ab(2l_1 + l_2)$.</p>
	<p>For right triangular prism (or wedge having parallel triangular bases perpendicular to sides): $l_2 = l_1 = l$:</p>
24. Rectangular prism (or rectangular parallelepiped) (and cube)	<p>$V = \frac{1}{2}abl$.</p>
	<p>For rectangular prism or rectangular parallelepiped:</p>
25. General prism	<p>$A_l = 2c(a + b)$; $A_t = 2(de + ac + bc)$;</p>
	<p>$V = A_r c = abc$. For cube (letting $b = c = a$):</p>
26. General truncated prism (and truncated triangular prism)	<p>$A_t = 6a^2$; $V = a^3$; diagonal $= a\sqrt{3}$.</p>
	<p>$A_l = hp_b = sp_r = s(a + b + \dots + n)$;</p>
27. Prismaticoid	<p>$V = hA_b = sA_r$.</p>
	<p>For general truncated prism: $V = A_r \cdot$ (length of line BC joining centers of gravity of bases).</p> <p>For truncated triangular prism: $V = \frac{1}{3}A_r(a + b + c)$.</p>
<p>Let area of midsection $= A_m$.</p>	<p>$V = \frac{1}{6}h(A_B + A_b + 4A_m)$.</p>

Table 4 (Continued)

1c. Solids Having Plane Surfaces (Continued)

28. Right regular pyramid (and prustum of right regular pyramid)

For right regular pyramid:

$$A_t = \frac{1}{2}sp_B; V = \frac{1}{3}hA_B.$$

For prustum of right regular pyramid:

$$A_t = \frac{1}{2}s(p_B + p_b); V = \frac{1}{3}h(A_B + A_b + \sqrt{A_B A_b}).$$

29. General pyramid (and prustum of pyramid)

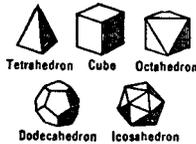

For general pyramid:

$$V = \frac{1}{3}hA_B.$$

For prustum of general pyramid:

$$V = \frac{1}{3}h(A_B + A_b + \sqrt{A_B A_b}).$$

30. Regular polyhedrons

Let edge = a , and radius of inscribed sphere = r . Then:

$$r = \frac{3V}{A_t} \text{ and:}$$

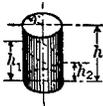

Number of Faces	Form of Faces	Total Area A_t	Volume V
4	Equilateral triangle	$1.7321a^2$	$0.1179a^3$
6	Square	$6.0000a^2$	$1.0000a^3$
8	Equilateral triangle	$3.4641a^2$	$0.4714a^3$
12	Regular pentagon	$20.6457a^2$	$7.6631a^3$
20	Equilateral triangle	$8.6603a^2$	$2.1817a^3$

(Factors shown only to four decimal places.)

1d. Solids Having Curved Surfaces

Notation. Lines, a, b, c, \dots ; altitude (perpendicular height), h, h_1, \dots ; slant height, s ; radius, r ; perimeter of base, p_b ; perimeter of a right section, p_r ; angle in radians, ϕ ; arc, s ; chord of segment, l ; rise, h ; area of base, A_b or A_B ; area of a right section, A_r ; total area of convex surface, A_t ; total area of all surfaces, A_t ; volume, V .

31. Right circular cylinder (and truncated right circular cylinder)

For right circular cylinder:

$$A_t = 2\pi rh; A_t = 2\pi r(r + h);$$

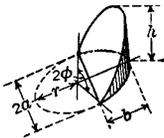

$$V = \pi r^2 h.$$

For truncated right circular cylinder:

$$A_t = \pi r(h_1 + h_2); A_t = \pi r[h_1 + h_2 + r + \sqrt{r^2 + \frac{1}{2}(h_1 - h_2)^2}];$$

$$V = \frac{1}{2}\pi r^2(h_1 + h_2).$$

32. Ungula (wedge) of right circular cylinder

$$A_t = \frac{2rh}{b}[a + (b - r)\phi];$$

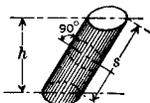

$$V = \frac{h}{3b}[a(3r^2 - a^2) + 3r^2(b - r)\phi]$$

$$= \frac{hr^3}{b}\left[\sin\phi - \frac{\sin^3\phi}{3} - \phi\cos\phi\right].$$

For semicircular base (letting $a = b = r$):

$$A_t = 2rh; V = \frac{2r^2h}{3}.$$

33. General cylinder

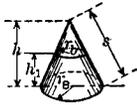

$$A_t = p_b h = p_r s;$$

$$V = A_b h = A_r s.$$

Table 4 (Continued)

1d. Solids Having Curved Surfaces (Continued)

34. Right circular cone (and frustum of right circular cone)

For right circular cone:

$$A_l = \pi r_B s = \pi r_B \sqrt{r_B^2 + h^2}; \quad A_t = \pi r_B (r_B + s);$$

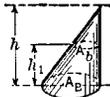

$$V = \frac{1}{3} \pi r_B^2 h.$$

For frustum of right circular cone:

$$s = \sqrt{h_1^2 + (r_B - r_b)^2}; \quad A_l = \pi s (r_B + r_b);$$

$$V = \frac{1}{3} \pi h_1 (r_B^2 + r_b^2 + r_B r_b).$$

35. General cone (and frustum of general cone)

For general cone:

$$V = \frac{1}{3} A_B h.$$

For frustum of general cone:

$$V = \frac{1}{3} h_1 (A_B + A_b + \sqrt{A_B A_b}).$$

36. Sphere

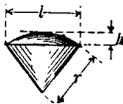

Let diameter = d .

$$A_t = 4\pi r^2 = \pi d^2;$$

$$V = \frac{4\pi r^3}{3} = \frac{\pi d^3}{6}.$$

37. Spherical sector (and hemisphere)

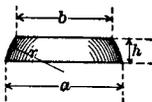

For spherical sector:

$$A_t = \frac{\pi r}{2} (4h + l); \quad V = \frac{2\pi r^2 h}{3}.$$

For hemisphere (letting $h = \frac{1}{2}l = r$):

$$A_t = 3\pi r^2; \quad V = \frac{2\pi r^3}{3}.$$

38. Spherical zone (and spherical segment)

For spherical zone bounded by two planes:

$$A_l = 2\pi r h; \quad A_t = \frac{1}{4} \pi (8rh + a^2 + b^2).$$

For spherical zone bounded by one plane ($b = 0$):

$$A_l = 2\pi r h = \frac{1}{4} \pi (4h^2 + a^2);$$

$$A_t = \frac{1}{4} \pi (8rh + a^2) = \frac{1}{2} \pi (2h^2 + a^2).$$

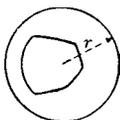

For spherical segment with two bases:

$$V = \frac{1}{24} \pi h (3a^2 + 3b^2 + 4h^2).$$

For spherical segment with one base ($b = 0$):

$$V = \frac{1}{24} \pi h (3a^2 + 4h^2) = \pi h^2 (r - \frac{1}{3}h).$$

39. Spherical polygon (and spherical triangle)

For spherical polygon:

Let sum of angles in radians = θ and number of sides = n .

$$A = [\theta - (n - 2)\pi] r^2$$

[The quantity $\theta - (n - 2)\pi$ is called "spherical excess."]

For spherical triangle ($n = 3$):

$$A = (\theta - \pi) r^2$$

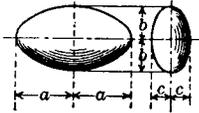

For additional formulas, see trigonometry.

Table 4 (Continued)

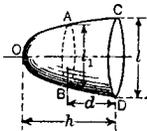

40. Torus

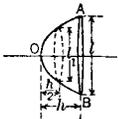

41. Ellipsoid (and spheroids)

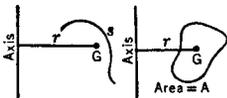

42. Paraboloid of revolution

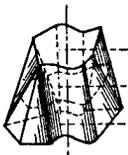

43. Hyperboloid of revolution

44. Surface and solid of revolution

45. Irregular solid

1d. Solids Having Curved Surfaces (Continued)

$$A_t = 4\pi^2 Rr;$$

$$V = 2\pi^2 Rr^2.$$

For ellipsoid:

$$V = \frac{4}{3}\pi abc.$$

For prolate spheroid:

$$\text{Let } c = b \text{ and } \frac{\sqrt{a^2 - b^2}}{a} = e.$$

$$A_t = 2\pi b^2 + 2\pi ab \frac{\sin^{-1} e}{e}; \quad V = \frac{4}{3}\pi ab^2.$$

For oblate spheroid:

$$\text{Let } c = a \text{ and } \frac{\sqrt{a^2 - b^2}}{a} = e.$$

$$A_t = 2\pi a^2 + \frac{\pi b^2}{e} \ln \left(\frac{1+e}{1-e} \right); \quad V = \frac{4}{3}\pi a^2 b.$$

$$A_t \text{ of segment } DOC = \frac{2\pi l}{3h^2} \left[\left(\frac{l^2}{16} + h^2 \right)^{3/2} - \left(\frac{l}{4} \right)^3 \right].$$

For paraboloidal segment with two bases:

$$V \text{ of } ABCD = \frac{\pi d}{8} (l^2 + l_1^2).$$

For paraboloidal segment with one base ($l_1 = 0$ and $d = h$):

$$V \text{ of } DOC = \frac{\pi h l^2}{8}.$$

$$V \text{ of segment } AOB = \frac{\pi h}{24} (l^2 + 4l_1^2).$$

Let perpendicular distance from axis to center of gravity (G) of curve (or surface) = r . Curve (or surface) must not cross axis. Then,

Area of surface generated by curve revolving about axis:

$$A_t = 2\pi r s.$$

Volume of solid generated by surface revolving about axis:

$$V = 2\pi r A.$$

One of the following methods can often be employed to determine the volume of an irregular solid with a reasonable approach to accuracy:

- Divide the solid into prisms, cylinders, etc., and sum their individual volumes.
- Divide one surface into triangles after replacing curved lines by straight ones and curved surfaces by plane ones. Then multiply the area of each triangle by the mean depth of the section beneath it (which generally approximates the average of the depths at its corners). Sum the volumes thus obtained.
- If two surfaces are parallel, replace any curved lateral surfaces by plane surfaces best suited to the contour and then employ the prismatoidal formula.

cone included between its base and a section parallel to the base.

A *sphere* is a solid bounded by a surface all points of which are equidistant from a point within called the *center*. Every plane section of a sphere is a circle. This circle is a *great circle* if its plane passes through the center of the sphere; otherwise, it is a *small circle*. *Poles* of such a circle are the extremities of the diameter of the sphere that is perpendicular to the plane of the circle. Through two points on a spherical surface, not extremities of a diameter, one great circle can be passed. The shortest line that can be drawn on the surface of a sphere between two such points is an arc of a great circle less than a semicircumference joining those points. If two spherical surfaces intersect, their line of intersection is a circle whose plane is perpendicular to the line of centers and whose center lies on this line.

A *spherical sector* is the portion of a sphere generated by the revolution of a circular sector about a diameter of the circle of which the sector is a part. A *hemisphere* is half of a sphere.

A *spherical segment* is the portion of a sphere contained between two parallel plane sections (the bases), one of which may be tangent to the sphere (in which case there is only one base). The term "segment" also is applied in an analogous manner to various solids of revolution, the planes in such cases being perpendicular to an axis. A *zone* is the portion of a spherical surface included between two parallel planes.

A *spherical polygon* is a figure on a spherical surface bounded by three or more arcs of great circles. The sum of the angles of a spherical triangle (polygon of three sides) is greater than two right angles and less than six right angles.

Other solids appearing in the mensuration table (Table 4), if not sufficiently defined by their figures, may be found discussed in the section on analytic geometry.

5.2 Mensuration

Perimeters of similar figures are proportional to their respective linear dimensions, areas to the squares of their linear dimensions, and volumes of similar solids to the cubes of their linear dimensions (see Table 4).

5.3 Constructions

Lines

1. To draw a line parallel to a given line.

CASE 1: At a given distance from the given line (Fig. 21). With the given distance as radius and with any centers m and n on the given line AB , describe arcs xy and zw , respectively. Draw CD touching these arcs. CD is the required parallel line.

CASE 2: Through a given point (Fig. 22). Let C be the given point and D be any point on the given line AB . Draw CD . With equal radii draw arcs bf and ce

Fig. 21

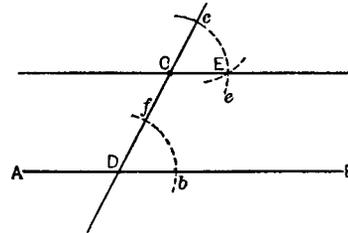

Fig. 22

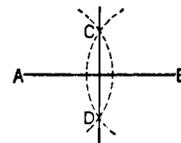

Fig. 23

with D and C , respectively, as centers. With radius equal to chord bf and with c as center draw an arc cutting arc ce at E . CE is the required parallel line.

2. To bisect a given line (Fig. 23). Let AB be the given line. With any radius greater than $0.5 AB$ describe two arcs with A and B as centers. The line CD , through points of intersection of the arcs, is the perpendicular bisector of the given line.

3. To divide a given line into a given number of equal parts (Fig. 24). Let AB be the given line and let the number of equal parts be five. Draw line AC at any convenient angle with AB , and step off with dividers five equal lengths from A to b . Connect b with B , and draw parallels to Bb through the other points in AC . The intersections of these parallels with AB determine the required equal parts on the given line.

4. To divide a given line into segments proportional to a number of given unequal parts. Follow the same procedure as under item 3 except make the

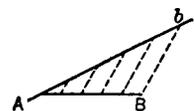

Fig. 24

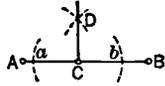

Fig. 25

lengths on AC equal to (or proportional to) the lengths of the given unequal parts.

5. To erect a perpendicular to a given line at a given point in the line.

CASE 1: Point C is at or near the middle of the line AB (Fig. 25). With C as center, describe arcs of equal radii intersecting AB at a and b . With a and b as centers, and any radius greater than Ca , describe arcs intersecting at D . CD is the required perpendicular.

CASE 2: Point C is at or near the extremity of the line AB (Fig. 26). With any point O as center and radius OC , describe an arc intersecting AB at a . Extend aO to intersect the arc at D . CD is the required perpendicular.

6. To erect a perpendicular to a given line through a given point outside the line.

CASE 1: Point C is opposite, or nearly opposite, the middle of the line AB (Fig. 27). With C as center, describe an arc intersecting AB at a and b . With a and b as centers, describe arcs of equal radii intersecting at D . CD is the required perpendicular.

CASE 2: Point C is opposite, or nearly opposite, the extremity of the line AB (Fig. 28). Through C , draw any line intersecting AB at a . Divide line Ca into two equal parts, ab and bC (method given previously). With b as center and radius bC , describe an arc intersecting AB at D . CD is the required perpendicular.

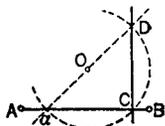

Fig. 26

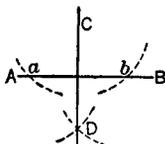

Fig. 27

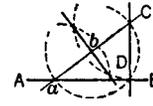

Fig. 28

Angles

7. To bisect a given angle.

CASE 1: Vertex B is accessible (Fig. 29). Let ABC be the given angle. With B as center and a large radius, describe an arc intersecting AB and BC at a and c , respectively. With a and c as centers, describe arcs of equal radii intersecting at D . DB is the required bisector.

CASE 2: The vertex is inaccessible (Fig. 30). Let the given angle be that between lines AB and BC . Draw lines ab and bc parallel to the given lines, and at equal distances from them, intersecting at b . Construct Db bisecting angle abc (method given previously). Db is the required bisector.

8. To construct an angle equal to a given angle if one new side and the new vertex are given (Fig. 31). Let ABC be the given angle, DE the new side, and E the new vertex. With center B and a convenient radius, describe arc ac . With the same radius and center E , draw arc df . With radius equal to chord ac and with center d draw an arc cutting the arc df at F . Draw EF . Then DEF is the required angle.

9. To construct angles of 60° and 30° (Fig. 32). About any point A on a line AB , describe with a

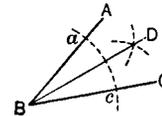

Fig. 29

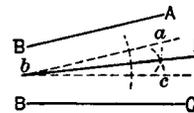

Fig. 30

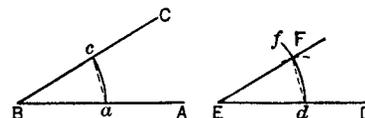

Fig. 31

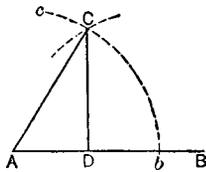

Fig. 32

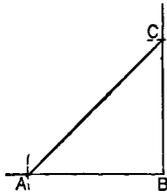

Fig. 33

convenient radius the arc bc . From b , using an equal radius, describe an arc cutting the former one at C . Draw AC , and drop a perpendicular CD from C to line AB . Then CAD is a 60° angle and ACD is a 30° angle.

10. To construct an angle of 45° (Fig. 33). Set off any distance AB ; draw BC perpendicular and equal to AB and join CA . Angles CAB and ACB are each 45° .

11. To draw a line making a given angle with a given line (Fig. 34). Let AB be the given line. With A as the center and with as large a radius as convenient, describe arc bc . Determine from Table 12 in Chapter 1, the length of chord to radius 1, corresponding to the given angle. Multiply this chord by the length of Ab , and with the product as a new radius and b as a center, describe an arc cutting bc at C . Draw AC . This line makes the required angle with AB .

Circles

12. To describe through two given points an arc of a circle having a given radius (Fig. 35). Let A and B

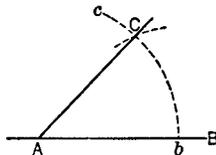

Fig. 34

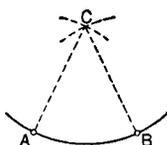

Fig. 35

be the given points. With the given radius and these points as centers, describe arcs cutting each other at C . From C , with the same radius, describe arc AB , which is the required arc.

13. To bisect a given arc of a circle. Draw the perpendicular bisector of the chord of the arc. The point in which this bisector meets the arc is the required midpoint.

14. To locate the center of a given circle or circular arc (Fig. 36). Select three points A, B, C on the circle (or arc) located well apart. Draw chords AB and BC and erect their perpendicular bisectors. The point O , where the bisectors intersect, is the required center.

15. To draw a circle through three given points not in the same straight line.

CASE 1: Radius small and center accessible (Fig. 36). Let A, B, C be the given points. Draw lines AB and BC and erect their perpendicular bisectors. From point O , where the bisectors intersect, describe a circle of radius OA that is the required circle.

CASE 2: Radius very long or center inaccessible (Fig. 37). Let A, O, A' be the given points (O not necessarily midpoint of AOA'). Draw arcs Aa' and $A'a$ with centers at A' and A , respectively; extend AO to determine a and $A'O$ to determine a' ; point off from a on aA' equal parts ab, bc , and so on; lay off $a'b', b'c'$, and so on, equal to ab ; join A with any point as b and A' with the corresponding point b' ; the intersection P of these joining lines is a point on the required circle.

16. To lay out a circular arc without locating the center of the circle, given the chord and the rise (Fig. 37). Let AA' be the chord and QO the rise. (In this case, O is the midpoint of AOA' .) The arc can be

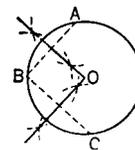

Fig. 36

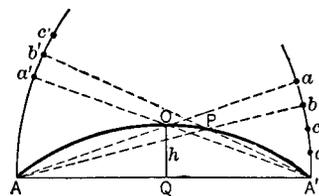

Fig. 37

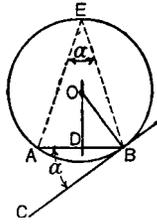

Fig. 38

constructed through the points A, O, A' , as under item 15, Case 2.

17. To construct, upon a given chord, a circle in which a given angle can be inscribed (Fig. 38). Let AB be the given chord and α the given angle. Construct angle ABC equal to angle α . Bisect line AB by the perpendicular at D . Draw a perpendicular to BC from point B . With O , the point of intersection of the perpendiculars, as center and OB as radius, describe a circle. The angle AEB , with vertex E located anywhere on the arc AEB , equals α , and therefore the circle just drawn is the one required.

18. To draw a tangent to a given circle through a given point.

CASE 1: Point A is on the circle (Fig. 39). Draw radius OA . Through A , perpendicular to OA , draw BAC , the required tangent.

CASE 2: Point A is outside the circle (Fig. 40). Two tangents can be drawn. Join O and A . Bisect OA at D , and with D as center and DO as radius, describe an arc intersecting the given circle at B and C . BA and CA are the required tangents.

19. To draw a common tangent to two given circles. Let the circles have centers O and O' and corresponding radii r and r' ($r > r'$).

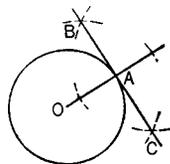

Fig. 39

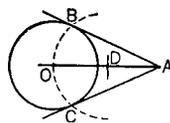

Fig. 40

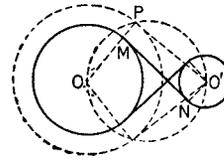

Fig. 41

CASE 1: Common internal tangents (when circles do not intersect) (Fig. 41). Construct a circle having the same center O as the larger circle and a radius equal to the sum of the radii of the given circles ($r + r'$). Construct a tangent $O'P$ from center O' of the smaller circle to this circle. Construct $O'N$ perpendicular to this tangent. Draw OP . The line MN joining the extremities of the radii OM and $O'N$ is a common tangent. The figure shows two such common internal tangents.

CASE 2: Common external tangents (Fig. 42). Construct a circle having the same center O as the larger circle and radius equal to the difference of the radii ($r - r'$). Construct a tangent to this circle from the center of the smaller circle. The line joining the extremities M, N of the radii of the given circles perpendicular to this tangent is a required common tangent. There are two such tangents.

20. To draw a circle with a given radius that will be tangent to two given circles. (Fig. 43). Let r be the given radius and A and B the given circles. About center of circle A with radius equal to r plus radius of A , and about center of B with radius equal to r plus radius of B , draw two arcs cutting each other in C , which is the center of the required circle.

21. To describe a circular arc touching two given circles, one of them at a given point. (Fig. 44). Let AB, FG be the given circles and F the given point. Draw the radius EF , and produce it both ways. Set off FH

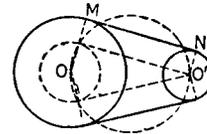

Fig. 42

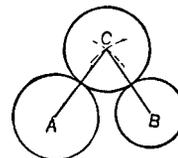

Fig. 43

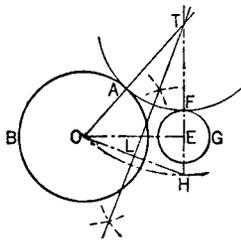

Fig. 44

equal to the radius AC of the other circle; join CH , and bisect it by the perpendicular LT , cutting EF at T . About center T , with radius TF , describe arc FA as required.

22. To draw a circular arc that will be tangent to two given lines inclined to one another, one tangential point being given (Fig. 45). Let AB and CD be the given lines and E the given point. Draw the line GH , bisecting the angle formed by AB and CD . From E draw EF at right angles to AB ; then F , its intersection with GH , is the center of the required circular arc.

23. To connect two given parallel lines by a reversed curve composed of two circular arcs of equal radius, the curve being tangent to the lines at given points (Fig. 46). Let AD and BE be the given lines and A and B the given points. Join A and B , and bisect the connecting line at C . Bisect CA and CB by perpendiculars. At A and B erect perpendiculars to the given lines, and the intersections a and b are the centers of the arcs composing the required curve.

24. To describe a circular arc that will be tangent to a given line at a given point and pass through another given point outside the line (Fig. 47). Let AB be the given line, A the given point on the line, and C the given point outside it. Draw from

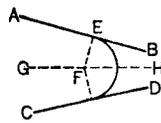

Fig. 45

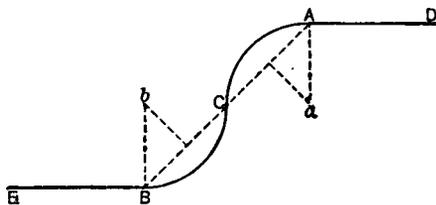

Fig. 46

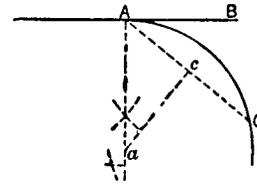

Fig. 47

A a line perpendicular to the given line. Connect A and C by a straight line, and bisect this line by the perpendicular ca . The point a where these two perpendiculars intersect is the center of the required circular arc.

25. To draw a circular arc joining two given relatively inclined lines, tangent to the lines, and passing through a given point on the line bisecting their included angle (Fig. 48). Let AB and DE be the given lines and F the given point on the line FC that bisects their included angle. Through F draw DA at right angles to FC ; bisect the angles A and D by lines intersecting at C , and about C as a center, with radius CF , draw the arc HFG required.

26. To draw a series of circles between two given relatively inclined lines touching the lines and touching each other (Fig. 49). Let AB and CD be the given lines. Bisect their included angle by the line NO . From a point P in this line draw the perpendicular PB to the line AB , and on P describe the circle BD , touching the given lines and cutting the center line at E . From E draw EF perpendicular to the center line, cutting AB at F ; and about F as a center describe an arc EG , cutting AB at G . Draw GH parallel to BP , giving H , the center of the next circle, to be described with the radius HE ; and so on for the next circle IN .

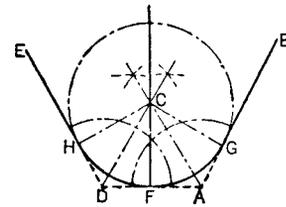

Fig. 48

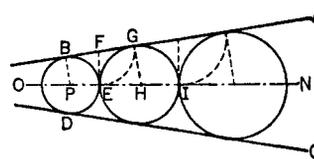

Fig. 49

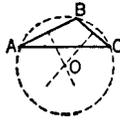

Fig. 50

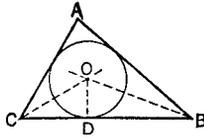

Fig. 51

27. To circumscribe a circle about a given triangle (Fig. 50). Construct perpendicular bisectors of two sides. Their point of intersection O is the center (circumcenter) of the required circle.

28. To inscribe a circle in a given triangle (Fig. 51). Draw bisectors of two angles intersecting in O (incenter). From O draw OD perpendicular to BC . Then the circle with center O and radius OD is the required circle.

29. To circumscribe a circle about a given square (Fig. 52). Let $ACBD$ be the given square. Draw diagonals AB and CD of the square intersecting at E . On center E , with radius AE , describe the required circle. The same procedure can be used for circumscribing a circle about a given rectangle.

30. To inscribe a circle in a given square (Fig. 53). Let $ACBD$ be the given square. Draw diagonals AB and CD of the square intersecting at E . Drop a perpendicular EF from E to one side. On center E , with radius EF , describe the required circle.

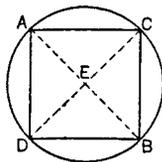

Fig. 52

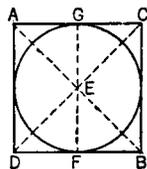

Fig. 53

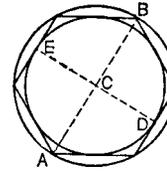

Fig. 54

31. To circumscribe a circle about a given regular polygon.

CASE 1: The polygon has an even number of sides (Fig. 54). Draw a diagonal AB joining two opposite vertices. Bisect the diagonal by a perpendicular line DE , which is another diagonal or a line bisecting two opposite sides, depending on whether the number of sides is or is not divisible by 4. With the midpoint C as the center and radius CA , describe the required circle.

CASE 2: The polygon has an odd number of sides (Fig. 55). Bisect two of the sides at D and E by the perpendicular lines DB and EA which pass through the respective opposite vertices and intersect at a point C . With C as the center and radius CA , describe the required circle.

32. To inscribe a circle in a given regular polygon (Figs. 54 and 55). Locate the center C as in item 31. With C as center and radius CD , describe the required circle.

Polygons

33. To construct a triangle on a given base, the lengths of the sides being given (Fig. 56). Let AB be the given base and a, b the given lengths of sides. With

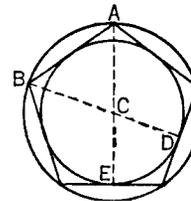

Fig. 55

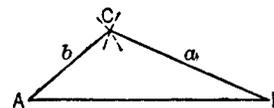

Fig. 56

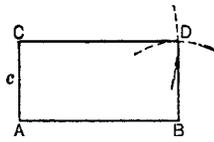

Fig. 57

A and B as centers and b and a as respective radii, describe arcs intersecting at C . Draw AC and BC to complete the required triangle.

34. To construct a rectangle of given base and given height (Fig. 57). Let AB be the base and c the height. Erect the perpendicular AC equal to c . With C and B as centers and AB and c as respective radii, describe arcs intersecting at D . Draw BD and CD to complete the required rectangle.

35. To construct a square with a given diagonal (Fig. 58). Let AC be the given diagonal. Draw a circle on AC as diameter and erect the diameter BD perpendicular to AC . Then $ABCD$ is the required square.

36. To inscribe a square in a given circle (Fig. 58). Draw perpendicular diameters AC and BD . Their extremities are the vertices of an inscribed square.

37. To circumscribe a square about a given circle (Fig. 59). Draw perpendicular diameters AC and BD . With A, B, C, D as centers and the radius of the circle as radius, describe the four semicircular arcs shown. Their outer intersections are the vertices of the required square.

38. To inscribe a regular pentagon in a given circle (Fig. 60). Draw perpendicular diameters AC and BD intersecting at O . Bisect AO at E and, with E as center

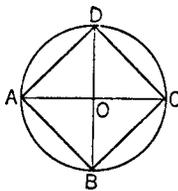

Fig. 58

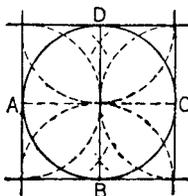

Fig. 59

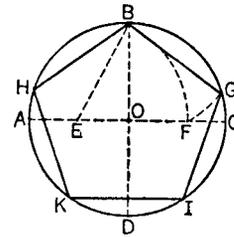

Fig. 60

and EB as radius, draw an arc cutting AC at F . With B as center and BF as radius, draw an arc cutting the circle at G and H ; also with the same radius, step around the circle to I and K . Join the points thus found to form the pentagon.

39. To inscribe a regular hexagon in a given circle (Fig. 61). Step around the circle with compasses set to the radius and join consecutive divisions thus marked off.

40. To circumscribe a regular hexagon about a given circle (Fig. 62). Draw a diameter ADB and, with center A and radius AD , describe an arc cutting the circle at C . Draw AC and bisect it with the radius DE . Through E , draw FG parallel to AC , cutting diameter AB extended at F . With center D and radius DF , describe the circumscribing circle FH ; within this circle inscribe a regular hexagon as under item 39. This hexagon circumscribes the given circle, as required.

41. To construct a regular hexagon having a side of given length (Fig. 61). Draw a circle with radius equal to the given length of side and inscribe a regular hexagon (see item 39).

42. To construct a regular octagon having a side of given length (Fig. 63). Let AB be the given side. Produce AB in both directions, and draw perpendiculars

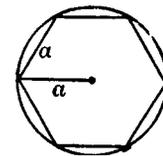

Fig. 61

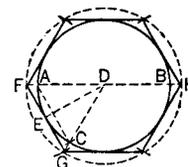

Fig. 62

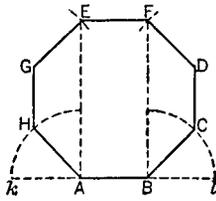

Fig. 63

AE and BF . Bisect the external angles at A and B by the lines AH and BC making them equal to AB . Draw CD and HG parallel to AE and equal to AB ; from the centers G, D , with the radius AB , draw arcs cutting the perpendiculars at E, F , and draw EF to complete the octagon.

43. To inscribe a regular octagon in a given circle (Fig. 64). Draw perpendicular diameters AC and BD . Bisect arcs AB, BC, \dots and join Ae, eB, \dots to form the octagon.

44. To inscribe a regular octagon in a given square (Fig. 65). Draw diagonals of the given square intersecting at O . With A, B, C, D as centers and AO as radius, describe arcs cutting the sides of the square at gn, fk, hm , and ol . Join the points thus found to form the octagon.

45. To circumscribe a regular octagon about a given circle (Fig. 66). Describe a square about the given circle. Draw perpendiculars ij, kl , and so on, to the diagonals of the squares, touching the circle. Then ij, jk, kl , and so on, form the octagon.

46. To describe a regular polygon of any given number of sides when one side is given (Fig. 67). Let

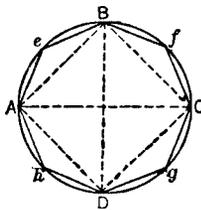

Fig. 64

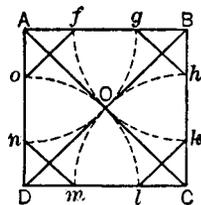

Fig. 65

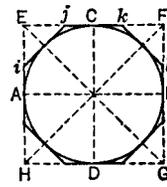

Fig. 66

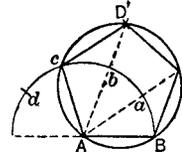

Fig. 67

AB be the given side and let the number of sides be five Produce the line AB , and with A as center and AB as radius, describe a semicircle. Divide this into as many equal parts as there are to be sides of the polygon—in this case, five Draw lines from A through the division points a, b , and c (omitting the last). With B and c as centers and AB as radius, cut Aa at C and Ab at D . Draw cD, DC , and CB to complete the polygon.

47. To inscribe a regular polygon of a given number of sides in a given circle. Determine the central angle subtended by any side by dividing 360° by the number of sides. Lay off this angle successively round the center of the circle by means of a protractor. The radii thus drawn intersect the circle at vertices of the required polygon.

Ellipse An *ellipse* is a curve for which the sum of the distances of any point on it from two fixe points (the *foci*) is constant.

48. To describe an ellipse for which the axes are given (Fig. 68). Let AB be the *major* and RS the *minor* axis ($AB > RS$). With O as center and OB and OR as radii, describe circles. From O draw any radial line intersecting the circles at M and N . Through M draw

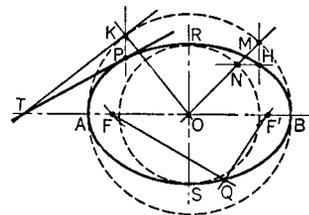

Fig. 68

a line parallel to OR and through N a line parallel to OB . These lines intersect at H , a point on the ellipse. Repeat the construction to obtain other points.

49. To locate the foci of an ellipse, given the axes (Fig. 68). With R as center and radius equal to AO , describe arcs intersecting AB at F and F' , the required foci.

50. To describe an ellipse mechanically, given an axis and the foci (Fig. 68). A cord of length equal to the major axis is pinned or fixed at its ends to the foci F and F' . With a pencil inside the loop, keeping the cord taut so as to guide the pencil point, trace the outline of the ellipse (Q represents the pencil point and length FQF' the cord). If the minor axis RS is given rather than the major axis AB , the length AB (for the cord) is readily determined as $FR + RF'$.

51. To draw a tangent to a given ellipse through a given point.

CASE 1: Point P is on the curve (Fig. 68). With O as center and OB as radius, describe a circle. Through P draw a line parallel to OR intersecting the circle at K . Through K draw a tangent to the circle intersecting the major axis at T . PT is the required tangent.

CASE 2: Point P is not on the curve (Fig. 69). With P as center and radius PF' , describe an arc. With F as center and radius AB , describe an arc intersecting the first arc at M and N . Draw FM and FN intersecting the ellipse at E and G . PE and PG are the required tangents.

52. To describe an ellipse approximately by means of circular arcs of three radii (Fig. 70). On the major

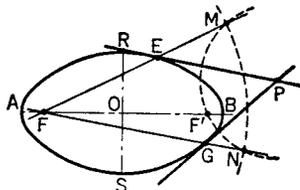

Fig. 69

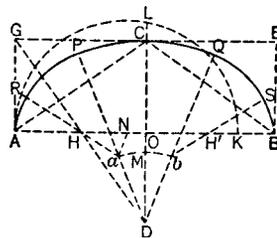

Fig. 70

axis AB draw the rectangle BG of altitude equal to half the minor axis, OC ; to the diagonal AC draw the perpendicular GHD ; set off OK equal to OC , and describe a semicircle on AK ; produce OC to L ; set off OM equal to CL , and from D describe an arc with radius DM ; from A , with radius OL , draw an arc cutting AB at N ; from H , with radius HN , draw an arc cutting arc ab at a . Thus the five centers H, a, D, b, H' are found, from which the arcs AR, RP, PQ, QS, SB are described. The part of the ellipse below axis AB can be constructed in like manner.

Parabola A parabola is a curve for which the distance of any point on it from a fixed line (the *directrix*) is equal to its distance from a fixed point (the *focus*). For a general discussion of its properties, see the section on analytic geometry.

53. To describe a parabola for which the vertex, the axis, and a point of the curve are given (Fig. 71). Let A be the given vertex, AB the given axis, and M the given point. Construct the rectangle $ABMC$. Divide MC and CA into the same number of equal parts (say four), numbering the divisions consecutively in the manner shown. Connect $A1, A2,$ and $A3$. Through $1', 2', 3'$, draw parallels to the axis AB . The intersections $I, II,$ and III of these lines are points on the required curve. A similar construction below the axis will give the other symmetric branch of the curve.

54. To locate the focus and directrix of a parabola, given the vertex, the axis, and a point of the curve (Fig. 71). Let A be the given vertex, AB the given axis, and M the given point. Drop the perpendicular MB from M to AB . Bisect it at E and draw AE . Draw ED perpendicular to AE at E and intersecting the axis at D . With A as center and BD as radius, describe arcs cutting the axis at F and J . Then F is the focus and the line GH , perpendicular to the axis through J , is the directrix.

55. To describe a parabola mechanically, given the focus and directrix (Fig. 72). Let F be the given focus and EN the given directrix. Place a straight edge to the directrix EN , and apply to it a square, LEG . Fasten to the end G one end of a cord equal in length to the edge EG , and attach the other end to the focus F ; slide the square along the straight edge, holding the cord taut

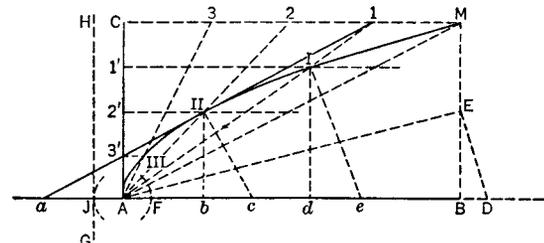

Fig. 71

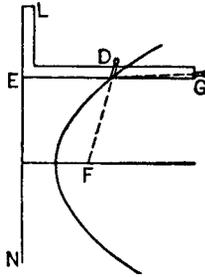

Fig. 72

against the edge of the square by a pencil *D*, by which the parabolic curve is described.

56. To draw a tangent to a given parabola through a given point.

CASE 1: The point is on the curve (Fig. 71). Let *II* be the given point. Drop a perpendicular from *II* to the axis, cutting it at *b*. Make *Aa* equal to *Ab*. Then a line through *a* and *II* is the required tangent. The line *IIc* perpendicular to the tangent at *II* is the normal; *bc* is the subnormal. All subnormals of a given parabola are equal to the distance from the directrix to the focus and hence equal to each other. Thus the subnormal at *I* is *de* equal to *bc*, where *d* is the foot of the perpendicular dropped from *I*. The tangent at *I* can be drawn as a perpendicular to *Ie* through *I*.

CASE 2: The point is off the curve (on the convex side) (Fig. 73). Let *P* be the given point and *F* the focus of the parabola. With *P* as center and *PF* as radius, draw arcs intersecting the directrix at *B* and *D*. Through *B* and *D* draw lines parallel to the axis intersecting the parabola at *E* and *H*. *PE* and *PH* are the required tangents.

Hyperbola A hyperbola is a curve for which the difference of the distances of any point on it from two fixed points (the foci) is constant. It has two distinct branches.

57. To describe a hyperbola for which the foci and the difference of the focal radii are given (Fig. 74). Let

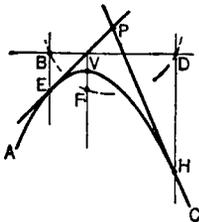

Fig. 73

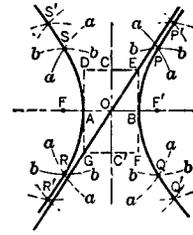

Fig. 74

F and *F'* be the given foci and *AOB* the given difference of the focal radii. Lay out *AOB* (the transverse axis) so that $AF = F'B$ and $AO = OB$. *A* and *B* are points on the required curve. With centers *F* and *F'* and any radius greater than *FB* or *F'A*, describe arcs *aa*. With the same centers and radius equal to the difference between the first radius and the transverse axis *AOB*, describe arcs *bb*, intersecting arcs *aa* at *P*, *Q*, *R*, and *S*, points on the required curve. Repeat the construction for additional points.

Make $BC = BC' = OF = OF'$, and construct the rectangle *DEFG*; *CC'* is the conjugate axis. The diagonals *DF* and *EG*, produced, are called *asymptotes*. The hyperbola is tangent to its asymptotes at infinity

58. To locate the foci of a hyperbola, given the axes (Fig. 74). With *O* as center and radius equal to *BC*, describe arcs intersecting *AB* extended at *F* and *F'*, the required foci.

59. To describe a hyperbola mechanically, having given the foci and the difference of the focal radii (Fig. 75). Let *F* and *F'* be the given foci and *AB* the given difference of focal radii. Using a ruler longer than the distance *F'F*, fasten one of its extremities at the focus *F'*. At the other extremity *H* attach a cord of such a length that the length of the ruler exceeds the length of the cord by the given distance *AB*. Attach the other extremity of the cord at the focus *F*. Press a pencil *P* against the ruler, and keep the cord constantly taut while the ruler is turned around *F'* as a center. The point of the pencil will describe one branch of the curve, and the other can be obtained in like manner.

60. To draw a tangent to a given hyperbola through a given point.

CASE 1: Point *P* is on the curve (Fig. 76). Draw lines connecting *P* with the foci. Bisect the angle *F'PF*. The bisecting line *TP* is the required tangent.

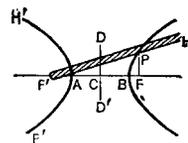

Fig. 75

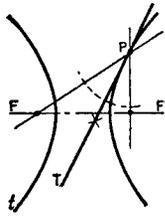

Fig. 76

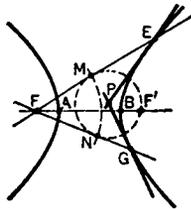

Fig. 77

CASE 2: Point P is off the curve on the convex side (Fig. 77). With P as center and radius PF' , describe an arc. With F as center and radius AB , describe an arc intersecting the first arc at M and N . Produce lines FM and FN to intersect the curve at E and G . PE and PG are the required tangents.

Cycloid A *cycloid* is a curve generated by a point on a circle rolling on a straight line.

61. To describe a cycloid for which the generating circle is given (Fig. 78). Let A be the generating point. Divide the circumference of the generating circle into an even number of equal arcs, as $A_1, 1-2, \dots$, and set off the rectified arcs on the base. Through the points $1, 2, 3, \dots$ on the circle, draw horizontal lines, and on them set off distances $1a = A_1, 2b = A_2, 3c = A_3, \dots$. The points A, a, b, c, \dots are points of the cycloid.

An *epicycloid* is a curve generated by a point on one circle rolling on the *outside* of another circle. A *hypocycloid* is a curve generated by the point if the generating circle rolls on the *inside* of the second circle.

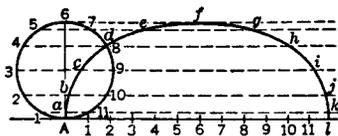

Fig. 78

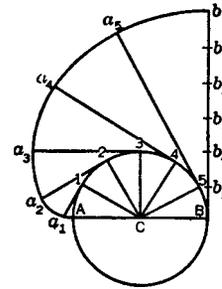

Fig. 79

Involute of a Circle An *involute of a circle* is a curve generated by the free end of a taut string as it is unwound from a circle.

62. To describe an involute of a given circle (Fig. 79). Let AB be the given circle. Through B draw Bb perpendicular to AB . Make Bb equal in length to half the circumference of the circle. Divide Bb and the semicircumference into the same number of equal parts, say six. From each point of division $1, 2, 3, \dots$ of the circumference, draw lines to the center C of the circle. Then draw $1a_1$ perpendicular to $C1$, $2a_2$ perpendicular to $C2$, and so on. Make $1a_1$ equal to bb_1 ; $2a_2$ equal to bb_2 ; $3a_3$ equal to bb_3 ; and so on. Join the points A, a_1, a_2, a_3, \dots , by a curve; this curve is the required involute.

6 TRIGONOMETRY

6.1 Circular Functions of Plane Angles

Definitions and Values

Trigonometric Functions. The angle α in Fig. 80 is measured in degrees or radians, as define in Section 5.1. The ratio of any two of the quantities $x, y,$ or r determines the extent of the opening between the lines OP and OX . Since these ratios are functions of the angle, they may be used to measure or construct it.

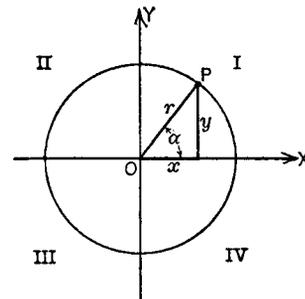

Fig. 80

The definition and terms used to designate the functions are as follows:

$$\begin{aligned}\text{Sine } \alpha &= \frac{y}{r} = \sin \alpha \\ \text{Cosine } \alpha &= \frac{x}{r} = \cos \alpha \\ \text{Tangent } \alpha &= \frac{y}{x} = \tan \alpha \\ \text{Cotangent } \alpha &= \frac{x}{y} = \cot \alpha \\ \text{Secant } \alpha &= \frac{r}{x} = \sec \alpha \\ \text{Cosecant } \alpha &= \frac{r}{y} = \csc \alpha \\ \text{Versine } \alpha &= \frac{r-x}{r} = \text{vers } \alpha = 1 - \cos \alpha \\ \text{Coversine } \alpha &= \frac{r-y}{r} = \text{covers } \alpha = 1 - \sin \alpha \\ \text{Haversine } \alpha &= \frac{r-x}{2r} = \text{hav } \alpha = \frac{1}{2} \text{vers } \alpha\end{aligned}$$

Values of Trigonometric Functions. An angle α (Fig. 80), if measured in a *counterclockwise* direction, is said to be *positive*; if measured *clockwise*, *negative*. Following the convention that x is positive if measured along OX to the right of the OY axis and negative if measured to the left, and similarly, y is positive if measured along OY above the OX axis and negative if measured below, the signs of the trigonometric functions are different for angles in the quadrants I, II, III, and IV (Table 5).

Values of trigonometric functions are *periodic*, the period of the \sin , \cos , \sec , \csc being 2π radians, and that of the \tan and \cot , π radians (Tables 6–8). For example, in Fig. 81 (n an integer)

$$\begin{aligned}\sin(\alpha + 2\pi n) &= \sin \alpha \\ \tan(\alpha + \pi n) &= \tan \alpha\end{aligned}$$

Inverse, or Antifunctions. The symbol $\sin^{-1} x$ means the angle whose sine is x and is read inverse sine of x , antisine of x , or arc sine x . Similarly for $\cos^{-1} x$, $\tan^{-1} x$, $\cot^{-1} x$, $\sec^{-1} x$, $\csc^{-1} x$, $\text{vers}^{-1} x$, the last meaning an angle α such that $1 - \cos \alpha = x$.

Table 5 Signs of Trigonometric Functions

Quadrant	sin	cos	tan	cot	sec	csc
I	+	+	+	+	+	+
II	+	-	-	-	-	+
III	-	-	+	+	-	-
IV	-	+	-	-	+	-

Table 6 Functions of Angles in Any Quadrant in Terms of Angles in First Quadrant

	$-\alpha$	$90^\circ \pm \alpha$	$180^\circ \pm \alpha$	$270^\circ \pm \alpha$	$360^\circ \pm \alpha$
sin	$-\sin \alpha$	$+\cos \alpha$	$\mp \sin \alpha$	$-\cos \alpha$	$\pm \sin \alpha$
cos	$+\cos \alpha$	$\mp \sin \alpha$	$-\cos \alpha$	$\pm \sin \alpha$	$+\cos \alpha$
tan	$-\tan \alpha$	$\mp \cot \alpha$	$\pm \tan \alpha$	$\mp \cot \alpha$	$\pm \tan \alpha$
cot	$-\cot \alpha$	$\mp \tan \alpha$	$\pm \cot \alpha$	$\mp \tan \alpha$	$\pm \cot \alpha$
sec	$+\sec \alpha$	$\mp \csc \alpha$	$-\sec \alpha$	$\pm \csc \alpha$	$+\sec \alpha$
csc	$-\csc \alpha$	$+\sec \alpha$	$\mp \csc \alpha$	$-\sec \alpha$	$\pm \csc \alpha$

While the direct functions (e.g., sine) are single valued, the indirect are many valued; thus $\sin 30^\circ = 0.5$, but $\sin^{-1} 0.5 = 30^\circ, 150^\circ, \dots$

Functional Relations Identities

Functions of the Sum and Difference of Two Angles

$$\begin{aligned}\sin(\alpha \pm \beta) &= \sin \alpha \cos \beta \pm \cos \alpha \sin \beta \\ \cos(\alpha \pm \beta) &= \cos \alpha \cos \beta \mp \sin \alpha \sin \beta \\ \tan(\alpha \pm \beta) &= 1 \mp \tan \alpha \tan \beta / \tan \alpha \pm \tan \beta \\ \cot(\alpha \pm \beta) &= \cot \beta \pm \cot \alpha / \cot \beta \cot \alpha \mp 1\end{aligned}$$

If x is small, say 3° or 4° , then the following are close approximations, in which the quantity x is to be expressed in radians ($1^\circ = 0.01745$ rad):

$$\begin{aligned}\sin \alpha &\approx \alpha & \cos \alpha &\approx 1 & \tan \alpha &\approx \alpha \\ \sin(\alpha \pm x) &\approx \sin \alpha \pm x \cos \alpha \\ \cos(\alpha \pm x) &\approx \cos \alpha \mp x \sin \alpha\end{aligned}$$

Functions of Half-Angles

$$\begin{aligned}\sin \frac{1}{2}\alpha &= \sqrt{\frac{1}{2}(1 - \cos \alpha)} \\ &= \frac{1}{2}\sqrt{1 + \sin \alpha} - \frac{1}{2}\sqrt{1 - \sin \alpha} \\ \cos \frac{1}{2}\alpha &= \sqrt{\frac{1}{2}(1 + \cos \alpha)} \\ &= \frac{1}{2}\sqrt{1 + \sin \alpha} + \frac{1}{2}\sqrt{1 - \sin \alpha} \\ \tan \frac{1}{2}\alpha &= \sqrt{1 + \cos \alpha} / \sqrt{1 - \cos \alpha} = \frac{1 - \cos \alpha}{\sin \alpha} \\ &= \frac{\sin \alpha}{1 + \cos \alpha} \\ \cot \frac{1}{2}\alpha &= \sqrt{1 + \cos \alpha} / \sqrt{1 - \cos \alpha} = \frac{1 + \cos \alpha}{\sin \alpha} \\ &= \frac{\sin \alpha}{1 - \cos \alpha}\end{aligned}$$

Table 7 Functions of Certain Angles

^aThe sign of the radical is to be determined by the quadrant.

Functions of Multiples of Angles

$$\sin 2\alpha = 2 \sin \alpha \cos \alpha$$

$$\tan 2\alpha = \frac{2 \tan \alpha}{1 - \tan^2 \alpha}$$

$$\cos 2\alpha = \cos^2 \alpha - \sin^2 \alpha = 2 \cos^2 \alpha - 1 = 1 - 2 \sin^2 \alpha$$

$$\cot 2\alpha = \frac{\cot^2 \alpha - 1}{2 \cot \alpha}$$

$$\sin 3\alpha = 3 \sin \alpha - 4 \sin^3 \alpha$$

$$\cos 3\alpha = 4 \cos^3 \alpha - 3 \cos \alpha$$

$$\sin 4\alpha = 8 \cos^3 \alpha \sin \alpha - 4 \cos \alpha \sin \alpha$$

$$\cos 4\alpha = 8 \cos^4 \alpha - 8 \cos^2 \alpha + 1$$

$$\sin n\alpha = 2 \sin(n-1)\alpha \cos \alpha - \sin(n-2)\alpha$$

$$= n \sin \alpha \cos^{n-1} \alpha - {}_n C_3 \sin^3 \alpha \cos^{n-3} \alpha + {}_n C_5 \sin^5 \alpha \cos^{n-5} \alpha - \dots$$

$$\cos n\alpha = 2 \cos(n-1)\alpha \cos \alpha - \cos(n-2)\alpha$$

$$= \cos^n \alpha - {}_n C_2 \sin^2 \alpha \cos^{n-2} \alpha + {}_n C_4 \sin^4 \alpha \cos^{n-4} \alpha - \dots$$

(For ${}_n C_r$, see p. 164.)

Products and Powers of Functions

$$\sin \alpha \sin \beta = \frac{1}{2} \cos(\alpha - \beta) - \frac{1}{2} \cos(\alpha + \beta)$$

$$\cos \alpha \cos \beta = \frac{1}{2} \cos(\alpha - \beta) + \frac{1}{2} \cos(\alpha + \beta)$$

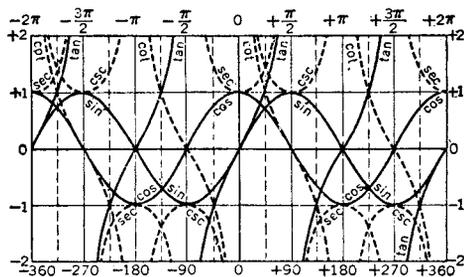

Fig. 81

$$\begin{aligned}\sin \alpha \cos \beta &= \frac{1}{2} \sin(\alpha - \beta) + \frac{1}{2} \sin(\alpha + \beta) \\ \tan \alpha \cot \alpha &= \sin \alpha \csc \alpha = \cos \alpha \sec \alpha = 1 \\ \sin^2 \alpha &= \frac{1}{2}(1 - \cos 2\alpha) \quad \cos^2 \alpha = \frac{1}{2}(1 + \cos 2\alpha) \\ \sin^3 \alpha &= \frac{1}{4}(3 \sin \alpha - \sin 3\alpha) \quad \cos^3 \alpha \\ &= \frac{1}{4}(3 \cos \alpha + \cos 3\alpha) \\ \sin^4 \alpha &= \frac{1}{8}(3 \sin 4 \cos 2\alpha + \cos 4\alpha) \quad \cos^4 \alpha \\ &= \frac{1}{8}(3 + 4 \cos 2\alpha + \cos 4\alpha) \\ \sin^5 \alpha &= \frac{1}{16}(10 \sin \alpha - 5 \sin 3\alpha + \sin 5\alpha) \\ \sin^6 \alpha &= \frac{1}{32}(10 - 15 \cos 2\alpha + 6 \cos 4\alpha - \cos 6\alpha) \\ \cos^5 \alpha &= \frac{1}{16}(10 \cos \alpha + 5 \cos 3\alpha + \cos 5\alpha) \\ \cos^6 \alpha &= \frac{1}{32}(10 + 15 \cos 2\alpha + 6 \cos 4\alpha + \cos 6\alpha)\end{aligned}$$

Sums and Differences of Functions

$$\begin{aligned}\sin \alpha + \sin \beta &= 2 \sin \frac{1}{2}(\alpha + \beta) \cos \frac{1}{2}(\alpha - \beta) \\ \sin \alpha - \sin \beta &= 2 \cos \frac{1}{2}(\alpha + \beta) \sin \frac{1}{2}(\alpha - \beta) \\ \cos \alpha + \cos \beta &= 2 \cos \frac{1}{2}(\alpha + \beta) \cos \frac{1}{2}(\alpha - \beta) \\ \cos \alpha - \cos \beta &= -2 \sin \frac{1}{2}(\alpha + \beta) \sin \frac{1}{2}(\alpha - \beta) \\ \tan \alpha + \tan \beta &= \frac{\sin(\alpha + \beta)}{\cos \alpha \cos \beta} \quad \cot \alpha + \cot \beta \\ &= \frac{\sin(\alpha + \beta)}{\sin \alpha \sin \beta} \\ \tan \alpha - \tan \beta &= \frac{\sin(\alpha - \beta)}{\cos \alpha \cos \beta} \quad \cot \alpha - \cot \beta \\ &= -\frac{\sin(\alpha - \beta)}{\sin \alpha \sin \beta}\end{aligned}$$

$$\begin{aligned}\sin^2 \alpha - \sin^2 \beta &= \sin(\alpha + \beta) \sin(\alpha - \beta) \\ \cos^2 \alpha - \cos^2 \beta &= -\sin(\alpha + \beta) \sin(\alpha - \beta) \\ \cos^2 \alpha - \sin^2 \beta &= \cos(\alpha + \beta) \cos(\alpha - \beta)\end{aligned}$$

Antitrigonometric or Inverse Functional Relations. In the following formulas the periodic constant is omitted:

$$\begin{aligned}\sin^{-1} x &= -\sin^{-1}(-x) = \frac{\pi}{2} - \cos^{-1} x \\ &= \cos^{-1} \sqrt{1 - x^2} = \tan^{-1} \frac{x}{\sqrt{1 - x^2}}\end{aligned}$$

$$\begin{aligned}&= \cot^{-1} \frac{\sqrt{1 - x^2}}{x} = \csc^{-1} \frac{1}{x} \\ &= \sec^{-1} \frac{1}{\sqrt{1 - x^2}} \\ \cos^{-1} x &= \pi - \cos^{-1}(-x) = \frac{\pi}{2} - \sin^{-1} x \\ &= \frac{1}{2} \cos^{-1}(2x^2 - 1) = \sin^{-1} \sqrt{1 - x^2} \\ &= \tan^{-1} \frac{\sqrt{1 - x^2}}{x} = \cot^{-1} \frac{x}{\sqrt{1 - x^2}} \\ &= \sec^{-1} \frac{1}{x} = \csc^{-1} \frac{1}{\sqrt{1 - x^2}} \\ \tan^{-1} x &= -\tan^{-1}(-x) = \frac{\pi}{2} - \cot^{-1} x \\ &= \sin^{-1} \frac{x}{\sqrt{1 + x^2}} = \cos^{-1} \frac{1}{\sqrt{1 + x^2}} \\ &= \cot^{-1} \frac{1}{x} = \sec^{-1} \sqrt{1 + x^2} \csc^{-1} \frac{\sqrt{1 + x^2}}{x} \\ \cot^{-1} x &= \tan^{-1} \frac{1}{x} \quad \sec^{-1} x = \cos^{-1} \frac{1}{x} \\ \csc^{-1} x &= \sin^{-1} \frac{1}{x} \\ \sin^{-1} x \pm \sin^{-1} y &= \sin^{-1}(x\sqrt{1 - y^2} \pm y\sqrt{1 - x^2}) \\ \cos^{-1} x \pm \cos^{-1} y &= \cos^{-1}[xy \mp \sqrt{(1 - x^2)(1 - y^2)}] \\ \sin^{-1} x \pm \cos^{-1} y &= \sin^{-1}[xy \pm \sqrt{(1 - x^2)(1 - y^2)}] \\ &= \cos^{-1}(y\sqrt{1 - x^2} \mp x\sqrt{1 - y^2}) \\ \tan^{-1} x \pm \tan^{-1} y &= \tan^{-1} \frac{x \pm y}{1 \mp xy} \\ \tan^{-1} x \pm \cot^{-1} y &= \tan^{-1} \frac{xy \pm 1}{y \mp x} = \cot^{-1} \frac{y \mp x}{xy \pm 1}\end{aligned}$$

6.2 Solution of Triangles

Relations between Angles and Sides of Plane Triangles. Let a, b, c be sides of triangle; α, β, γ be angles opposite a, b, c , respectively; A = area of triangle; $s = \frac{1}{2}(a + b + c)$; r = radius of inscribed circle (Fig. 82).

$$\begin{aligned}\frac{a}{\sin \alpha} &= \frac{b}{\sin \beta} = \frac{c}{\sin \gamma} \quad (\text{law of sines}) \\ a^2 &= b^2 + c^2 - 2bc \cos \alpha \quad (\text{law of cosines})\end{aligned}$$

$$\frac{a - b}{a + b} = \frac{\tan \frac{1}{2}(\alpha - \beta)}{\tan \frac{1}{2}(\alpha + \beta)} \quad (\text{law of tangents})$$

$$\alpha + \beta + \gamma = 180^\circ$$

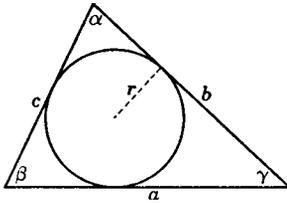

Fig. 82

$$a = b \cos \gamma + c \cos \beta \quad b = c \cos \alpha + a \cos \gamma$$

$$c = a \cos \beta + b \cos \alpha$$

$$A = \sqrt{s(s-a)(s-b)(s-c)}$$

$$\sin \alpha = \frac{2}{bc}A \quad \sin \beta = \frac{2}{ca}A \quad \sin \gamma = \frac{2}{ab}A$$

$$\sin \frac{\alpha}{2} = \sqrt{\frac{(s-b)(s-c)}{bc}}$$

$$\sin \frac{\beta}{2} = \sqrt{\frac{(s-c)(s-a)}{ca}}$$

$$\sin \frac{\gamma}{2} = \sqrt{\frac{(s-a)(s-b)}{ab}}$$

$$\cos \frac{\alpha}{2} = \sqrt{\frac{s(s-a)}{bc}}$$

$$\cos \frac{\beta}{2} = \sqrt{\frac{s(s-b)}{ca}} \quad \cos \frac{\gamma}{2} = \sqrt{\frac{s(s-c)}{ab}}$$

$$\tan \frac{\alpha}{2} = \sqrt{\frac{(s-b)(s-c)}{s(s-a)}}$$

$$\tan \frac{\beta}{2} = \sqrt{\frac{(s-c)(s-a)}{s(s-b)}}$$

$$\tan \frac{\gamma}{2} = \sqrt{\frac{(s-a)(s-b)}{s(s-c)}}$$

Solution of Plane Oblique Triangles. Given a, b, c (if logarithms are to be used, use 1):

$$1. \quad r = \sqrt{\frac{(s-a)(s-b)(s-c)}{s}}$$

$$A = \sqrt{s(s-a)(s-b)(s-c)} = rs,$$

$$\tan \frac{\alpha}{2} = \frac{r}{s-a} \quad \tan \frac{\beta}{2} = \frac{r}{s-b},$$

$$\tan \frac{\gamma}{2} = \frac{r}{s-c}.$$

$$2. \quad \cos \alpha = \frac{b^2 + c^2 - a^2}{2bc},$$

$$\cos \beta = \frac{a^2 + c^2 - b^2}{2ac},$$

$$\cos \gamma = \frac{a^2 + b^2 - c^2}{2ab} \quad \text{or}$$

$$\gamma = 180^\circ - (\alpha + \beta).$$

Given a, b, α :

$$\sin \beta = \frac{b \sin \alpha}{a}$$

(if $a > b, \beta < \pi/2$ and has only one value; if $b > a, \beta$ has two values, $\beta_1, \beta_2 = 180^\circ - \beta_1$); $\gamma = 180^\circ - (\alpha + \beta)$; $c = a \sin \gamma / \sin \alpha$; $A = \frac{1}{2}ab \sin \gamma$.

Given a, α, β :

$$b = \frac{a \sin \beta}{\sin \alpha} \quad \gamma = 180^\circ - (\alpha + \beta)$$

$$c = \frac{a \sin \gamma}{\sin \alpha} \quad A = \frac{1}{2}ab \sin \gamma$$

Given a, b, γ (if logarithms are to be used, use 1):

$$1. \quad \tan \frac{1}{2}(\alpha - \beta) = \frac{a-b}{a+b} \cot \frac{1}{2}\gamma,$$

$$\frac{1}{2}(\alpha + \beta) = 90^\circ - \frac{1}{2}\gamma, \quad c = \frac{a \sin \gamma}{\sin \alpha},$$

$$A = \frac{1}{2}ab \sin \gamma.$$

$$2. \quad c = \sqrt{a^2 + b^2 - 2ab \cos \gamma}, \quad \sin \alpha = \frac{a \sin \gamma}{c},$$

$$\beta = 180^\circ - (\alpha + \gamma).$$

$$3. \quad \tan \alpha = \frac{a \sin \gamma}{b - a \cos \gamma}, \quad \beta = 180^\circ - (\alpha + \gamma),$$

$$c = \frac{a \sin \gamma}{\sin \alpha}.$$

Mollweide's Check Formulas

$$\frac{a-b}{c} = \frac{\sin \frac{1}{2}(\alpha - \beta)}{\cos \frac{1}{2}\gamma} \quad \frac{a+b}{c} = \frac{\cos \frac{1}{2}(\alpha - \beta)}{\sin \frac{1}{2}\gamma}$$

Solution of Plane Right Triangles. Let $\gamma = 90^\circ$ and c be the hypotenuse. Given any two sides or one side and an acute angle α :

$$a = \sqrt{c^2 - b^2} = \sqrt{(c+b)(c-b)} = b \tan \alpha = c \sin \alpha$$

$$b = \sqrt{c^2 - a^2} = \sqrt{(c+a)(c-a)} = \frac{a}{\tan \alpha} = c \cos \alpha$$

$$c = \sqrt{a^2 + b^2} = \frac{a}{\sin \alpha} = \frac{b}{\cos \alpha}$$

$$\alpha = \sin^{-1} \frac{a}{c} = \cos^{-1} \frac{b}{c} = \tan^{-1} \frac{a}{b} \quad \beta = 90^\circ - \alpha$$

$$A = \frac{ab}{2} = \frac{a^2}{2 \tan \alpha} = \frac{b^2 \tan \alpha}{2} = \frac{c^2 \sin 2\alpha}{4}$$

6.3 Spherical Trigonometry

Spherical Trigonometry. Let O be the center of the sphere and a, b, c the sides of a triangle on the surface with opposite angles α, β, γ , respectively, the sides being measured by the angle subtended at the center of the sphere. Let $s = \frac{1}{2}(a + b + c)$, $\sigma = \frac{1}{2}(\alpha + \beta + \gamma)$, $E = \alpha + \beta + \gamma - 180^\circ$, the spherical excess. The following formulas are valid usually only for triangles of which the sides and angles are all between 0° and 180° . To each such triangle there is a polar triangle whose sides are $180^\circ - \alpha, 180^\circ - \beta, 180^\circ - \gamma$ and whose angles are $180^\circ - a, 180^\circ - b, 180^\circ - c$.

General Formulas

$$\frac{\sin a}{\sin \alpha} = \frac{\sin b}{\sin \beta} = \frac{\sin c}{\sin \gamma} \quad (\text{law of sines})$$

$$\cos a = \cos b \cos c + \sin b \sin c \cos \alpha$$

(law of cosines)

$$\cos \alpha = -\cos \beta \cos \gamma + \sin \beta \sin \gamma \cos a$$

(law of cosines)

$$\cos a \sin b = \sin a \cos b \cos \gamma + \sin c \cos \alpha$$

$$\cot a \sin b = \sin \gamma \cot \alpha + \cos \gamma \cos b$$

$$\cos \alpha \sin \beta = \sin \gamma \cos a - \sin \alpha \cos \beta \cos c$$

$$\cot \alpha \sin \beta = \sin c \cot a - \cos c \cos \beta$$

$$\sin \frac{a}{2} = \sqrt{\frac{-\cos \sigma \cos(\sigma - \alpha)}{\sin \beta \sin \gamma}}$$

$$\sin \frac{\alpha}{2} = \sqrt{\frac{\sin(s - b) \sin(s - c)}{\sin b \sin c}}$$

$$\cos \frac{a}{2} = \sqrt{\frac{\cos(\sigma - \beta) \cos(\sigma - \gamma)}{\sin \beta \sin \gamma}}$$

$$\cos \frac{\alpha}{2} = \sqrt{\frac{\sin s \sin(s - a)}{\sin b \sin c}}$$

$$\tan \frac{a}{2} = \sqrt{\frac{-\cos \sigma \cos(\sigma - \alpha)}{\cos(\sigma - \beta) \cos(\sigma - \gamma)}}$$

$$\tan \frac{\alpha}{2} = \sqrt{\frac{\sin(s - b) \sin(s - c)}{\sin s \sin(s - a)}}$$

$$\tan \frac{E}{4}$$

$$= \sqrt{\tan \frac{s}{2} \tan \frac{(s - a)}{2} \tan \frac{(s - b)}{2} \tan \frac{(s - c)}{2}}$$

$$\cot \frac{E}{2} = \frac{\cot(a/2) \cot(b/2) + \cos \gamma}{\sin \gamma}$$

$$\tan \left(\frac{a + b}{2} \right) = \frac{\cos[(\alpha - \beta)/2]}{\cos[(\alpha + \beta)/2]} \tan \frac{c}{2}$$

$$\tan \left(\frac{a - b}{2} \right) = \frac{\sin[(\alpha - \beta)/2]}{\sin[(\alpha + \beta)/2]} \tan \frac{c}{2}$$

$$\tan \left(\frac{\alpha + \beta}{2} \right) = \frac{\cos[(a - b)/2]}{\cos[(a + b)/2]} \cot \frac{\gamma}{2}$$

$$\tan \left(\frac{\alpha - \beta}{2} \right) = \frac{\sin[(a - b)/2]}{\sin[(a + b)/2]} \cot \frac{\gamma}{2}$$

$$\cos \left(\frac{\alpha + \beta}{2} \right) \cos \frac{c}{2} = \cos \left(\frac{a + b}{2} \right) \sin \frac{\gamma}{2}$$

$$\sin \left(\frac{\alpha + \beta}{2} \right) \cos \frac{c}{2} = \cos \left(\frac{a - b}{2} \right) \cos \frac{\gamma}{2}$$

$$\cos \left(\frac{\alpha - \beta}{2} \right) \sin \frac{c}{2} = \sin \left(\frac{a + b}{2} \right) \sin \frac{\gamma}{2}$$

$$\sin \left(\frac{\alpha - \beta}{2} \right) \sin \frac{c}{2} = \sin \left(\frac{a - b}{2} \right) \cos \frac{\gamma}{2}$$

The Right Spherical Triangle. Let $\gamma = 90^\circ$ and c be the hypotenuse.

$$\cos c = \cos a \cos b = \cot \alpha \cot \beta \quad \cos a = \frac{\cos \alpha}{\sin \beta}$$

$$\cos b = \frac{\cos \beta}{\sin \alpha}$$

$$\sin \alpha = \frac{\sin a}{\sin c} \quad \cos \alpha = \frac{\tan b}{\tan c}$$

$$\tan \alpha = \frac{\tan a}{\sin b}$$

6.4 Hyperbolic Trigonometry

Hyperbolic Angles. These are defined in a manner similar to circular angles but with reference to an *equilateral hyperbola*. The comparative relations are shown in Figs. 83 and 84. A *circular angle* is a central angle measured in radians by the ratio s/r or the ratio $2A/r^2$, where A is the area of the sector included by the angle α and the arc s (Fig. 83). For the *hyperbola* the radius ρ is not constant and only the value of the *differential hyperbolic angle* $d\theta$ is defined by the ratio ds/ρ . Thus

$$\theta = \int \frac{ds}{\rho} = \frac{2A}{a^2}$$

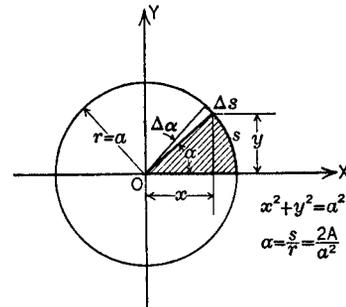

Fig. 83

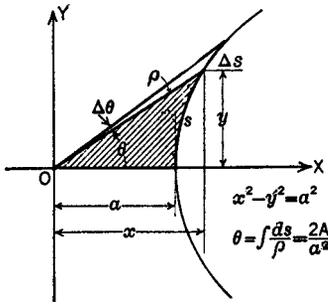

Fig. 84

where A represents the shaded area in Fig. 84. If both s and ρ are measured in the same units, the angle is expressed in *hyperbolic radians*.

Hyperbolic Functions. These are defined by ratios similar to those defining functions of circular angles and also named similarly. Their names and abbreviations are

$$\text{Hyperbolic sine } \theta = \frac{y}{a} = \sinh \theta$$

$$\text{Hyperbolic cosine } \theta = \frac{x}{a} = \cosh \theta$$

$$\text{Hyperbolic tangent } \theta = \frac{y}{x} = \tanh \theta$$

$$\text{Hyperbolic cotangent } \theta = \frac{x}{y} = \coth \theta$$

$$\text{Hyperbolic secant } \theta = \frac{a}{x} = \operatorname{sech} \theta$$

$$\text{Hyperbolic cosecant } \theta = \frac{a}{y} = \operatorname{csch} \theta$$

Values and Exponential Equivalents. The values of hyperbolic functions may be computed from their exponential equivalents. The graphs are shown in Fig. 85. Values for increments of 0.01 rad are given in Table 18.

$$\sinh \theta = \frac{e^\theta - e^{-\theta}}{2} \quad \cosh \theta = \frac{e^\theta + e^{-\theta}}{2}$$

$$\tanh \theta = \frac{e^\theta - e^{-\theta}}{e^\theta + e^{-\theta}}$$

If θ is extremely small, $\sinh \theta \approx \theta$, $\cosh \theta \approx 1$, and $\tanh \theta \approx \theta$. For large values of θ , $\sinh \theta \approx \cosh \theta$ and $\tanh \theta \approx \coth \theta \approx 1$.

Fundamental Identities

$$\operatorname{csch} \theta = \frac{1}{\sinh \theta} \quad \operatorname{sech} \theta = \frac{1}{\cosh \theta}$$

$$\coth \theta = \frac{1}{\tanh \theta}$$

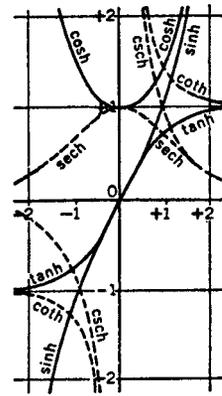

Fig. 85

$$\cosh^2 \theta - \sinh^2 \theta = 1 \quad \operatorname{sech}^2 \theta = 1 - \tanh^2 \theta$$

$$\operatorname{csch}^2 \theta = \coth^2 \theta - 1$$

$$\cosh \theta + \sinh \theta = e^\theta \quad \cosh \theta - \sinh \theta = e^{-\theta}$$

$$\sinh(-\theta) = -\sinh \theta \quad \cosh(-\theta) = \cosh \theta$$

$$\tanh(-\theta) = -\tanh \theta \quad \coth(-\theta) = -\coth \theta$$

$$\sinh(\theta_1 \pm \theta_2) = \sinh \theta_1 \cosh \theta_2 \pm \cosh \theta_1 \sinh \theta_2$$

$$\cosh(\theta_1 \pm \theta_2) = \cosh \theta_1 \cosh \theta_2 \pm \sinh \theta_1 \sinh \theta_2$$

$$\tanh(\theta_1 \pm \theta_2) = \frac{\tanh \theta_1 \pm \tanh \theta_2}{1 \pm \tanh \theta_1 \tanh \theta_2}$$

$$\coth(\theta_1 \pm \theta_2) = \frac{1 \pm \coth \theta_1 \coth \theta_2}{\coth \theta_1 \pm \coth \theta_2}$$

$$\sinh 2\theta = 2 \sinh \theta \cosh \theta = \frac{2 \tanh \theta}{1 - \tanh^2 \theta}$$

$$\cosh 2\theta = \sinh^2 \theta + \cosh^2 \theta = 1 + 2 \sinh^2 \theta$$

$$= 2 \cosh^2 \theta - 1 = \frac{1 + \tanh^2 \theta}{1 - \tanh^2 \theta}$$

$$\tanh 2\theta = \frac{2 \tanh \theta}{1 + \tanh^2 \theta}$$

$$\coth 2\theta = \frac{1 + \coth^2 \theta}{2 \coth \theta}$$

$$\sinh \frac{1}{2}(\theta) = \sqrt{\frac{1}{2}(\cosh \theta - 1)}$$

$$\cosh \frac{1}{2}(\theta) = \sqrt{\frac{1}{2}(\cosh \theta + 1)}$$

$$\tanh \frac{\theta}{2} = \sqrt{\frac{\cosh \theta - 1}{\cosh \theta + 1}} = \frac{\sinh \theta}{\cosh \theta + 1}$$

$$= \frac{\cosh \theta - 1}{\sinh \theta}$$

$$\begin{aligned}\sinh \theta_1 \pm \sinh \theta_2 &= 2 \sinh \frac{1}{2}(\theta_1 \pm \theta_2) \cosh \frac{1}{2}(\theta_1 \mp \theta_2) \\ \cosh \theta_1 + \cosh \theta_2 &= 2 \cosh \frac{1}{2}(\theta_1 + \theta_2) \cosh \frac{1}{2}(\theta_1 - \theta_2) \\ \cosh \theta_1 - \cosh \theta_2 &= 2 \sinh \frac{1}{2}(\theta_1 + \theta_2) \sinh \frac{1}{2}(\theta_1 - \theta_2) \\ \tanh \theta_1 \pm \tanh \theta_2 &= \frac{\sinh(\theta_1 \pm \theta_2)}{\cosh \theta_1 \cosh \theta_2} \\ (\cosh \theta \pm \sinh \theta)^n &= \cosh n\theta \pm \sinh n\theta\end{aligned}$$

Antihyperbolic or Inverse Functions. The inverse hyperbolic sine of u is written $\sinh^{-1} u$. Values of the inverse functions may be computed from their logarithmic equivalents:

$$\begin{aligned}\sinh^{-1} u &= \log_e(u + \sqrt{u^2 + 1}) \\ \cosh^{-1} u &= \log_e(u + \sqrt{u^2 - 1}) \\ \tanh^{-1} u &= \frac{1}{2} \log_e \frac{1+u}{1-u} \\ \coth^{-1} u &= \frac{1}{2} \log_e \frac{u+1}{u-1}\end{aligned}$$

6.5 Functions of Imaginary and Complex Angles

Relations of Hyperbolic to Circular Functions. By comparison of the exponential equivalents of hyperbolic and circular functions, the following identities are established ($i = \sqrt{-1}$):

$$\begin{array}{ll}\sin \alpha = -i \sinh i\alpha & \sinh \beta = -i \sin i\beta \\ \cos \alpha = \cosh i\alpha & \cosh \beta = \cos i\beta \\ \tan \alpha = -i \tanh i\alpha & \tanh \beta = -i \tan i\beta \\ \cot \alpha = i \coth i\alpha & \coth \beta = i \cot i\beta \\ \sec \alpha = \operatorname{sech} i\alpha & \operatorname{sech} \beta = \sec i\beta \\ \csc \alpha = i \operatorname{csch} i\alpha & \operatorname{csch} \beta = i \csc i\beta\end{array}$$

Relations between Inverse Functions

$$\begin{array}{ll}\sin^{-1} A = -i \sinh^{-1} iA & \sinh^{-1} B = -i \sin^{-1} iB \\ \cos^{-1} A = -i \cosh^{-1} iA & \cosh^{-1} B = -i \cos^{-1} iB \\ \tan^{-1} A = -i \tanh^{-1} iA & \tanh^{-1} B = -i \tan^{-1} iB \\ \cot^{-1} A = i \coth^{-1} iA & \coth^{-1} B = i \cot^{-1} iB \\ \sec^{-1} A = -i \operatorname{sech}^{-1} iA & \operatorname{sech}^{-1} B = i \sec^{-1} iB \\ \csc^{-1} A = i \operatorname{csch}^{-1} iA & \operatorname{csch}^{-1} B = i \csc^{-1} iB\end{array}$$

Functions of a Complex Angle. In complex, notation $c = a + ib = |c|(\cos \theta + i \sin \theta) = |c|e^{i\theta}$, where $|c| = \sqrt{a^2 + b^2}$, $i = \sqrt{-1}$, and $\theta = \tan^{-1} b/a$. Frequently $|c|e^{i\theta}$ is written $c \angle \theta$.

$\operatorname{Log}_e |c|e^{i\theta} = \log |c| + i(\theta + 2k\pi)$ and is infinitel many valued. By its principal part will be understood $\log_e |c| + i\theta$. Some convenient identities are

$$\log_e 1 = 0 \quad \log_e(-1) = i\pi$$

$$\begin{aligned}\log_e i &= i \frac{\pi}{2} & \log_e(-i) &= i \frac{3\pi}{2} \\ (\cos \theta \pm i \sin \theta)^n &= \cos n\theta \pm i \sin n\theta \\ \sqrt[n]{\cos \theta \pm i \sin \theta} &= \cos \frac{\theta + 2\pi k}{n} \pm i \sin \frac{\theta + 2\pi k}{n}\end{aligned}$$

The use of complex angles occurs frequently in electric circuit problems where it is often necessary to express the functions of them as a complex number:

$$\begin{aligned}\sin(\alpha \pm i\beta) &= \sin \alpha \cosh \beta \pm i \cos \alpha \sinh \beta \\ &= \sqrt{\cosh^2 \beta - \cos^2 \alpha} e^{\pm i\theta}\end{aligned}$$

where $\theta = \tan^{-1} \cot \alpha \tanh \beta$;

$$\begin{aligned}\cos(\alpha \pm i\beta) &= \cos \alpha \cosh \beta \mp i \sin \alpha \sinh \beta \\ &= \sqrt{\cosh^2 \beta - \sin^2 \alpha} e^{\pm i\theta}\end{aligned}$$

where $\theta = \tan^{-1} \tan \alpha \tanh \beta$;

$$\begin{aligned}\sinh(\alpha \pm i\beta) &= \sinh \alpha \cos \beta \pm i \cosh \alpha \sin \beta \\ &= \sqrt{\sinh^2 \alpha + \sin^2 \beta} e^{\pm i\theta} \\ &= \sqrt{\cosh^2 \alpha + \cos^2 \beta} e^{\pm i\theta}\end{aligned}$$

where $\theta = \tan^{-1} \coth \alpha \tan \beta$;

$$\begin{aligned}\cosh(\alpha \pm i\beta) &= \cosh \alpha \cos \beta \pm i \sinh \alpha \sin \beta \\ &= \sqrt{\sinh^2 \alpha + \cos^2 \beta} e^{\pm i\theta} \\ &= \sqrt{\cosh^2 \alpha + \sin^2 \beta} e^{\pm i\theta}\end{aligned}$$

where $\theta = \tan^{-1} \tanh \alpha \tan \beta$; and

$$\begin{aligned}\tan(\alpha \pm i\beta) &= \frac{\sin 2\alpha \pm i \sinh 2\beta}{\cos 2\alpha + \cosh 2\beta} \\ \tanh(\alpha \pm i\beta) &= \frac{\sinh 2\alpha \pm i \sin 2\beta}{\cosh 2\alpha + \cos 2\beta}\end{aligned}$$

The hyperbolic sine and cosine have the period $2\pi i$; the hyperbolic tangent has the period πi :

$$\begin{aligned}\sinh(\alpha + 2k\pi i) &= \sinh \alpha & \cosh(\alpha + 2k\pi i) &= \cosh \alpha \\ \tanh(\alpha + k\pi i) &= \tanh \alpha & \coth(\alpha + k\pi i) &= \coth \alpha\end{aligned}$$

Inverse Functions of Complex Numbers

$$\begin{aligned} \sin^{-1}(A \pm iB) &= \sin^{-1} \left[\frac{1}{2}(\sqrt{B^2 + (1+A)^2} - \sqrt{B^2 + (1-A)^2}) \right] \\ &\pm i \cosh^{-1} \left[\frac{1}{2}(\sqrt{B^2 + (1+A)^2} + \sqrt{B^2 + (1-A)^2}) \right] \end{aligned}$$

$$\begin{aligned} \cos^{-1}(A \pm iB) &= \cos^{-1} \left[\frac{1}{2}(\sqrt{B^2 + (1+A)^2} - \sqrt{B^2 + (1-A)^2}) \right] \\ &\mp i \cosh^{-1} \left[\frac{1}{2}(\sqrt{B^2 + (1+A)^2} + \sqrt{B^2 + (1-A)^2}) \right] \end{aligned}$$

$$\begin{aligned} \tan^{-1}(A \pm iB) &= \left[\frac{1}{2} \left(\pi - \tan^{-1} \frac{A}{\pm B - 1} + \tan^{-1} \frac{A}{\pm B + 1} \right) \right] \\ &\pm i \frac{1}{4} \log_e \frac{A^2 + (1 \pm B)^2}{A^2 + (1 \mp B)^2} \end{aligned}$$

$$\begin{aligned} \sinh^{-1}(A \pm iB) &= \cosh^{-1} \left[\frac{1}{2}(\sqrt{A^2 + (1+B)^2} - \sqrt{A^2 + (1-B)^2}) \right] \\ &\pm i \sin^{-1} \left[\frac{1}{2}(\sqrt{A^2 + (1+B)^2} - \sqrt{A^2 + (1-B)^2}) \right] \end{aligned}$$

$$\begin{aligned} \cosh^{-1}(A \pm iB) &= \cosh^{-1} \left[\frac{1}{2}(\sqrt{B^2 + (1+A)^2} + \sqrt{B^2 + (1-A)^2}) \right] \\ &\pm i \cos^{-1} \left[\frac{1}{2}(\sqrt{B^2 + (1+A)^2} - \sqrt{B^2 + (1-A)^2}) \right] \end{aligned}$$

$$\begin{aligned} \tanh^{-1}(A \pm iB) &= \frac{1}{2} \tanh^{-1} \frac{2A}{1+A^2+B^2} + i \frac{1}{2} \tan^{-1} \frac{\pm 2B}{1-2A-B^2} \end{aligned}$$

7 PLANE ANALYTIC GEOMETRY

7.1 Point and Line

Coordinates. The position of a point P_1 in a plane is determined if its distance and direction from each of two lines or axes OX and OY which are perpendicular to each other are known. The distances x and y (Fig. 86) perpendicular to the axes are called the *Cartesian* or *rectangular coordinates* of the point. The directions to the right of OY and above OX are called *positive* and opposite directions *negative*. The point O of intersection of OY and OX is called the *origin*.

The position of a point P is also given by its radial distance r from the origin and the angle θ between the radius r and the horizontal axis OX (Fig. 87). These coordinates r, θ are called *polar coordinates*.

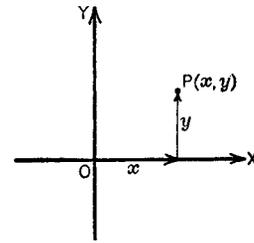

Fig. 86

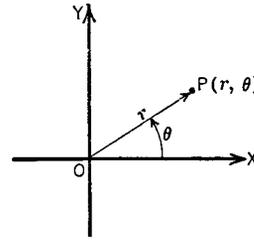

Fig. 87

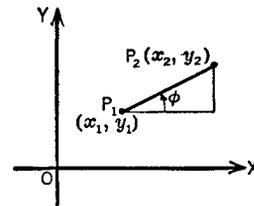

Fig. 88

The distance s between two points $P_1(x_1, y_1)$ and $P_2(x_2, y_2)$ (Fig. 88) on a straight line is

$$s = \sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2} \tag{15}$$

In polar coordinates the distance s between $P_1(r_1, \theta_1)$ and $P_2(r_2, \theta_2)$ is

$$s = \sqrt{r_1^2 + r_2^2 - 2r_1r_2 \cos(\theta_2 - \theta_1)} \tag{16}$$

The slope m of the line P_1P_2 is define as the tangent of the angle ϕ which the line makes with OX :

$$m = \tan \phi = \frac{y_2 - y_1}{x_2 - x_1} \tag{17}$$

To divide the segment P_1P_2 in the ratio c_1/c_2 , internally or externally,

$$x = \frac{c_2x_1 \pm c_1x_2}{c_2 \pm c_1} \quad y = \frac{c_2y_1 \pm c_1y_2}{c_2 \pm c_1}$$

The midpoint of P_1P_2 is

$$x = \frac{1}{2}(x_1 + x_2) \quad y = \frac{1}{2}(y_1 + y_2)$$

Equation of a Straight Line. In Cartesian coordinates the equation of a straight line is of the first degree and is expressed as

$$Ax + By + C = 0 \quad (18)$$

where A , B , and C are constants.

Other forms of the equation are

$$y = mx + b \quad (19)$$

where m is the slope and b is the y intercept;

$$y - y_1 = m(x - x_1) \quad (20)$$

where m is the slope and (x_1, y_1) is a point on the line;

$$\frac{x - x_1}{y - y_1} = \frac{x_1 - x_2}{y_1 - y_2} \quad (21)$$

where (x_1, y_1) and (x_2, y_2) are two points on the line;

$$\frac{x}{a} + \frac{y}{b} = 1 \quad (22)$$

where a and b are the x and y intercepts, respectively;

$$x \cos \alpha + y \sin \alpha - p = 0 \quad (23)$$

where α is the angle between OX and the perpendicular from the origin to the line and p is the length of the perpendicular (Fig. 89). This is called the *perpendicular* form and is obtained by dividing the general form

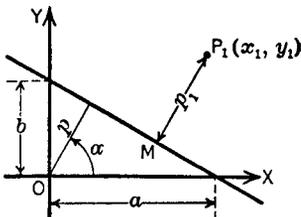

Fig. 89

$Ax + By + C = 0$ by $\pm\sqrt{A^2 + B^2}$. The sign before the radical is taken opposite to that of C if $C \neq 0$ and the same as that of B if $C = 0$.

Equations of lines parallel to the x and y axes, respectively, are

$$y = k \quad x = k \quad (24)$$

The *perpendicular distance of a point* $P_1(x_1, y_1)$ (Fig. 89) from the line $Ax + By + C = 0$ is

$$p_1 = \frac{Ax_1 + By_1 + C}{\pm\sqrt{A^2 + B^2}} \quad (25)$$

where the sign before the radical is opposite to that of C if $C \neq 0$ and the same as B if $C = 0$.

Parallel Lines. The two lines $y = m_1x + b_1$, $y = m_2x + b_2$ are parallel if $m_1 = m_2$. For the form $A_1x + B_1y + C_1 = 0$, $A_2x + B_2y + C_2 = 0$, the lines are parallel if

$$\frac{A_1}{A_2} = \frac{B_1}{B_2} \quad (26)$$

The equation of a line through the point (x_1, y_1) and parallel to the line $Ax + By + C = 0$ is

$$A(x - x_1) + B(y - y_1) = 0 \quad (27)$$

Perpendicular Lines. The two lines $y = m_1x + b_1$ and $y = m_2x + b_2$ are perpendicular if

$$m_1 = -\frac{1}{m_2} \quad (28)$$

For the form $A_1x + B_1y + C_1 = 0$, $A_2x + B_2y + C_2 = 0$, the lines are perpendicular if

$$A_1A_2 + B_1B_2 = 0 \quad (29)$$

The equation of a line through the point (x_1, y_1) perpendicular to the line $Ax + By + C = 0$ is

$$B(x - x_1) - A(y - y_1) = 0 \quad (30)$$

Intersecting Lines. Let $A_1x + B_1y + C_1 = 0$ and $A_2x + B_2y + C_2 = 0$ be the equations of two intersecting lines and λ an arbitrary real number. Then

$$(A_1x + B_1y + C_1) + \lambda(A_2x + B_2y + C_2) = 0 \quad (31)$$

represents the system of lines through the point of intersection.

The three lines $A_1x + B_1y + C_1 = 0$, $A_2x + B_2y + C_2 = 0$, $A_3x + B_3y + C_3 = 0$ meet in a point if

$$\begin{vmatrix} A_1 & B_1 & C_1 \\ A_2 & B_2 & C_2 \\ A_3 & B_3 & C_3 \end{vmatrix} = 0 \quad (32)$$

The angle θ between two lines with equations $A_1x + B_1y + C_1 = 0$ and $A_2x + B_2y + C_2 = 0$ can be found from

$$\begin{aligned} \sin \theta &= \frac{A_1B_2 - A_2B_1}{\sqrt{(A_1^2 + B_1^2)(A_2^2 + B_2^2)}} \\ \cos \theta &= \frac{A_1A_2 + B_1B_2}{\sqrt{(A_1^2 + B_1^2)(A_2^2 + B_2^2)}} \\ \tan \theta &= \frac{A_1B_2 - A_2B_1}{A_1A_2 + B_1B_2} \end{aligned} \quad (33)$$

The signs of $\tan \theta$ and $\cos \theta$ determine whether the acute or obtuse angle is meant. If the equations are in the form $y = m_1x + b_1$, $y = m_2x + b_2$, then

$$\begin{aligned} \sin \theta &= \frac{m_2 - m_1}{\sqrt{(1 + m_1^2)(1 + m_2^2)}} \\ \cos \theta &= \frac{1 + m_1m_2}{\sqrt{(1 + m_1^2)(1 + m_2^2)}} \\ \tan \theta &= \frac{m_2 - m_1}{1 + m_1m_2} \end{aligned} \quad (34)$$

7.2 Transformation of Coordinates

Change of Origin O to O' . Let (x, y) denote the coordinates of a point P with respect to the old axes and (x', y') the coordinates with respect to the new axes (Fig. 90). Then, if the coordinates of the new origin O' with respect to the old axes are $x = h$, $y = k$,

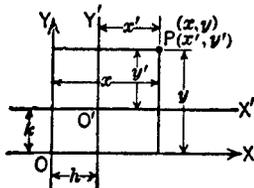

Fig. 90

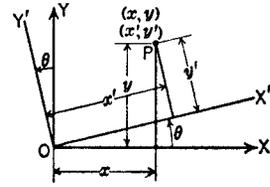

Fig. 91

the relations between the old and the new coordinates under transformation are

$$x = x' + h \quad y = y' + k \quad (35)$$

Rotation of Axes about the Origin. Let θ (Fig. 91) be the angle through which the axes are rotated. Then

$$x = x' \cos \theta - y' \sin \theta \quad y = x' \sin \theta + y' \cos \theta \quad (36)$$

If the axes are both translated and rotated,

$$\begin{aligned} x &= x' \cos \theta - y' \sin \theta + h \\ y &= x' \sin \theta + y' \cos \theta + k \end{aligned} \quad (37)$$

Coordinate Transformation. The relations between the rectangular coordinates x, y and the polar coordinates r, θ are

$$\begin{aligned} x &= r \cos \theta \quad y = r \sin \theta \quad r = \sqrt{x^2 + y^2} \\ \theta &= \tan^{-1} \frac{y}{x} \end{aligned} \quad (38)$$

7.3 Conic Sections

Conic Section. This is a curve traced by a point P moving in a plane so that the distance PF of the point from a fixed point (*focus*) is in constant ratio to the distance PM of the point from a fixed line (*directrix*) in the plane of the curve. The ratio $e = PF/PM$ is called the *eccentricity*. If $e < 1$, the curve is an *ellipse*; $e = 1$, a *parabola*; $e > 1$, a *hyperbola*; and $e = 0$, a *circle*, which is a special case of an ellipse.

Circle. The equation is

$$(x - x_0)^2 + (y - y_0)^2 = r^2 \quad (39)$$

where (x_0, y_0) is the center and r the radius. If the center is at the origin,

$$x^2 + y^2 = r^2 \quad (40)$$

Another form is

$$x^2 + y^2 + 2gx + 2fy + c = 0 \quad (41)$$

with center $(-g, -f)$ and radius $\sqrt{g^2 + f^2 - c}$.

The equation of the tangent to (41) at a point $P_1(x_1, y_1)$ is

$$xx_1 + yy_1 + g(x + x_1) + f(y + y_1) + c = 0 \quad (42)$$

Ellipse (Fig. 92). The equation is

$$\frac{(x - x_0)^2}{a^2} + \frac{(y - y_0)^2}{b^2} = 1 \quad (43)$$

where (x_0, y_0) is the center, a the semimajor axis, and b the semiminor axis. In Fig. 92, $(x_0, y_0) = (0, 0)$.

Coordinates of foci are $F_1 = (-ae, 0)$, $F_2 = (ae, 0)$; $e^2 = (F_1P)^2 / (MP)^2 = 1 - b^2/a^2 < 1$; and the directrices are the lines $x = -a/e$, $x = a/e$.

The chord LL' through F is called the *latus rectum* and has the length $2b^2/a = 2a(1 - e^2)$. If P_1 is any point on the ellipse, $F_1P_1 = a + ex_1$, $F_2P_1 = a - ex_1$, and $F_1P_1 + F_2P_1 = 2a$ (a constant).

The area of the ellipse with semiaxes a and b is

$$A = \pi ab \quad (44)$$

The equation of the tangent to the ellipse (Fig. 92) at the point (x_1, y_1) is

$$\frac{xx_1}{a^2} + \frac{yy_1}{b^2} = 1 \quad (45)$$

the equation of the tangent with slope m is

$$y = mx \pm \sqrt{a^2m^2 + b^2} \quad (46)$$

The equation of the normal to the ellipse at the point (x_1, y_1) is

$$a^2y_1(x - x_1) - b^2x_1(y - y_1) = 0 \quad (47)$$

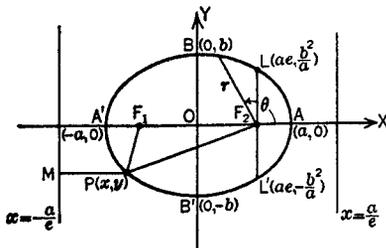

Fig. 92

Conjugate Diameters. A line through the center of an ellipse is a *diameter*; if the slopes m and m' of the two diameters $y = mx$ and $y = m'x$ are such that $mm' = -b^2/a^2$ each diameter bisects all chords parallel to the other and the diameters are called *conjugate*.

Other Forms of the Equation of the Ellipse

$$\frac{x^2}{a^2} + \frac{y^2}{a^2(1 - e^2)} = 1 \quad (48)$$

$$ax^2 + by^2 + 2gx + 2fy + c = 0 \quad (49)$$

If a , b , and $g^2/a + f^2/b - c$ have the same sign, (49) is an ellipse whose axes are parallel to the coordinate axes.

The parametric form is

$$x = a \cos \phi \quad y = b \sin \phi \quad (50)$$

Hyperbola (Fig. 93). The equation is

$$\frac{(x - x_0)^2}{a^2} - \frac{(y - y_0)^2}{b^2} = 1 \quad (51)$$

where (x_0, y_0) is the center, $AA' = 2a$ is the transverse axis, and $BB' = 2b$ is the conjugate axis. In Fig. 93, $(x_0, y_0) = (0, 0)$;

$$e^2 = \frac{(F_1P)^2}{(PM)^2} = 1 + \frac{b^2}{a^2} > 1$$

the coordinates of the foci are $F_1 = (-ae, 0)$, $F_2 = (ae, 0)$; and the directrices are the lines $x = -a/e$, $x = a/e$.

The chord LL' through F is called the *latus rectum* and has the length $2b^2/a = 2a(e^2 - 1)$. If P_1 is any point on the curve, $F_1P_1 = ex_1 - a$, $F_2P_1 = ex_1 + a$, and $|F_2P_1 - F_1P_1| = 2a$ (a constant).

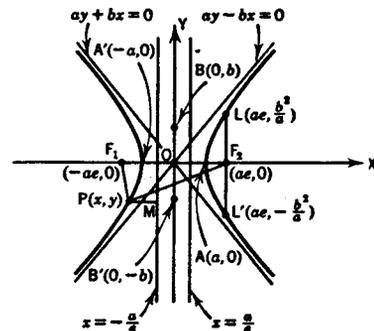

Fig. 93

The equation of the tangent to the hyperbola (Fig. 93) at the point (x_1, y_1) is

$$\frac{xx_1}{a^2} - \frac{yy_1}{b^2} = 1 \tag{52}$$

The equation of the tangent whose slope is m is

$$y = mx \pm \sqrt{a^2m^2 - b^2} \tag{53}$$

The equation of the normal to the hyperbola at the point (x_1, y_1) is

$$a^2y_1(x - x_1) + b^2x_1(y - y_1) = 0 \tag{54}$$

Conjugate Hyperbolas and Diameters. The two hyperbolas

$$\frac{x^2}{a^2} - \frac{y^2}{b^2} = 1 \quad \frac{y^2}{b^2} - \frac{x^2}{a^2} = 1$$

are conjugate. The transverse axis of each is the conjugate axis of the other.

If the slopes of the two lines $y = mx$ and $y = m_1x$ through the center O are connected by the relation $mm_1 = b^2/a^2$, each of these lines bisects all chords of the hyperbola that are parallel to the other line. Two such lines are called *conjugate diameters*. The equation of the hyperbola referred to its conjugate diameters as oblique axes is

$$\frac{x'^2}{a_1^2} - \frac{y'^2}{b_1^2} = 1 \tag{55}$$

where $2a_1$ and $2b_1$ are the conjugate axes.

Asymptotes. The lines $y = (b/a)x$ and $y = -(b/a)x$ are the *asymptotes* of the hyperbola $x^2/a^2 - y^2/b^2 = 1$. The asymptotes are two tangents whose points of contact with the curve are at an infinite distance from the center. The equation of the hyperbola when referred to its asymptotes as oblique axes is

$$4x'y' = a^2 + b^2 \tag{56}$$

If $a = b$, the asymptotes are the perpendicular lines $y = x, y = -x$; the corresponding hyperbola

$$x^2 - y^2 = a^2 \tag{57}$$

is called the *rectangular* or *equilateral hyperbola*.

Other Forms of the Equation of the Hyperbola

$$\frac{x^2}{a^2} - \frac{y^2}{a^2(e^2 - 1)} = 1 \tag{58}$$

$$ax^2 + by^2 + 2gx + 2fy + c = 0 \tag{59}$$

If a and b have unlike signs, (59) is a hyperbola with axes parallel to the coordinate axes.

The parametric form is

$$x = a \sec \phi \quad y = a \tan \phi \tag{60}$$

Parabola. The equation of the parabola is

$$(y - y_0)^2 = 4a(x - x_0) \tag{61}$$

If $(x_0, y_0) = (0, 0)$, the vertex is at the origin (Fig. 94); the focus F is on OX , called the *axis of the parabola*, and has the coordinates $(a, 0)$; and the directrix is $x = -a$. The chord LL' through F is the *latus rectum* and has the length $4a$. The eccentricity $e = FP/PM = 1$.

The tangent to the parabola $y^2 = 4ax$ at the point (x_1, y_1) is

$$yy_1 = 2a(x + x_1) \tag{62}$$

The equation of the tangent whose slope is m is

$$y = mx + \frac{a}{m} \tag{63}$$

The normal to the parabola at the point (x_1, y_1) is

$$2a(y - y_1) + y_1(x - x_1) = 0 \tag{64}$$

A diameter of the curve is a straight line parallel to the axis. It bisects all chords parallel to the tangent at the point where the diameter meets the parabola.

If P_1T is tangent to the curve at (x_1, y_1) , then $TQ = 2x_1$ is the *subtangent*, and $QN = 2a$ (a constant) is the *subnormal*, where P_1N is perpendicular to P_1T .

The equation of the form $y^2 + 2gx + 2fy + c = 0$, where $g \neq 0$, is a parabola whose axis is parallel to OX ; and the equation $x^2 + 2gx + 2fy + c = 0$, where $f \neq 0$, is a parabola whose axis is parallel to OY .

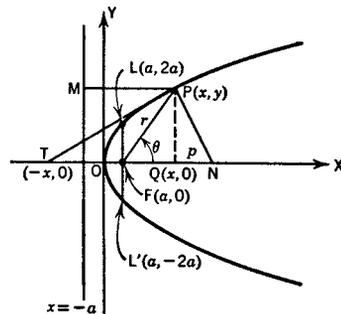

Fig. 94

The parabola referred to the tangents at the extremities of its latus rectum as axes of coordinates is

$$x^{1/2} \pm y^{1/2} = b^{1/2} \tag{65}$$

where b is the distance from the origin to each point of tangency.

Polar Equations of the Conics. If e is the eccentricity, the directrix is vertical, the focus is at a distance p to the right or left of it, respectively, and the polar origin is taken at the focus, the polar equation is

$$r = \begin{cases} \frac{ep}{1 \mp e \cos \theta} & \text{for ellipse, hyperbola, or parabola} \\ \frac{a(1 - e^2)}{1 \mp e \cos \theta} & \text{for ellipse or circle} \\ \frac{a(e^2 - 1)}{1 \mp e \cos \theta} & \text{for hyperbola} \end{cases} \tag{66}$$

If the directrix is horizontal and the focus is at a distance p above or below it, respectively, the polar equation is

$$r = \begin{cases} \frac{ep}{1 \mp e \sin \theta} & \text{for ellipse, hyperbola, or parabola} \\ \frac{a(1 - e^2)}{1 \mp e \sin \theta} & \text{for ellipse or circle} \\ \frac{a(e^2 - 1)}{1 \mp e \sin \theta} & \text{for hyperbola} \end{cases} \tag{69}$$

General Equation of a Conic Section. This equation has the form

$$ax^2 + 2hxy + by^2 + 2gx + 2fy + c = 0 \tag{72}$$

Let

$$D = \begin{vmatrix} a & h & g \\ h & b & f \\ g & f & c \end{vmatrix} \quad d = \begin{vmatrix} a & h \\ h & b \end{vmatrix} \quad \delta = a + b \tag{73}$$

Then the following is a classification of conic sections:

1. A parabola for $d = 0, D \neq 0$
2. Two parallel lines (possibly coincident or imaginary) for $d = 0, D = 0$
3. An ellipse for $d > 0, \delta D < 0$
4. No locus (imaginary ellipse) for $d > 0, \delta D > 0$
5. Point ellipse for $d > 0, D = 0$
6. A hyperbola for $d < 0, D \neq 0$
7. Two intersecting lines for $d < 0, D = 0$

Let $A + B = a + b, AB = ab - h^2 = d,$ and $A - B$ have the same sign as $h.$ Let $c' = D/d;$ then the equation of the conic referred to its axes is

$$\frac{x^2}{-c'/A} + \frac{y^2}{-c'/B} = 1 \tag{74}$$

To find the center (x_0, y_0) of the conic solve the equations

$$ax_0 + hy_0 + g = 0 \quad hx_0 + by_0 + f = 0 \tag{75}$$

To remove the term in xy from (64), rotate the axes about the origin through an angle θ such that $\tan 2\theta = 2h/(a - b).$

7.4 Higher Plane Curves

Plane Curves. The point (x, y) describes a plane curve if x and y are continuous functions of a variable t (parameter), as $x = x(t), y = y(t).$ The elimination of t from the two equations gives $F(x, y) = 0$ or in explicit form $y = f(x).$ The angle $\tau,$ which a tangent to the curve makes with $OX,$ can be found from

$$\sin \tau = \frac{dy}{ds} \quad \cos \tau = \frac{dx}{ds} \quad \tan \tau = \frac{dy}{dx} = y' \tag{76}$$

where ds is the element of arc length:

$$ds = \sqrt{dx^2 + dy^2} = \sqrt{1 + y'^2} dx \tag{77}$$

In polar coordinates,

$$ds = \sqrt{dr^2 + r^2 d\theta^2} = \sqrt{\left(\frac{dr}{d\theta}\right)^2 \theta p + r^2} \tag{78}$$

From (Fig. 95), it may be seen that

$$\sin \psi = \frac{r d\theta}{ds} \quad \cos \psi = \frac{dr}{ds} \quad \tan \psi = \frac{r d\theta}{dr} \tag{79}$$

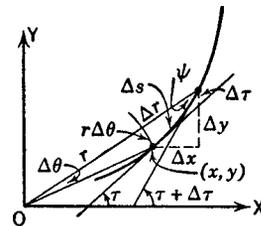

Fig. 95

The equation of the tangent to the curve $F(x, y) = 0$ at the point (x_1, y_1) is

$$\left(\frac{\partial F}{\partial x}\right)_{x=x_1, y=y_1} (x - x_1) + \left(\frac{\partial F}{\partial y}\right)_{x=x_1, y=y_1} (y - y_1) = 0 \quad (80)$$

The equation of the normal to the curve $F(x, y) = 0$ at the point (x_1, y_1) is

$$\left(\frac{\partial F}{\partial y}\right)_{x=x_1, y=y_1} (x - x_1) - \left(\frac{\partial F}{\partial x}\right)_{x=x_1, y=y_1} (y - y_1) = 0 \quad (81)$$

The equation of the tangent to the curve $y = f(x)$ at the point (x_1, y_1) is

$$y - y_1 = \left(\frac{dy}{dx}\right)_{x=x_1} (x - x_1) \quad (82)$$

The equation of the normal to the curve $y = f(x)$ at the point (x_1, y_1) is

$$y - y_1 = -\frac{1}{(dy/dx)_{x=x_1}} (x - x_1) \quad (83)$$

The radius of curvature of the curve at the point (x, y) is

$$\rho = \frac{ds}{d\tau} = \frac{[1 + (dy/dx)^2]^{3/2}}{d^2y/dx^2} = \frac{[1 + y'^2]^{3/2}}{y''} \quad (84)$$

The reciprocal $1/\rho$ is called the *curvature of the curve* at (x, y) .

The coordinates (x_0, y_0) of the center of curvature for the point (x, y) on the curve [the center of the circle of curvature tangent to the curve at (x, y) and of radius ρ] are

$$x_0 = x - \rho \frac{dy}{ds} = x - y' \frac{[1 + y'^2]}{y''}$$

$$y_0 = y + \rho \frac{dx}{ds} = y + \frac{[1 + y'^2]}{y''}$$

A curve has a *singular point* if, simultaneously,

$$F(x, y) = 0 \quad \frac{\partial F}{\partial x} = 0 \quad \frac{\partial F}{\partial y} = 0 \quad (85)$$

Let

$$D = \left(\frac{\partial^2 F}{\partial x \partial y}\right)^2 - \frac{\partial^2 F}{\partial x^2} \frac{\partial^2 F}{\partial y^2} \quad (86)$$

Then for $D > 0$, the curve has a *double point* with two real different tangents. For $D = 0$, the curve has a *cusp* with two coincident tangents. For $D < 0$, the curve has an *isolated point* with no real tangents. See Figs. 96–100 for special curves.

For l large compared with d ,

$$s \approx l \left[1 + \frac{2}{3} \left(\frac{2d}{l}\right)^2 \right]$$

8.1 Coordinate Systems

Right-Hand Rectangular (Fig. 127). The position of a point $P(x, y, z)$ is fixed by its distances x, y, z from the mutually perpendicular planes $yz, xz,$ and $xy,$ respectively.

Spherical, or Polar (Fig. 128). The position of a point $P(r, \theta, \phi)$ is fixed by its distance from a given point $O,$ the origin, and its direction from $O,$ determined by the angles θ and $\phi.$

Cylindrical (Fig. 128). The position of a point $P(\rho, \phi, z)$ is fixed by its distance z from a given plane and the polar coordinates (ρ, ϕ) of the projection Q of P on the given plane.

$$r = b \sec \theta - a$$

Fig. 120

To divide the segment P_1P_2 in the ratio c_1/c_2 , internally or externally,

$$x = \frac{c_2x_1 \pm c_1x_2}{c_2 \pm c_1} \quad y = \frac{c_2y_1 \pm c_1y_2}{c_2 \pm c_1}$$

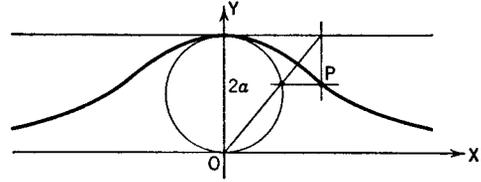

$$z = \frac{c_2z_1 \pm c_1z_2}{c_2 \pm c_1} \tag{96}$$

The midpoint of P_1P_2 is

$$x = \frac{1}{2}(x_1 + x_2) \quad y = \frac{1}{2}(y_1 + y_2)$$

$$z = \frac{1}{2}(z_1 + z_2) \tag{97}$$

Witch of Agnesi

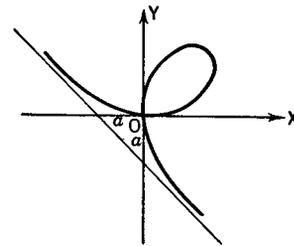

$$y = \frac{8a^2}{x^2 + 4a^2}$$

$$x = 2a \tan \phi$$

$$y = 2a \cos^2 \phi$$

Fig. 121

Folium of Descartes

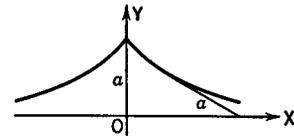

$$x^3 + y^3 - 3axy = 0$$

$$r = \frac{3a \sin \theta \cos \theta}{\sin^2 \theta + \cos^3 \theta}$$

Fig. 122

Tractrix

$$x = a \cosh^{-1} \frac{a}{y} - \sqrt{a^2 - y^2}$$

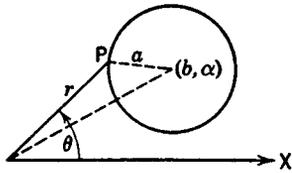

Fig. 123

Angles. The angles α, β, γ that the line P_1P_2 makes with the coordinate directions x, y, z , respectively, are the *direction angles* of P_1P_2 . The cosines

$$\cos \alpha = \frac{x_2 - x_1}{s} \quad \cos \beta = \frac{y_2 - y_1}{s}$$

$$\cos \gamma = \frac{z_2 - z_1}{s} \tag{98}$$

Circles in Polar Coordinates

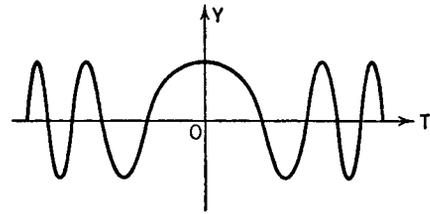

$$r^2 + b^2 - 2rb \cos(\theta - \alpha) = a^2$$

Center at (b, α) , radius a

Fig. 124

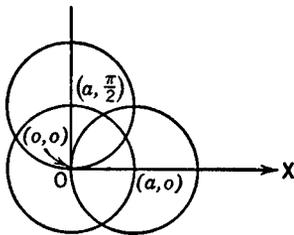

Frequency-modulated Wave

$$y = k \cos[\phi(t)] \quad \text{instantaneous frequency} = \Omega(t) = \frac{d\phi}{dt}$$

Fig. 126

Circles in Polar Coordinates

- Center $(0, 0) \quad r = a$
- Center $(a, 0) \quad r = 2a \cos \theta$
- Center $(a, \frac{\pi}{2}) \quad r = 2a \sin \theta$

Fig. 125

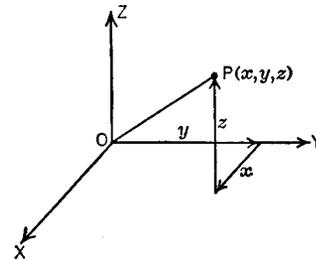

Fig. 127

are the *direction cosines* of $P_1 P_2$, and

$$\cos^2 \alpha + \cos^2 \beta + \cos^2 \gamma = 1 \quad (99)$$

If $l : m : n = \cos \alpha : \cos \beta : \cos \gamma$, then

$$\begin{aligned} \cos \alpha &= \frac{l}{\sqrt{l^2 + m^2 + n^2}} & \cos \beta &= \frac{m}{\sqrt{l^2 + m^2 + n^2}} \\ \cos \gamma &= \frac{n}{\sqrt{l^2 + m^2 + n^2}} \end{aligned} \quad (100)$$

The angle θ between two lines in terms of their direction angles $\alpha_1, \beta_1, \gamma_1$ and $\alpha_2, \beta_2, \gamma_2$ is obtained from

$$\cos \theta = \cos \alpha_1 \cos \alpha_2 + \cos \beta_1 \cos \beta_2 + \cos \gamma_1 \cos \gamma_2 \quad (101)$$

If $\cos \theta = 0$, the lines are perpendicular to each other.

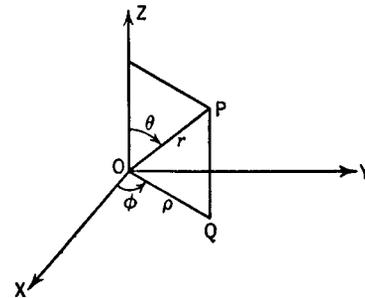

Fig. 128

Planes. A plane is represented by

$$Ax + By + Cz + D = 0 \quad (102)$$

If one of the variables is missing, the plane is parallel to the axis of the missing variable. For example, $Ax + By + D = 0$ represents a plane parallel to the z axis. If two of the variables are missing, the plane is parallel to the plane of the missing variables. For example, $z = k$ represents a plane parallel to the xy plane and k units from it.

A plane through *three points* $P_1(x_1, y_1, z_1)$, $P_2(x_2, y_2, z_2)$, and $P_3(x_3, y_3, z_3)$ has the equation

$$\begin{vmatrix} x & y & z & 1 \\ x_1 & y_1 & z_1 & 1 \\ x_2 & y_2 & z_2 & 1 \\ x_3 & y_3 & z_3 & 1 \end{vmatrix} = 0 \quad (103)$$

The equation of a plane whose x, y, z intercepts are, respectively, a, b, c (Fig. 129) is

$$\frac{x}{a} + \frac{y}{b} + \frac{z}{c} = 1 \quad (104)$$

The perpendicular form of the equation of a plane, where $OP = p$ is the perpendicular distance of the plane from the origin O and has the direction angles α, β, γ , is

$$x \cos \alpha + y \cos \beta + z \cos \gamma - p = 0 \quad (105)$$

To bring the general form $Ax + By + Cz + D = 0$ into the perpendicular form, divide it by $\pm\sqrt{A^2 + B^2 + C^2}$, where the sign before the radical is opposite to that of D .

The coefficients A, B, C are proportional to the direction cosines λ, μ, ν of a line perpendicular to the plane. Therefore,

$$A(x - x_1) + B(y - y_1) + C(z - z_1) = 0 \quad (106)$$

is a plane through $P_1(x_1, y_1, z_1)$ and perpendicular to a line with direction cosines λ, μ, ν proportional to A, B, C .

Perpendicular Distance between Point and Plane. The distance between point P_1 from a plane $Ax + By + Cz + D = 0$ is given by

$$PP_1 = \frac{Ax_1 + By_1 + Cz_1 + D}{\pm\sqrt{A^2 + B^2 + C^2}} \quad (107)$$

where the sign before the radical is opposite to that of D .

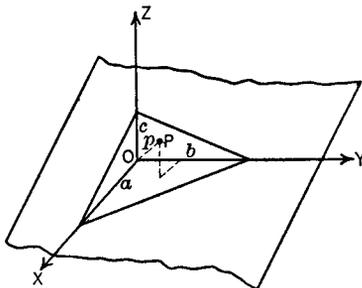

Fig. 129

Parallel Planes. Two planes $A_1x + B_1y + C_1z + D_1 = 0$ and $A_2x + B_2y + C_2z + D_2 = 0$ are parallel if $A_1 : B_1 : C_1 = A_2 : B_2 : C_2$;

$$A(x - x_1) + B(y - y_1) + C(z - z_1) = 0 \quad (108)$$

is a plane through the point $P_1(x_1, y_1, z_1)$ and parallel to the plane $Ax + By + Cz + D = 0$.

Angle θ between Two Planes. The angle between $Ax + By + Cz + D = 0$ and $A_1x + B_1y + C_1z + D_1 = 0$ is the angle between two intersecting lines, each perpendicular to one of the planes:

$$\cos \theta = \frac{AA_1 + BB_1 + CC_1}{\pm\sqrt{(A^2 + B^2 + C^2)(A_1^2 + B_1^2 + C_1^2)}} \quad (109)$$

The two planes are perpendicular if $AA_1 + BB_1 + CC_1 = 0$.

Points, Planes, and Lines. Four points, $P_k(x_k, y_k, z_k)$ ($k = 1, 2, 3, 4$), lie in the same plane if

$$\begin{vmatrix} 1 & x_1 & y_1 & z_1 \\ 1 & x_2 & y_2 & z_2 \\ 1 & x_3 & y_3 & z_3 \\ 1 & x_4 & y_4 & z_4 \end{vmatrix} = 0 \quad (110)$$

Four planes, $A_kx + B_ky + C_kz + D_k = 0$ ($k = 1, 2, 3, 4$), pass through the same point if

$$\begin{vmatrix} A_1 & B_1 & C_1 & D_1 \\ A_2 & B_2 & C_2 & D_2 \\ A_3 & B_3 & C_3 & D_3 \\ A_4 & B_4 & C_4 & D_4 \end{vmatrix} = 0 \quad (111)$$

A *straight line* is represented as the intersection of two planes by two first-degree equations

$$\begin{aligned} A_1x + B_1y + C_1z + D_1 &= 0 \\ A_2x + B_2y + C_2z + D_2 &= 0 \end{aligned} \quad (112)$$

The three planes through the line perpendicular to the coordinate planes are its *projecting planes*. The equation of the xy projecting plane is found by eliminating z between the two given equations, and so on. The line can be represented by any two of its projecting planes, for example,

$$y = m_1x + b_1 \quad z = m_2x + b_2 \quad (113)$$

If the line goes through a point $P_1(x_1, y_1, z_1)$ and has the direction angles α, β, γ , then

$$\frac{x - x_1}{\cos \alpha} = \frac{y - y_1}{\cos \beta} = \frac{z - z_1}{\cos \gamma} \quad (114)$$

and

$$m_1 = \frac{\cos \beta}{\cos \alpha} \quad m_2 = \frac{\cos \gamma}{\cos \alpha}$$

The equations of a line through two points (x_1, y_1, z_1) and (x_2, y_2, z_2) are

$$\frac{x - x_1}{x_2 - x_1} = \frac{y - y_1}{y_2 - y_1} = \frac{z - z_1}{z_2 - z_1} \quad (115)$$

A line through a point P_1 perpendicular to a plane $Ax + By + Cz + D = 0$ has the equations

$$\frac{x - x_1}{A} = \frac{y - y_1}{B} = \frac{z - z_1}{C} \quad (116)$$

Line of Intersection of Two Planes. The direction cosines λ, μ, ν of the line of intersection of two planes $Ax + By + Cz + D = 0$ and $A_1x + B_1y + C_1z + D_1 = 0$ are found from the ratios

$$\lambda : \mu : \nu = \left| \begin{matrix} B & C \\ B_1 & C_1 \end{matrix} \right| : \left| \begin{matrix} C & A \\ C_1 & A_1 \end{matrix} \right| : \left| \begin{matrix} A & B \\ A_1 & B_1 \end{matrix} \right| \quad (117)$$

8.3 Transformation of Coordinates

Changing the Origin. Let the coordinates of a point P with respect to the original axes be x, y, z and with respect to the new axes x', y', z' . For a parallel displacement of the axes with x_0, y_0, z_0 the coordinates of the new origin

$$x = x_0 + x' \quad y = y_0 + y' \quad z = z_0 + z' \quad (118)$$

Rotation of the Axes about the Origin. Let the cosines of the angles of the new axes x', y', z' with the x axis be λ_1, μ_1, ν_1 , with the y axis be λ_2, μ_2, ν_2 , with the z axis be λ_3, μ_3, ν_3 . Then

$$\begin{aligned} x &= \lambda_1 x' + \mu_1 y' + \nu_1 z' & x' &= \lambda_1 x + \lambda_2 y + \lambda_3 z \\ y &= \lambda_2 x' + \mu_2 y' + \nu_2 z' & y' &= \mu_1 x + \mu_2 y + \mu_3 z \\ z &= \lambda_3 x' + \mu_3 y' + \nu_3 z' & z' &= \nu_1 x + \nu_2 y + \nu_3 z \end{aligned} \quad (119)$$

The following relations exist:

$$\begin{aligned} (1) \quad & \lambda_1^2 + \mu_1^2 + \nu_1^2 = 1 \\ & \lambda_2^2 + \mu_2^2 + \nu_2^2 = 1 \\ & \lambda_3^2 + \mu_3^2 + \nu_3^2 = 1 \\ (2) \quad & \lambda_1^2 + \lambda_2^2 + \lambda_3^2 = 1 \\ & \mu_1^2 + \mu_2^2 + \mu_3^2 = 1 \\ & \nu_1^2 + \nu_2^2 + \nu_3^2 = 1 \\ (3) \quad & \lambda_1 \lambda_2 + \mu_1 \mu_2 + \nu_1 \nu_2 = 0 \\ & \lambda_2 \lambda_3 + \mu_2 \mu_3 + \nu_2 \nu_3 = 0 \\ & \lambda_3 \lambda_1 + \mu_3 \mu_1 + \nu_3 \nu_1 = 0 \\ (4) \quad & \lambda_1 \mu_1 + \lambda_2 \mu_2 + \lambda_3 \mu_3 = 0 \\ & \mu_1 \nu_1 + \mu_2 \nu_2 + \mu_3 \nu_3 = 0 \\ & \nu_1 \lambda_1 + \nu_2 \lambda_2 + \nu_3 \lambda_3 = 0 \\ (5) \quad & \lambda_1 = \mu_2 \nu_3 - \nu_2 \mu_3 \\ & \mu_1 = \nu_2 \lambda_3 - \lambda_2 \nu_3 \\ & \nu_1 = \lambda_2 \mu_3 - \mu_2 \lambda_3 \\ (6) \quad & \lambda_2 = \nu_1 \mu_3 - \mu_1 \nu_3 \\ & \mu_2 = \lambda_1 \nu_3 - \nu_1 \lambda_3 \\ & \nu_2 = \mu_1 \lambda_3 - \lambda_1 \mu_3 \\ (7) \quad & \lambda_3 = \mu_1 \nu_2 - \nu_1 \mu_2 \\ & \mu_3 = \nu_1 \lambda_2 - \lambda_1 \nu_2 \\ & \nu_3 = \lambda_1 \mu_2 - \mu_1 \lambda_2 \\ (8) \quad & \begin{vmatrix} \lambda_1 & \mu_1 & \nu_1 \\ \lambda_2 & \mu_2 & \nu_2 \\ \lambda_3 & \mu_3 & \nu_3 \end{vmatrix} = 1 \end{aligned}$$

For a combination of displacement and rotation, apply the corresponding equations simultaneously.

8.4 Quadric Surfaces

The general form of the equation of a surface of the second degree is

$$\begin{aligned} F(x, y, z) &\equiv a_{11}x^2 + 2a_{12}xy + 2a_{13}xz + a_{22}y^2 \\ &+ 2a_{23}yz + a_{33}z^2 + 2a_{14}x \\ &+ 2a_{24}y + 2a_{34}z + a_{44} = 0 \end{aligned} \quad (120)$$

where the a_{ik} are constants and $a_{ik} = a_{ki}$, that is, $a_{12} = a_{21}$, and so on. Let

$$D = \begin{vmatrix} a_{11} & a_{12} & a_{13} & a_{14} \\ a_{21} & a_{22} & a_{23} & a_{24} \\ a_{31} & a_{32} & a_{33} & a_{34} \\ a_{41} & a_{42} & a_{43} & a_{44} \end{vmatrix} \quad d = \begin{vmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{vmatrix}$$

Let $I \equiv a_{11} + a_{22} + a_{33}$, and $J \equiv a_{22}a_{33} + a_{33}a_{11} + a_{11}a_{22} - a_{23}^2 - a_{13}^2 - a_{12}^2$. Here, D, d, I , and J are invariant under coordinate transformation. The following is a classification of the quadratic surfaces, so far as they are real and do not degenerate into curves in one plane:

Ellipsoid for $D < 0, Id > 0, J > 0$

Hyperboloid of two sheets for $D < 0, Id$ and J not both > 0

Hyperboloid of one sheet for $D > 0, Id$ and J not both > 0

Cone for $D = 0, d \neq 0, Id$ and J not both > 0

Elliptic paraboloid for $D < 0, d = 0, J > 0$

Hyperbolic paraboloid for $D > 0, d = 0, J < 0$

Cylinder for $D = 0, d = 0$

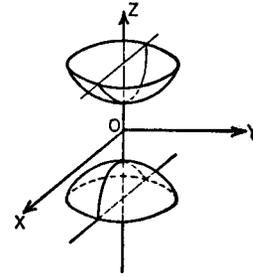

Fig. 132

Ellipsoid and Hyperboloids. Consider the center of the quadric as the origin and the principal axes of the quadric as the orthogonal coordinate axes. Then

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} + \frac{z^2}{c^2} = 1 \quad [\text{ellipsoid (Fig. 130)}] \quad (121)$$

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} - \frac{z^2}{c^2} = 1 \quad [\text{hyperboloid of one sheet (Fig. 131)}] \quad (122)$$

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} + \frac{z^2}{c^2} = -1 \quad [\text{hyperboloid of two sheets (Fig. 132)}] \quad (123)$$

where a, b, c are the semiaxes.

The length of the semiaxis is found from

$$a^2 = -\frac{D}{\lambda_1 d} \quad b^2 = -\frac{D}{\lambda_2 d} \quad c^2 = -\frac{D}{\lambda_3 d} \quad (124)$$

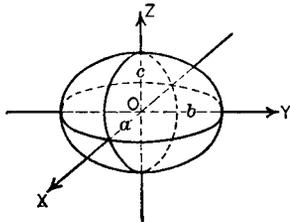

Fig. 130

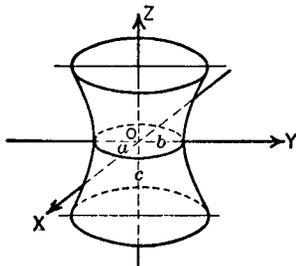

Fig. 131

where $\lambda_1, \lambda_2, \lambda_3$ are the real roots of the cubic equation

$$\begin{vmatrix} a_{11} - \lambda & a_{12} & a_{13} \\ a_{12} & a_{22} - \lambda & a_{23} \\ a_{13} & a_{23} & a_{33} - \lambda \end{vmatrix} = 0 \quad (125)$$

Cone. The equation

$$ax^2 + by^2 + cz^2 + 2hxy + 2gxz + 2fyz = 0 \quad (126)$$

represents a cone with vertex at the origin. If the cross section of the cone is an ellipse with axes $2a$ and $2b$ whose plane is parallel to the xy plane and at a distance c from the origin, then the equation of the cone with vertex at the origin is

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} - \frac{z^2}{c^2} = 0 \quad (127)$$

If $a = b$, the cross section is circular and the cone is a cone of revolution.

Sphere. An equation of the form

$$x^2 + y^2 + z^2 + ax + by + cz + d = 0 \quad (128)$$

represents a sphere with radius

$$r = \frac{1}{2} \sqrt{a^2 + b^2 + c^2 - 4d} \quad (129)$$

and center

$$x_0 = -\frac{1}{2}a \quad y_0 = -\frac{1}{2}b \quad z_0 = -\frac{1}{2}c \quad (130)$$

If (x_0, y_0, z_0) are the coordinates of the center and r is the radius, then the equation of the sphere is

$$(x - x_0)^2 + (y - y_0)^2 + (z - z_0)^2 = r^2 \quad (131)$$

If $x_0 = 0, y_0 = 0, z_0 = 0$, then the equation is

$$x^2 + y^2 + z^2 = r^2 \quad (132)$$

Paraboloids. The equation

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} = 2cz \quad (133)$$

represents an *elliptic paraboloid* (Fig. 133).

If $a = b$, the equation is of the form

$$x^2 + y^2 = 2cz \quad (\text{paraboloid of revolution}) \quad (134)$$

The equation

$$\frac{x^2}{a^2} - \frac{y^2}{b^2} = 2cz \quad [\text{hyperbolic paraboloid (Fig. 134)}] \quad (135)$$

Cylinder. The equation of a cylinder perpendicular to the yz , xz , or xy plane is the same as the equation of a section of the cylinder in the corresponding plane. Thus

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1 \quad (136)$$

$$\frac{x^2}{a^2} - \frac{y^2}{b^2} = 1 \quad (137)$$

$$y^2 = 4ax \quad (138)$$

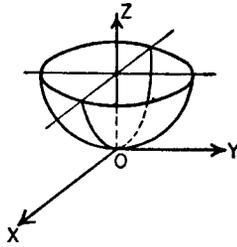

Fig. 133

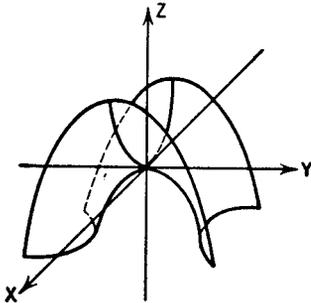

Fig. 134

are elliptic, hyperbolic, and parabolic cylinders, respectively, with elements or generators parallel to OZ .

Tangent Plane. The equation of the tangent plane to any quadric

$$F(x, y, z) \equiv a_{11}x^2 + 2a_{12}xy + 2a_{13}xz + a_{22}y^2 + 2a_{23}yz + a_{33}z^2 + 2a_{14}x + 2a_{24}y + 2a_{34}z + a_{44} = 0 \quad (139)$$

at the point (x_1, y_1, z_1) is

$$\begin{aligned} & \left(\frac{\partial F}{\partial x} \right)_{x=x_1, y=y_1, z=z_1} (x - x_1) \\ & + \left(\frac{\partial F}{\partial y} \right)_{x=x_1, y=y_1, z=z_1} (y - y_1) \\ & + \left(\frac{\partial F}{\partial z} \right)_{x=x_1, y=y_1, z=z_1} (z - z_1) = 0 \quad (140) \end{aligned}$$

Example 47. Find the tangent plane to the hyperboloid of one sheet at point (x_1, y_1, z_1) . Given $x^2/a^2 + y^2/b^2 - z^2/c^2 = 1$. Then

$$\begin{aligned} & \left(\frac{\partial F}{\partial x} \right)_{x=x_1, y=y_1, z=z_1} (x - x_1) \\ & + \left(\frac{\partial F}{\partial y} \right)_{x=x_1, y=y_1, z=z_1} (y - y_1) \\ & + \left(\frac{\partial F}{\partial z} \right)_{x=x_1, y=y_1, z=z_1} (z - z_1) \\ & = \frac{2x_1(x - x_1)}{a^2} + \frac{2y_1(y - y_1)}{b^2} - \frac{2z_1(z - z_1)}{c^2} = 0 \\ & \frac{xx_1}{a^2} + \frac{yy_1}{b^2} - \frac{zz_1}{c^2} - \frac{x_1^2}{a^2} - \frac{y_1^2}{b^2} + \frac{z_1^2}{c^2} \\ & = \frac{xx_1}{a^2} + \frac{yy_1}{b^2} - \frac{zz_1}{c^2} - 1 = 0 \quad (\text{tangent plane}) \end{aligned}$$

The Normal. The line through a point P_1 on a surface and perpendicular to the tangent plane at P_1 is called the normal to the surface at P_1 .

The equations of the normal to the surface $F(x, y, z) = 0$ at the point (x_1, y_1, z_1) are

$$\begin{aligned} \frac{x - x_1}{\left(\frac{\partial F}{\partial x} \right)_{x=x_1, y=y_1, z=z_1}} & = \frac{y - y_1}{\left(\frac{\partial F}{\partial y} \right)_{x=x_1, y=y_1, z=z_1}} \\ & = \frac{z - z_1}{\left(\frac{\partial F}{\partial z} \right)_{x=x_1, y=y_1, z=z_1}} \quad (141) \end{aligned}$$

9 DIFFERENTIAL CALCULUS

9.1 Functions and Derivatives

Function. If two variables x and y are so related that to each value of x in a given domain there corresponds a value of y , then y is a *function* of x in that domain. The variable x is the *independent* variable and y the *dependent* variable. The symbols $F(x)$, $f(x)$, $\phi(x)$, and so on, are used to represent functions of x ; the symbol $f(a)$ represents the value of $f(x)$ for $x = a$.

Limit, Derivative, Differential. The function $f(x)$ approaches the limit l as x approaches a if the difference $|f(x) - l|$ can be made arbitrarily small for all values of x except a within a sufficiently small interval with a as midpoint. In symbols, $\lim_{x \rightarrow a} f(x) = l$.

The symbols $\lim_{x \rightarrow a} f(x) = \infty$ or $\lim_{x \rightarrow a} f(x) = -\infty$ mean that, for all values of x except a within a sufficiently small interval with a as midpoint, the values of $f(x)$ can be made arbitrarily large positively or negatively, respectively.

The symbols $\lim_{x \rightarrow \infty} f(x) = l$ and $\lim_{x \rightarrow -\infty} f(x) = l$ mean that the difference $|f(x) - l|$ can be made arbitrarily small for all values of x sufficiently large positively or negatively, respectively.

A change in x is called an *increment* of x and is denoted by Δx . The corresponding change in y is denoted by Δy . If

$$\lim_{\Delta x \rightarrow 0} \frac{f(x + \Delta x) - f(x)}{\Delta x}$$

exists, it is called the *derivative* of y with respect to x and is denoted by dy/dx , $f'(x)$, or $D_x y$.

The geometric interpretation of $f'(x)$ is

$$f'(x) = \frac{dy}{dx} = \tan \theta \tag{142}$$

or $f'(x)$ is equal to the slope of the tangent to the curve $y = f(x)$ at the point $P(x, y)$ (Fig. 135):

$$\begin{aligned} \frac{RS}{PR} &= \lim_{PR \rightarrow 0} \frac{RQ}{PR} = \lim_{\Delta x \rightarrow 0} \frac{\Delta y}{\Delta x} \\ &= \lim_{\Delta x \rightarrow 0} \frac{f(x + \Delta x) - f(x)}{\Delta x} \\ &= \frac{dy}{dx} = f'(x) = \tan \theta \end{aligned} \tag{143}$$

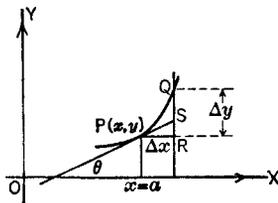

Fig. 135

The differentials of x and y , respectively, are

$$dx = \Delta x \quad dy = f'(x) dx$$

Continuity. A function is *continuous* at $x = b$ if it has a definite value at b and approaches that value as a limit whenever x approaches b as a limit. The notion of continuity at a point suggests that the graph of the function can be drawn without lifting pencil from paper at the point. The analytic conditions that $f(x)$ be continuous at b are that $f(b)$ have a definite value and that for an arbitrarily small positive number ϵ there exist a $\delta(\epsilon)$ such that

$$\begin{aligned} |f(x) - f(b)| < \epsilon \quad \text{for all values of } x \\ \text{for which } |x - b| < \delta(\epsilon) \end{aligned} \tag{144}$$

A function that is continuous at each point of an interval is said to be continuous in that interval. An example of a continuous function is $f(x) = x^2$. The function $\phi(x) = 1/(x - a)$ is continuous for all values of x except $x = a$, at which point it becomes infinite. Every differentiable function is continuous, although the reverse is not always true.

If, in the preceding definition of continuity, the number δ can be chosen the same for all points in the interval, the function is said to be *uniformly continuous* in that interval.

Derivatives of Higher Order. The derivative of the *first derivative* of y with respect to x is called the *second derivative* of y with respect to x and is denoted by

$$\frac{d}{dx} \left(\frac{dy}{dx} \right) = \frac{d^2 y}{dx^2} = f''(x) = D_x^2 y \tag{145}$$

By successive differentiations the n th derivative

$$\frac{d^n y}{dx^n} = f^{(n)}(x) = D_x^n y \tag{146}$$

is obtained.

The n th differential of y is denoted by

$$d^n y = f^{(n)}(x) dx^n \tag{147}$$

Parametric Differentiation. To find the derivatives of y with respect to x if $y = y(t)$ and $x = x(t)$:

$$y' = \frac{dy}{dx} = \frac{dy/dt}{dx/dt} \tag{148}$$

$$y'' = \frac{d^2 y}{dx^2} = \frac{dy'/dt}{dx/dt} \tag{149}$$

$$y^{(n)} = \frac{d^n y}{dx^n} = \frac{dy^{(n-1)}/dt}{dx/dt} \tag{150}$$

Example 48. Find the derivatives of y with respect to x for the ellipse $x = a \cos t, y = b \sin t$:

$$y' = \frac{dy}{dx} = \frac{b \cos t}{-a \sin t} = -\frac{b}{a} \cot t$$

$$y'' = \frac{dy'}{dx} = \frac{(b/a) \csc^2 t}{-a \sin t} = -\frac{b}{a^2} \csc^3 t$$

$$y''' = \frac{dy''}{dx} = \frac{(3b/a^2) \csc^3 t \cot t}{-a \sin t} = -\frac{3b}{a^3} \csc^4 t \cot t$$

Logarithmic Differentiation for Products and Quotients. If

$$y = \frac{u^m v^n}{w^p} \tag{151}$$

take the logarithms of both sides before differentiating:

$$\ln y = l \ln u + m \ln v - n \ln w \tag{152}$$

$$\frac{1}{y} \frac{dy}{dx} = \frac{l}{u} \frac{du}{dx} + \frac{m}{v} \frac{dv}{dx} - \frac{n}{w} \frac{dw}{dx} \tag{153}$$

$$\frac{dy}{dx} = y \left(\frac{l}{u} \frac{du}{dx} + \frac{m}{v} \frac{dv}{dx} - \frac{n}{w} \frac{dw}{dx} \right) \tag{154}$$

Example 49. Find dy/dx if

$$y = \frac{\sqrt{x^2 - 25}}{(x - 1)^3(x + 5)^2}$$

$$\ln y = \frac{1}{2} \ln(x^2 - 25) - 3 \ln(x - 1) - 2 \ln(x + 5)$$

$$\frac{1}{y} \frac{dy}{dx} = \frac{2x}{2(x^2 - 25)} - \frac{3}{x - 1} - \frac{2}{x + 5}$$

$$\frac{dy}{dx} = \frac{y(-4x^2 + 11x + 65)}{(x^2 - 25)(x - 1)}$$

Mean Value Theorem. If $f(x)$ is single valued, continuous in the interval $a \leq x \leq b$, and has a derivative for all values of x between a and b , then there is a value $x = \xi, a < \xi < b$, such that

$$f(b) - f(a) = (b - a)f'(\xi) \tag{155}$$

Another form is

$$f(x + h) = f(x) + hf'(x + \theta h) \quad 0 < \theta < 1 \tag{156}$$

Indeterminate Forms If a function $f(x)$ for $x = a$ (where a can also be ∞) has no determined value but

appears in one of the meaningless forms

$$\frac{0}{0} \quad \frac{\infty}{\infty} \quad 0 \cdot \infty \quad \infty - \infty \quad 0^0 \quad \infty^0 \quad 0^\infty \quad 1^\infty$$

then it may happen that $\lim f(x)$ has a definite value. For the determination of this limiting value, if it exists, the following rules can be used:

0/0. If $f(x) = \phi(x)/\psi(x), \phi(a) = 0,$ and $\psi(a) = 0,$ then

$$\lim_{x \rightarrow a} f(x) = \lim_{x \rightarrow a} \frac{\phi'(x)}{\psi'(x)} \quad (1' \text{ Hospital's rule}) \tag{157}$$

If, however, $\phi'(a) = 0$ and $\psi'(a) = 0,$ the rule is applied again, with the result

$$\lim_{x \rightarrow a} \frac{\phi(x)}{\psi(x)} = \lim_{\xi \rightarrow a} \frac{\phi'(\xi)}{\psi'(\xi)} = \frac{\phi''(a)}{\psi''(a)} \tag{158}$$

unless $\phi''(a) = 0$ and $\psi''(a) = 0.$ In this case, the rule is applied again, and so forth.

Example 50. Find the value of $\sin x/x$ for $x = 0$:

$$\lim_{x \rightarrow 0} \frac{\sin x}{x} = \lim_{x \rightarrow 0} \frac{\cos x}{1} = 1$$

$\infty/\infty.$ If $f(x) = \phi(x)/\psi(x), \phi(a) = \infty,$ and $\psi(a) = \infty,$ then

$$\lim_{x \rightarrow a} \frac{\phi(x)}{\psi(x)} = \lim_{x \rightarrow a} \frac{\phi'(x)}{\psi'(x)} \tag{159}$$

as before.

$0 \cdot \infty.$ If $f(x) = \phi(x) \cdot \psi(x), \phi(a) = 0,$ and $\psi(a) = \infty,$ then place $1/\psi(x) = \omega(x)$ and obtain the previous case 0/0.

$\infty - \infty.$ If $f(x) = \phi(x) - \psi(x), \phi(a) = \infty,$ and $\psi(a) = \infty,$ then place $\phi(x) = 1/u(x), \psi(x) = 1/v(x)$ and obtain

$$f(x) = \frac{v(x) - u(x)}{u(x)v(x)} \tag{160}$$

which takes the form 0/0.

$0^0, \infty^0, 0^\infty, 1^\infty.$ An expression of the type $[\psi(x)]^{\phi(x)}$ may, for $x = a,$ give rise to the forms $0^0, \infty^0, 0^\infty, 1^\infty.$

Such an expression may be reduced to a type 0/0 or ∞/∞ by the use of logarithms. Thus,

$$u = [\psi(x)]^{\phi(x)} \quad \log_e u = \phi(x) \log_e \psi(x) \tag{161}$$

If $\lim_{x \rightarrow a} \phi(x) \log_e \psi(x)$ can be found by the previous methods, the limit approached by u can be found.

Example 51. $u = (1 - x)^{1/x}$ for $x = 0$:

$$\log_e u = \frac{\log_e(1 - x)}{x}$$

$$\lim_{x \rightarrow 0} \frac{\log_e(1 - x)}{x} = \lim_{x \rightarrow 0} \frac{-1/(1 - x)}{1} = -1$$

Therefore $\lim_{x \rightarrow 0} \log_e u = -1$ and $\lim_{x \rightarrow 0} u = e^{-1}$

9.2 Differentiation Formulas

These are listed in Table 9.

9.3 Partial Derivatives

Functions of Two Variables. If three variables $f(x, y)$, x , y are so related that to each pair of values of x and y in a given domain there corresponds a value of $f(x, y)$, then $f(x, y)$ is a function of x and y in that domain. If x is considered as the only variable while y is taken as constant, then the derivative of $f(x, y)$

Table 9 Differentiation Formulas

Let u, v, w, \dots be functions of x ; a and n be constants; and e be the base of the natural or Napierian logarithms. Then $e = 2.7183$.

$$\frac{d}{dx} a = 0$$

$$\frac{d}{dx} (u + v + w + \dots) = \frac{du}{dx} + \frac{dv}{dx} + \frac{dw}{dx} + \dots$$

$$\frac{d}{dx} au = a \frac{du}{dx}$$

$$\frac{d}{dx} uv = u \frac{dv}{dx} + v \frac{du}{dx}$$

$$\frac{d}{dx} (uvw \dots)$$

$$= \left(\frac{1}{u} \cdot \frac{du}{dx} + \frac{1}{v} \frac{dv}{dx} + \frac{1}{w} \frac{dw}{dx} + \dots \right) (uvw \dots)$$

$$\frac{d}{dx} f(u) = \frac{df(u)}{du} \cdot \frac{du}{dx}$$

$$\frac{d^2 f(u)}{dx^2} = \frac{df(u)}{du} \cdot \frac{d^2 u}{dx^2} + \frac{d^2 f(u)}{du^2} \left(\frac{du}{dx} \right)^2$$

$$\frac{d}{dx} \sin u = \cos u \frac{du}{dx}$$

$$\frac{d}{dx} \cos u = -\sin u \frac{du}{dx}$$

$$\frac{d}{dx} \tan u = \sec^2 u \frac{du}{dx}$$

$$\frac{d}{dx} \cot u = -\csc^2 u \frac{du}{dx}$$

$$\frac{d}{dx} \sec u = \sec u \tan u \frac{du}{dx}$$

$$\frac{d}{dx} \csc u = -\csc u \cot u \frac{du}{dx}$$

$$\frac{d}{dx} \sin^{-1} u = \frac{1}{\sqrt{1 - u^2}} \frac{du}{dx} \left(-\frac{\pi}{2} \leq \sin^{-1} u \leq \frac{\pi}{2} \right)$$

$$\frac{d}{dx} \cos^{-1} u = -\frac{1}{\sqrt{1 - u^2}} \frac{du}{dx} \left(0 \leq \cos^{-1} u \leq \pi \right)$$

$$\frac{d}{dx} \tan^{-1} u = \frac{1}{1 + u^2} \frac{du}{dx}$$

$$\frac{d}{dx} \cot^{-1} u = -\frac{1}{1 + u^2} \frac{du}{dx}$$

$$\frac{d}{dx} \sec^{-1} u = \frac{1}{u\sqrt{u^2 - 1}} \frac{du}{dx}$$

$$\frac{d}{dx} \left(\frac{u}{v} \right) = \frac{v(du/dx) - u(dv/dx)}{v^2}$$

$$\frac{d}{dx} u^n = nu^{n-1} \frac{du}{dx}$$

$$\frac{d}{dx} \log_e u = \frac{1}{u} \frac{du}{dx}$$

$$\frac{d}{dx} \log_{10} u = \frac{1}{u} \frac{du}{dx} \log_{10} e = (0.4343) \frac{1}{u} \frac{du}{dx}$$

$$\frac{d}{dx} e^u = e^u \frac{du}{dx}$$

$$\frac{d}{dx} u^v = vu^{v-1} \frac{du}{dx} + u^v \frac{dv}{dx} \log_e u$$

$$\frac{d}{dx} \csc^{-1} u = -\frac{1}{u\sqrt{u^2 - 1}} \frac{du}{dx}$$

$$\frac{d}{dx} \sinh u = \cosh u \frac{du}{dx}$$

$$\frac{d}{dx} \cosh u = \sinh u \frac{du}{dx}$$

$$\frac{d}{dx} \tanh u = \operatorname{sech}^2 u \frac{du}{dx}$$

$$\frac{d}{dx} \coth u = -\operatorname{csch}^2 u \frac{du}{dx}$$

$$\frac{d}{dx} \operatorname{sech} u = -\operatorname{sech} u \tanh u \frac{du}{dx}$$

$$\frac{d}{dx} \operatorname{csch} u = -\operatorname{csch} u \coth u \frac{du}{dx}$$

$$\frac{d}{dx} \sinh^{-1} u = \frac{1}{\sqrt{u^2 + 1}} \frac{du}{dx}$$

$$\frac{d}{dx} \cosh^{-1} u = \frac{1}{\sqrt{u^2 - 1}} \frac{du}{dx}$$

$$\frac{d}{dx} \tanh^{-1} u = \frac{1}{1 - u^2} \frac{du}{dx}$$

$$\frac{d}{dx} \coth^{-1} u = \frac{1}{1 - u^2} \frac{du}{dx}$$

$$\frac{d}{dx} \operatorname{sech}^{-1} u = -\frac{1}{u\sqrt{1 - u^2}} \frac{du}{dx}$$

$$\frac{d}{dx} \operatorname{csch}^{-1} u = -\frac{1}{u\sqrt{u^2 + 1}} \frac{du}{dx}$$

^aFor angles in the first and third quadrants. Use the opposite sign in the second and fourth quadrants.

with respect to x is called the *partial derivative* of f with respect to x and is denoted by

$$\frac{\partial f}{\partial x} = f_x = \lim_{\Delta x \rightarrow 0} \frac{f(x + \Delta x, y) - f(x, y)}{\Delta x} \quad (162)$$

Likewise, the partial derivative of f with respect to y is obtained by considering x to be constant while y varies:

$$\frac{\partial f}{\partial y} = f_y = \lim_{\Delta y \rightarrow 0} \frac{f(x, y + \Delta y) - f(x, y)}{\Delta y} \quad (163)$$

If $\partial f/\partial x$ and $\partial f/\partial y$ are again differentiable, partial derivatives of second order may be found:

$$\begin{aligned} \frac{\partial}{\partial x} \left(\frac{\partial f}{\partial x} \right) &= \frac{\partial^2 f}{\partial x^2} = f_{xx} \\ \frac{\partial}{\partial y} \left(\frac{\partial f}{\partial y} \right) &= \frac{\partial^2 f}{\partial y^2} = f_{yy} \\ \frac{\partial}{\partial x} \left(\frac{\partial f}{\partial y} \right) &= \frac{\partial^2 f}{\partial x \partial y} = f_{yx} \\ \frac{\partial}{\partial y} \left(\frac{\partial f}{\partial x} \right) &= \frac{\partial^2 f}{\partial y \partial x} = f_{xy} \end{aligned} \quad (164)$$

If the derivatives in question are continuous, the order of differentiation is immaterial, that is,

$$\frac{\partial^2 f}{\partial y \partial x} = \frac{\partial^2 f}{\partial x \partial y} \quad (165)$$

Similarly, the third and higher partial derivatives of $f(x, y)$ may be found. The third partial derivatives, if continuous, are four in number:

$$\begin{aligned} \frac{\partial}{\partial x} \left(\frac{\partial^2 f}{\partial x^2} \right) &= \frac{\partial^3 f}{\partial x^3} & \frac{\partial}{\partial x} \left(\frac{\partial^2 f}{\partial y^2} \right) &= \frac{\partial}{\partial y} \left(\frac{\partial^2 f}{\partial x \partial y} \right) \\ &= \frac{\partial^2}{\partial y^2} \left(\frac{\partial f}{\partial x} \right) & &= \frac{\partial^3 f}{\partial x \partial y^2} \\ \frac{\partial}{\partial y} \left(\frac{\partial^2 f}{\partial y^2} \right) &= \frac{\partial^3 f}{\partial y^3} & \frac{\partial}{\partial y} \left(\frac{\partial^2 f}{\partial x^2} \right) &= \frac{\partial}{\partial x} \left(\frac{\partial^2 f}{\partial x \partial y} \right) \\ &= \frac{\partial^2}{\partial x^2} \left(\frac{\partial f}{\partial y} \right) & &= \frac{\partial^3 f}{\partial x^2 \partial y} \end{aligned} \quad (166)$$

Functions of N Variables. The preceding formulas may be generalized to the case where f is a function

of more than two variables, that is, there corresponds a value of $f(x, y, z, \dots)$ to every set of values of x, y, z, \dots .

If the increments $\Delta x, \Delta y, \Delta z, \dots$ are assigned to x, y, z, \dots in $f(x, y, z, \dots)$, the *total increment* of f is

$$\begin{aligned} \Delta f &= f(x + \Delta x, y + \Delta y, z + \Delta z, \dots) \\ &\quad - f(x, y, z, \dots) \end{aligned} \quad (167)$$

The *total differential* of f is

$$df = \frac{\partial f}{\partial x} dx + \frac{\partial f}{\partial y} dy + \frac{\partial f}{\partial z} dz + \dots \quad (168)$$

The *second total differential* of f is

$$\begin{aligned} d^2 f &= \frac{\partial^2 f}{\partial x^2} (dx)^2 + \frac{\partial^2 f}{\partial y^2} (dy)^2 + \frac{\partial^2 f}{\partial z^2} (dz)^2 + \dots \\ &\quad + 2 \frac{\partial^2 f}{\partial x \partial y} dx \, dy + \dots \end{aligned} \quad (169)$$

In general,

$$\begin{aligned} d^n f &= \left(\frac{\partial}{\partial x} dx + \frac{\partial}{\partial y} dy + \frac{\partial}{\partial z} dz + \dots \right)^n \\ &\quad \times f(x, y, z, \dots) \end{aligned} \quad (170)$$

Exact Differential. In order for the expression $P(x, y) dx + Q(x, y) dy$ to be the *exact* or *complete differential* of a function of two variables, it is necessary and sufficient that

$$\frac{\partial Q}{\partial x} = \frac{\partial P}{\partial y} \quad (\text{integrability condition}) \quad (171)$$

For three variables, $P dx + Q dy + R dz$, the corresponding conditions are

$$\frac{\partial Q}{\partial z} = \frac{\partial R}{\partial y} \quad \frac{\partial R}{\partial x} = \frac{\partial P}{\partial z} \quad \frac{\partial P}{\partial y} = \frac{\partial Q}{\partial x} \quad (172)$$

Differentiation of Composite Functions. If $u = f(x, y, z, \dots, w)$, and x, y, z, \dots, w are functions of a single variable t , then

$$\frac{du}{dt} = \frac{\partial u}{\partial x} \frac{dx}{dt} + \frac{\partial u}{\partial y} \frac{dy}{dt} + \dots + \frac{\partial u}{\partial w} \frac{dw}{dt} \quad (173)$$

which is the total derivative of u with respect to t .

Example 52. Given $u = x^2 + y^2 + 3xy$, $x = t^2$, $y = 1/t$. Then

$$\frac{dx}{dt} = 2t \quad \frac{dy}{dt} = -\frac{1}{t^2}$$

and

$$\frac{du}{dt} = \left(2t^2 + \frac{3}{t}\right)2t - \left(\frac{2}{t} + 3t^2\right)\frac{1}{t^2}$$

The equation reduces to

$$\frac{du}{dt} = 4t^3 + 3 - \frac{2}{t^3}$$

which expresses the rate of change of u with respect to t as a function of t .

Implicit Functions. The equation $F(x, y) = 0$ define y as an *implicit* function of x and x as an implicit function of y . If the equation is solved for y in terms of x , $y = f(x)$, then y is called an *explicit* function of x .

Example 53. Implicit function: $F(x, y) = x^2 + y^2 - r^2 = 0$. Explicit function: $y = \pm\sqrt{r^2 - x^2}$. To find dy/dx , either differentiate $y = f(x)$ or use

$$\frac{dy}{dx} = -\frac{\partial F/\partial x}{\partial F/\partial y} \quad \left(\frac{\partial F}{\partial y} \neq 0\right) \quad (174)$$

$$\frac{d^2y}{dx^2} = -\frac{\frac{\partial^2 F}{\partial x^2} \left(\frac{\partial F}{\partial y}\right)^2 - 2\frac{\partial^2 F}{\partial x \partial y} \frac{\partial F}{\partial x} \frac{\partial F}{\partial y} + \frac{\partial^2 F}{\partial y^2} \left(\frac{\partial F}{\partial x}\right)^2}{\left(\frac{\partial F}{\partial y}\right)^3} \quad \left(\frac{\partial F}{\partial y} \neq 0\right) \quad (175)$$

9.4 Infinite Series

Let $a_1, a_2, \dots, a_n, \dots$ be a sequence of numbers formed according to some rule. The indicated sum

$$\sum_{n=1}^{\infty} a_n = a_1 + a_2 + \dots + a_n + \dots \quad (176)$$

is called an *infinite series*. Let $s_n = a_1 + a_2 + \dots + a_n$. If the partial sums s_n approach a limit S as $n \rightarrow \infty$, then the series is *convergent* and S is the *sum* or *value* of the series. A series that is not convergent is *divergent*.

If the series of absolute values $|a_1| + |a_2| + \dots + |a_n| + \dots$ is convergent, then series (176) is *absolutely convergent*. A series that converges, but not absolutely, is *conditionally convergent*. The sum of an absolutely convergent series is not changed by rearrangement of its terms.

Tests for Convergence

Comparison Test. A comparison test for series of positive terms. If there is a convergent series of positive terms $c_1 + c_2 + \dots + c_n + \dots$ such that $a_n \leq c_n$ for every n from some term on, then series (176) converges. If there is a divergent series of positive terms $d_1 + d_2 + \dots + d_n + \dots$ such that $a_n \geq d_n$ for every n from some term on, then series (176) diverges. Two useful comparison series are:

1. The *geometric* series $a + ar + ar^2 + \dots + ar^{n-1} + \dots$, which converges for $|r| < 1$ and diverges for $|r| \geq 1$
2. The *p* series $1 + 1/2^p + 1/3^p + \dots + 1/n^p + \dots$, which converges for $p > 1$ and diverges for $p \leq 1$

Ratio Test. Let

$$L = \lim_{n \rightarrow \infty} \left| \frac{a_{n+1}}{a_n} \right| \quad (177)$$

If $L < 1$, series (176) converges absolutely; if L does not exist or if $L > 1$, series (176) diverges; if $L = 1$, the test fails.

Example 54

$$(1) \quad 10 + \frac{10^2}{2!} + \frac{10^3}{3!} + \dots + \frac{10^n}{n!} + \dots$$

Since

$$L = \lim_{n \rightarrow \infty} \frac{10^{n+1}/(n+1)!}{10^n/n!} = \lim_{n \rightarrow \infty} \frac{10}{n+1} = 0$$

the series converges.

$$(2) \quad \frac{1+1}{1+3} + \frac{(1+1)(2+1)}{(1+3)(2+3)} + \dots + \frac{(1+1)(2+1)\dots(n+1)}{(1+3)(2+3)\dots(n+3)} + \dots$$

Since

$$L = \lim_{n \rightarrow \infty} \frac{(n+1)+1}{(n+1)+3} = 1$$

the test fails. Raabe's test can be used. See Eq. (179).

Root Test. Let

$$L = \lim_{n \rightarrow \infty} |a_n|^{1/n} \quad (178)$$

If $L < 1$, series (176) converges; if $L > 1$, series (176) diverges; if $L = 1$, the test fails.

Example 55

$$1 + \frac{1}{(\log 2)^2} + \frac{1}{(\log 3)^3} + \dots + \frac{1}{(\log n)^n} + \dots$$

Since

$$L = \lim_{n \rightarrow \infty} \frac{1}{\log n} = 0$$

the series converges.

Integral Test. Let $f(n) = a_n$. If $f(x)$ is a positive nonincreasing function of x for $x > k$, then series (176) converges or diverges with the improper integral $\int_k^\infty f(x) dx$.

Example 56

$$1 + \frac{1}{2(\log 2)^3} + \frac{1}{3(\log 3)^3} + \dots + \frac{1}{n(\log n)^3} + \dots$$

Then

$$f(x) = \frac{1}{x(\log x)^3} \quad \text{for } x \geq 2$$

and

$$\begin{aligned} \int_2^\infty \frac{dx}{x(\log x)^3} &= \lim_{n \rightarrow \infty} \frac{1}{2} \left(\frac{1}{(\log 2)^2} - \frac{1}{(\log n)^2} \right) \\ &= \frac{1}{2(\log 2)^2} \end{aligned}$$

Since the integral is convergent, the series is also.

Raabe's Test. Let

$$L = \lim_{n \rightarrow \infty} n \left(\frac{a_n}{a_{n+1}} - 1 \right) \quad (179)$$

If $L > 1$, series (176) converges; if $L < 1$, series (176) diverges; if $L = 1$, the test fails.

Example 57

$$\begin{aligned} \frac{1+1}{1+3} + \frac{(1+1)(2+1)}{(1+3)(2+3)} + \dots \\ + \frac{(1+1)(2+1) \dots (n+1)}{(1+3)(2+3) \dots (n+3)} + \dots \end{aligned}$$

Since

$$L = \lim_{n \rightarrow \infty} n \left(\frac{(n+1)+3}{(n+1)+1} - 1 \right) = \lim_{n \rightarrow \infty} \frac{2n}{n+2} = 2 > 1$$

the series converges.

Convergence of an Alternating Series. A series

$$a_1 - a_2 + a_3 - + \dots + (-1)^{n+1} a_n + \dots \quad (180)$$

in which the terms are alternately positive and negative is an *alternating series*. If, from some term on, $|a_{n+1}| \leq |a_n|$ and $a_n \rightarrow 0$ as $n \rightarrow \infty$, the series converges. The sum of the first n terms differs numerically from the sum of the series by less than $|a_{n+1}|$.

Series of Functions A *power series* is a series of the form

$$\sum_{n=0}^\infty a_n x^n = a_0 + a_1 x + a_2 x^2 + \dots + a_n x^n + \dots \quad (181)$$

If $\lim_{n \rightarrow \infty} |a_{n-1}/a_n| = r$, the power series converges absolutely for all values of x in the interval $-r < x < r$. For $|x| = r$, it is necessary to use one of the convergence tests for series of numerical terms.

Example 58

$$1 - \frac{x}{1 \cdot 2} + \frac{x^2}{2 \cdot 2^2} - \frac{x^3}{3 \cdot 2^3} + \dots + (-1)^n \frac{x^n}{n \cdot 2^n} + \dots$$

Since

$$\lim_{n \rightarrow \infty} \frac{n \cdot 2^n}{(n-1)2^{n-1}} = 2$$

the interval of convergence is $-2 < x < 2$. For $x = 2$, the series is a convergent alternating series. For $x = -2$, it is a divergent p series.

Taylor's Series. If $f(x)$ has continuous derivatives in the neighborhood of a point $x = a$, then

$$\begin{aligned} f(x) &= f(a) + \frac{f'(a)}{1!}(x-a) + \frac{f''(a)}{2!}(x-a)^2 + \dots \\ &+ \frac{f^{(n-1)}(a)}{(n-1)!}(x-a)^{n-1} + \dots \end{aligned} \quad (182)$$

with the remainder after n terms

$$\begin{aligned} R_n &= \frac{f^{(n)}(\xi)}{n!}(x-a)^n \\ \xi &= a + \theta(x-a) \quad 0 < \theta < 1 \end{aligned} \quad (183)$$

Another form of Taylor's series is

$$\begin{aligned} f(x+h) &= f(x) + \frac{h}{1!} f'(x) + \frac{h^2}{2!} f''(x) + \dots \\ &+ \frac{h^{n-1}}{(n-1)!} f^{(n-1)}(x) + \dots \end{aligned} \quad (184)$$

with the remainder after n terms

$$R_n = \frac{h^n}{n!} f^{(n)}(\xi) \quad \xi = x + \theta h \quad 0 < \theta < 1 \quad (185)$$

Maclaurin's Series. If $a = 0$ in Eq. (182),

$$f(x) = f(0) + \frac{f'(0)}{1!}x + \frac{f''(0)}{2!}x^2 + \dots + \frac{f^{(n-1)}(0)}{(n-1)!}x^{n-1} + \dots \quad (186)$$

with the remainder after n terms

$$R_n = \frac{f^{(n)}(\xi)}{n!}x^n \quad \xi = \theta x \quad 0 < \theta < 1 \quad (187)$$

A Taylor or Maclaurin series represents a function in an interval if and only if $R_n \rightarrow 0$ as $n \rightarrow \infty$.

Example 59. Expand e^{ax} in powers of x :

$$\begin{aligned} f(x) &= e^{ax} & f'(x) &= ae^{ax} \\ f''(x) &= a^2e^{ax} & f'''(x) &= a^3e^{ax}, \dots \\ f(0) &= 1 & f'(0) &= a \\ f''(0) &= a^2 & f'''(0) &= a^3, \dots \\ f(x) &= e^{ax} = 1 + \frac{a}{1!}x + \frac{a^2}{2!}x^2 + \frac{a^3}{3!}x^3 + \dots \end{aligned}$$

Since

$$\lim_{n \rightarrow \infty} \frac{a^{n-1}/(n-1)!}{a^n/n!} = \lim_{n \rightarrow \infty} \frac{n}{a} = \infty$$

the series converges for all values of x .

Taylor's Series for Two Variables

$$\begin{aligned} f(x+h, y+k) &= f(x, y) + \frac{1}{1!} \left(h \frac{\partial}{\partial x} + k \frac{\partial}{\partial y} \right) f(x, y) \\ &+ \frac{1}{2!} \left(h \frac{\partial}{\partial x} + k \frac{\partial}{\partial y} \right)^2 f(x, y) + \dots \\ &+ \frac{1}{(n-1)!} \left(h \frac{\partial}{\partial x} + k \frac{\partial}{\partial y} \right)^{n-1} f(x, y) + \dots \end{aligned} \quad (188)$$

with the remainder

$$R_n = \frac{1}{n!} \left(h \frac{\partial}{\partial x} + k \frac{\partial}{\partial y} \right)^n \times f(x + \theta h, y + \theta k) \quad 0 < \theta < 1 \quad (189)$$

Fourier Series. If $f(x)$ is of bounded variation over an interval of length $2l$, that is, if it can be expressed as the difference of two nondecreasing or nonincreasing bounded functions, then

$$\begin{aligned} f(x) &= \frac{a_0}{2} + \sum_{n=1}^{\infty} \left(a_n \cos \frac{n\pi x}{l} + b_n \sin \frac{n\pi x}{l} \right) \\ &= \frac{a_0}{2} + a_1 \cos \frac{\pi x}{l} + a_2 \cos \frac{2\pi x}{l} \\ &+ \dots + b_1 \sin \frac{\pi x}{l} + b_2 \sin \frac{2\pi x}{l} + \dots \end{aligned} \quad (190)$$

in which

$$\begin{aligned} a_n &= \frac{1}{l} \int_k^{k+2l} f(x) \cos \frac{n\pi x}{l} dx \\ b_n &= \frac{1}{l} \int_k^{k+2l} f(x) \sin \frac{n\pi x}{l} dx \quad n = 0, 1, 2, \dots \end{aligned} \quad (191)$$

In exponential form

$$\begin{aligned} f(x) &= \sum_{n=-\infty}^{\infty} c_n e^{in\pi x/l} \\ c_n &= \frac{1}{2l} \int_k^{k+2l} f(x) e^{-in\pi x/l} dx \\ n &= \dots, -2, -1, 0, 1, 2, \dots \end{aligned} \quad (192)$$

At a point of discontinuity, a Fourier series gives the value at the midpoint of the jump.

Example 60. Expand e^x in the interval 0 to 2π :

$$\begin{aligned} a_0 &= \frac{1}{\pi} \int_0^{2\pi} e^x dx = \frac{1}{\pi} (e^{2\pi} - 1) \\ a_n &= \frac{1}{\pi} \int_0^{2\pi} e^x \cos nx dx = \frac{e^{2\pi} - 1}{\pi(n^2 + 1)} \\ b_n &= -\frac{n(e^{2\pi} - 1)}{\pi(n^2 + 1)} \end{aligned}$$

Hence

$$\begin{aligned} e^x &= \frac{1}{\pi} (e^{2\pi} - 1) \left[\frac{1}{2} + \frac{1}{1^2 + 1} \cos x + \frac{1}{2^2 + 1} \cos 2x \right. \\ &+ \left. \frac{1}{3^2 + 1} \cos 3x + \dots \right] \\ &- \frac{1}{\pi} (e^{2\pi} - 1) \left[\frac{1}{1^2 + 1} \sin x + \frac{2}{2^2 + 1} \sin 2x \right. \\ &+ \left. \frac{3}{3^2 + 1} \sin 3x + \dots \right] \end{aligned}$$

The expansion is valid only in the interval from 0 to 2π ; outside that interval the series repeats itself owing to the periodic property of $\sin nx$ and $\cos nx$.

Fourier Series for Even or Odd Functions. If $f(-x) = f(x)$, it is an *even* function. Then

$$\begin{aligned} a_n &= \frac{2}{l} \int_0^l f(x) \cos \frac{n\pi x}{l} dx \quad n = 0, 1, 2, \dots \\ b_n &= 0 \end{aligned} \tag{193}$$

If $f(-x) = -f(x)$, it is an *odd* function. Then

$$\begin{aligned} a_n &= 0 \\ b_n &= \frac{2}{l} \int_0^l f(x) \sin \frac{n\pi x}{l} dx \quad n = 0, 1, 2, \dots \end{aligned} \tag{194}$$

Example 61. Expand $f(x) = x$ in a cosine series in the interval $(0, \pi)$. Here

$$\begin{aligned} \frac{1}{2}a_0 &= \frac{1}{\pi} \int_0^\pi x \, dx = \frac{\pi}{2} \\ a_n &= \frac{2}{\pi} \int_0^\pi x \cos nx \, dx \\ &= \frac{2}{\pi} \left(\left[\frac{x \sin nx}{n} \right]_0^\pi - \int_0^\pi \frac{\sin nx}{n} dx \right) \\ &= \frac{2}{\pi} \left[\frac{1}{n^2} \cos nx \right]_0^\pi = \frac{2}{\pi n^2} (\cos n\pi - 1) \end{aligned}$$

Therefore

$$x = \frac{\pi}{2} - \frac{4}{\pi} \left(\cos x + \frac{\cos 3x}{3^2} + \frac{\cos 5x}{5^2} + \dots \right) \quad (0 < x < \pi)$$

If $x = 0$, the sum of the series is 0; if $x = \pi$, the sum of the series is π .

Uniform Convergence. Let $R_n(x)$ be the remainder after n terms of the series of functions

$$\sum_{n=1}^{\infty} u_n(x) = u_1(x) + u_2(x) + \dots + u_n(x) + \dots \tag{195}$$

The series is uniformly convergent in the interval $a \leq x \leq b$ if, for any $\varepsilon > 0$, there exists an N dependent on ε but not on x such that $|R_n(x)| < \varepsilon$ for $n > N$.

If a power series converges in the interval $-r < x < r$, then it converges uniformly in any interval within this interval.

The sum of a uniformly convergent series of continuous functions is also a continuous function.

Weierstrass M Test. If $\sum_{n=1}^{\infty} u_n(x)$ is a series of functions define in an interval, $\sum_{n=1}^{\infty} M_n$ is a series of positive constants, and $|u_n(x)| \leq M_n$ for all values of x in the interval, then $\sum_{n=1}^{\infty} u_n(x)$ is absolutely and uniformly convergent in the interval.

Operations

Term-by-Term Differentiation If $f(x) = \sum_{n=1}^{\infty} u_n(x)$ is a convergent series of differentiable functions in an interval and $\sum_{n=1}^{\infty} u'_n(x)$ is a series of continuous functions that converges uniformly in the interval, then

$$\sum_{n=1}^{\infty} u'_n(x) = f'(x)$$

Term-by-Term Integration If

$$f(x) = \sum_{n=1}^{\infty} u_n(x)$$

converges uniformly in an interval and a and x are any two values in the interval, then $\sum_{n=1}^{\infty} \int_a^x u_n(t) dt$ converges to $\int_a^x f(t) dt$. It converges uniformly with respect to x for each fixed value of a .

Two power series can be *added*, *subtracted*, or *multiplied* term by term, and the result is a power series that converges when both of the first do and represents the *sum*, *difference*, or *product*, respectively, of the two series. The product of two power series $\sum_{n=0}^{\infty} a_n x^n$ and $\sum_{n=0}^{\infty} b_n x^n$ is

$$\begin{aligned} &a_0 b_0 + (a_0 b_1 + a_1 b_0)x + (a_0 b_2 + a_1 b_1 + a_2 b_0)x^2 \\ &+ \dots + (a_0 b_n + a_1 b_{n-1} + \dots + a_n b_0)x^n + \dots \end{aligned} \tag{196a}$$

The *quotient* of two convergent power series $\sum_{n=0}^{\infty} a_n x^n$ and $\sum_{n=0}^{\infty} b_n x^n$, $b_0 \neq 0$, is

$$\begin{aligned} \sum_{n=0}^{\infty} q_n x^n &= \frac{a_0}{b_0} + \frac{a_1 b_0 - a_0 b_1}{b_0^2} x \\ &+ \frac{a_2 b_0^2 - a_1 b_0 b_1 + a_0 b_1^2 - a_0 b_0 b_2}{b_0^3} x^2 + \dots \end{aligned} \tag{196b}$$

The interval of convergence of the quotient series must be determined. To obtain q_3, q_4, \dots , solve the equations

$$\begin{aligned} a_0 &= q_0 b_0 \\ a_1 &= q_0 b_1 + q_1 b_0 \\ a_2 &= q_0 b_2 + q_1 b_1 + q_2 b_0 \\ a_n &= q_0 b_n + q_1 b_{n-1} + \dots + q_n b_0 \end{aligned} \tag{197}$$

See Table 10 for series expansions of various functions.

Table 10 Functions Expanded in Series (log = log_e)

$(a+x)^n = a^n + na^{n-1}x + \frac{n(n-1)}{2!}a^{n-2}x^2 + \frac{n(n-1)(n-2)}{3!}a^{n-3}x^3 + \dots$	$(x^2 < a^2)$

9.5 Maxima and Minima

Function of One Variable. A function $f(x)$ has a relative *maximum* (*minimum*) at a point $x = a$ if at every point in some neighborhood of $x = a$ the values of $f(x)$ are all less (greater) than $f(a)$. Either a maximum or a minimum is an *extreme*. If the derivative exists at a relative extreme, it must be zero, that is, the tangent must be parallel to the x axis. To locate possible extreme points solve the equation $f'(x) = 0$. A solution $x = a$ gives a maximum (minimum) value of $f(x)$ if and only if the derivative is positive (negative) for $x < a$ and negative (positive) for $x > a$. If the derivative does not change sign, $x = a$ gives a *point of inflection*.

A solution $x = a$ can be tested also by using the higher derivatives of $f(x)$. Let $f^{(n)}(x)$ be the first derivative that does not equal zero for $x = a$, $f^{(n)}(a) \neq 0$. If n is even, there is a maximum (Fig. 136) if $f^{(n)}(a) < 0$ and a minimum (Fig. 137)

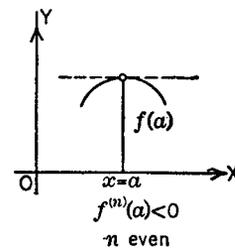

Fig. 136

if $f^{(n)}(a) > 0$. If n is odd, there is a point of inflection (Figs. 138 and 139). In many problems physical considerations make testing unnecessary.

Example 62. A piece of wire of length 30 in. is bent into a rectangle. Find the maximum area. Let x = the base, then $\frac{1}{2}(30 - 2x)$ = the altitude. The area

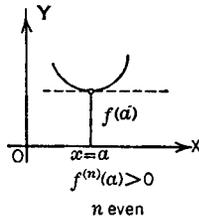

Fig. 137

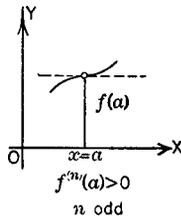

Fig. 138

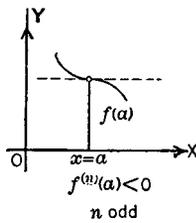

Fig. 139

$A = x(15 - x) = 15x - x^2$. For a maximum or minimum, $dA/dx = 15 - 2x = 0$, $x = 7.5$. Then $A = 7.5(15 - 7.5) = 56.25$ in.² To find whether the area is maximum or minimum, $d^2A/dx^2 = -2$, which is less than 0, and therefore the area 56.25 in.² is a maximum.

Function of Two or More Variables. A function $f(x, y)$ has a relative maximum (minimum) at a point $(x, y) = (a, b)$ if at every point in some neighborhood of (a, b) the values of $f(x, y)$ are all less (greater) than $f(a, b)$. If the first partial derivatives exist at a relative extreme, it is necessary that

$$\frac{\partial f}{\partial x} = \frac{\partial f}{\partial y} = 0 \quad (198)$$

If, furthermore, at the point (a, b)

$$\frac{\partial^2 f}{\partial x^2} \frac{\partial^2 f}{\partial y^2} - \left(\frac{\partial^2 f}{\partial x \partial y} \right)^2 > 0 \quad (199)$$

then $f(a, b)$ is an extreme value, which is a maximum if

$$\frac{\partial^2 f}{\partial x^2} < 0 \quad \left(\text{and consequently } \frac{\partial^2 f}{\partial y^2} < 0 \right) \quad (200)$$

and a minimum if

$$\frac{\partial^2 f}{\partial x^2} > 0 \quad (201)$$

If

$$\frac{\partial^2 f}{\partial x^2} \frac{\partial^2 f}{\partial y^2} - \left(\frac{\partial^2 f}{\partial x \partial y} \right)^2 < 0 \quad (202)$$

then $f(x, y)$ does not have an extreme value but has a saddle point. If

$$\frac{\partial^2 f}{\partial x^2} \frac{\partial^2 f}{\partial y^2} - \left(\frac{\partial^2 f}{\partial x \partial y} \right)^2 = 0 \quad (203)$$

the test gives no information.

For a function of several variables $f(x, y, z, \dots)$, necessary conditions for an extreme value are

$$\frac{\partial f}{\partial x} = \frac{\partial f}{\partial y} = \frac{\partial f}{\partial z} = \dots = 0 \quad (204)$$

10 INTEGRAL CALCULUS

10.1 Integration

The operation of *integration* is the inverse of differentiation. If $F'(x) = f(x)$, then $F(x)$ is an *indefinite integral* of $f(x)$. Any other indefinite integral of $f(x)$ differs from $F(x)$ at most by an additive constant. In symbols, $F(x) = \int f(x) dx + c$; or, more precisely, $F(x) = \int_a^x f(\xi) d\xi + c$, where a and c are constants (see Section 10.2). The function $f(x)$ is the *integrand*.

The integrals of many functions are given in Table 18 of Chapter 1. Table 11 is a convenient short table of fundamental integrals. The constant of integration is usually omitted in tables.

In general, with the exception of the square root of polynomials of the second degree, integrals containing fractional powers of polynomials above the first degree cannot be integrated in terms of the elementary integral forms.

Elliptic Integrals. An elliptic integral has the form

$$\int R[x, \sqrt{f(x)}] dx \quad (205)$$

where R represents a rational function and $f(x) = a + bx + cx^2 + dx^3 + ex^4$, an algebraic function of the third or fourth degree.

Table 11 Fundamental Integrals

<p>1. $\int u^n du = \frac{u^{n+1}}{n+1}$</p> <p>2. $\int \frac{du}{u} = \ln u$</p> <p>3. $\int a^u du = \frac{a^u}{\ln a}$</p> <p>4. $\int e^u du = e^u$</p> <p>5. $\int \cos u du = \sin u$</p> <p>6. $\int \sin u du = -\cos u$</p> <p>7. $\int \sec^2 u du = \tan u$</p> <p>8. $\int \csc^2 u du = -\cot u$</p> <p>9. $\int \sec u \tan u du = \sec u$</p> <p>10. $\int \csc u \cot u du = -\csc u$</p> <p>11. $\int \tan u du = \ln \sec u$ $= -\ln \cos u$</p> <p>12. $\int \cot u du = \ln \sin u$ $= -\ln \csc u$</p> <p>13. $\int \sec u du = \ln(\sec u + \tan u)$ $= \ln \tan\left(\frac{\pi}{4} + \frac{u}{2}\right)$</p> <p>14. $\int \csc u du = \ln(\csc u - \cot u)$ $= \ln \tan \frac{u}{2}$</p> <p>15. $\int \frac{du}{u^2 + a^2} = \frac{1}{a} \tan^{-1} \frac{u}{a}$ $= -\frac{1}{a} \cot^{-1} \frac{u}{a}$</p>	<p>16. $\int \frac{du}{u^2 - a^2} = \frac{1}{2a} \ln \frac{u-a}{u+a} \quad (u^2 > a^2)$ $= \frac{1}{2a} \ln \frac{a-u}{a+u} \quad (u^2 < a^2)$ $= -\frac{1}{a} \tanh^{-1} \frac{u}{a} \quad (u^2 < a^2)$ $= -\frac{1}{a} \coth^{-1} \frac{u}{a} \quad (u^2 > a^2)$</p> <p>17. $\int \frac{du}{\sqrt{a^2 - u^2}} = \sin^{-1} \frac{u}{a}$ $= -\cos^{-1} \frac{u}{a}$</p> <p>18. $\int \frac{du}{\sqrt{u^2 \pm a^2}} = \ln(u + \sqrt{u^2 \pm a^2})$ $\int \frac{du}{\sqrt{u^2 + a^2}} = \sinh^{-1} \frac{u}{a}$ $\int \frac{du}{\sqrt{u^2 - a^2}} = \cosh^{-1} \frac{u}{a}$</p> <p>19. $\int \frac{du}{u\sqrt{u^2 - a^2}} = \frac{1}{a} \sec^{-1} \frac{u}{a}$ $= -\frac{1}{a} \csc^{-1} \frac{u}{a}$</p> <p>20. $\int \frac{du}{\sqrt{2au - u^2}} = \text{vers}^{-1} \frac{u}{a}$ $= \cos^{-1} \left(1 - \frac{u}{a}\right)$</p> <p>21. $\int \sinh u du = \cosh u$</p> <p>22. $\int \cosh u du = \sinh u$</p> <p>23. $\int \tanh u du = \ln \cosh u$</p> <p>24. $\int \coth u du = \ln \sinh u$</p> <p>25. $\int \text{sech } u du = 2 \tan^{-1} e^u$</p> <p>26. $\int \text{csch } u du = \ln \tanh \frac{u}{2}$</p>
--	--

The constant of integration is omitted in the above integrals.

Elliptic integral of the first kind:

$$\begin{aligned}
 F(\phi, k) &= \int_0^\phi \frac{d\theta}{\sqrt{1 - k^2 \sin^2 \theta}} \\
 &= \int_0^x \frac{d\xi}{\sqrt{(1 - \xi^2)(1 - k^2 \xi^2)}} \\
 x &= \sin \phi \quad k^2 < 1 \quad (206)
 \end{aligned}$$

Elliptic integral of the second kind:

$$E(\phi, k) = \int_0^\phi \sqrt{1 - k^2 \sin^2 \theta} d\theta$$

$$\begin{aligned}
 &= \int_0^x \frac{\sqrt{1 - k^2 \xi^2}}{\sqrt{1 - \xi^2}} d\xi \\
 x &= \sin \phi \quad k^2 < 1 \quad (207)
 \end{aligned}$$

Elliptic integral of the third kind:

$$\begin{aligned}
 \Pi(\phi, n, k) &= \int_0^\phi \frac{d\theta}{(1 + n \sin^2 \theta)\sqrt{1 - k^2 \sin^2 \theta}} \\
 &= \int_0^x \frac{d\xi}{(1 + n\xi^2)\sqrt{(1 - \xi^2)(1 - k^2 \xi^2)}} \\
 x &= \sin \phi \quad k^2 < 1 \quad (208)
 \end{aligned}$$

The "complete" integrals are

$$K = F\left(\frac{\pi}{2}, k\right) = \frac{\pi}{2} \left[1 + \left(\frac{1}{2}\right)^2 k^2 + \left(\frac{3}{2 \cdot 4}\right)^2 k^4 + \left(\frac{3 \cdot 5}{2 \cdot 4 \cdot 6}\right)^3 k^6 + \dots \right] \quad (209)$$

$$E = E\left(\frac{\pi}{2}, k\right) = \frac{\pi}{2} \left[1 - \left(\frac{1}{2^2}\right) k^2 - \left(\frac{3}{2^2 \cdot 4^2}\right) k^4 - \left(\frac{3^2 \cdot 5}{2^2 \cdot 4^2 \cdot 6^2}\right) k^6 - \dots \right] \quad (210)$$

$$K = F\left(\frac{\pi}{2}, \sqrt{1-k^2}\right) \quad E' = E\left(\frac{\pi}{2}, \sqrt{1-k^2}\right) \quad (211)$$

They are connected by the relation

$$KE' + EK' - KK' = \frac{1}{2}\pi \quad (212)$$

The inverse function of $u = F(\phi, k)$ is $\phi = \text{am } u$ (am = amplitude),

$$x \equiv \sin \phi \equiv \text{sn } u = u - (1+k^2)\frac{u^3}{3!} + (1+14k^2+k^4)\frac{u^5}{5!} - \dots \quad (213)$$

$$\cos \phi \equiv \text{cn } u = 1 - \frac{u^2}{2!} + (1+4k^2)\frac{u^4}{4!} - (1+44k^2+16k^4)\frac{u^6}{6!} + \dots \quad (214)$$

$$\sqrt{1-k^2x^2} \equiv \Delta\phi \cong \text{dn } u = 1 - k^2\frac{u^2}{2!} + k^2(4+k^2)\frac{u^4}{4!} - k^2(16+44k^2+k^4)\frac{u^6}{6!} + \dots \quad (215)$$

Methods of Integration

Integration by Parts. The formula

$$\int u \, dv = uv - \int v \, du \quad (u \text{ and } v \text{ functions of } x) \quad (216)$$

is useful in integrating a product if factors of the product are a function of x and the derivative of another function of x .

Example 63. To find $\int x \sin x \, dx$, let $u = x$, $dv = \sin x \, dx$. Then $du = dx$, $v = -\cos x$, and $\int x \sin x \, dx = -x \cos x + \int \cos x \, dx = -x \cos x + \sin x + c$.

Integration of Rational Fractions. If the quotient of two polynomials

$$R(x) = \frac{P_n(x)}{P_d(x)} \quad (217)$$

is not a proper fraction, that is, if the degree of the numerator is not less than that of the denominator, $R(x)$ can be changed, by dividing as indicated, to the sum of a polynomial, which is immediately integrable, and a proper fraction. If the proper fraction cannot be integrated by reference to Table 18, use the methods of Section 2.8 to resolve it, if possible, into partial fractions. These can be integrated from the table.

Irrational Functions. These can sometimes be put into integrable forms by rationalizing them by a change of variable.

Form	Substitution
$f[(ax+b)^{p/q}] dx$	Let $ax+b = y^q$
$f[(ax+b)^{p/q}(ax+b)^{r/s}] dx$	Let $ax+b = y^n$, where n is the LCM of q, s
$f[x, \sqrt{x^3+ax+b}] dx$	Let $\sqrt{x^2+ax+b} = y-x$
$f[x, \sqrt{-x^2+ax+b}] dx$	Let $\sqrt{-x^2+ax+b} = \sqrt{(\alpha-x)(\beta+x)}$ $= (\alpha-x)y$ or $= (\beta+x)y$
$f[\sin x, \cos x] dx$	Let $\tan \frac{x}{2} = y$
$f[x, \sqrt{a^2-x^2}] dx$	Let $x = a \sin y$
$f[x, \sqrt{x^2-a^2}] dx$	Let $x = a \sec y$ or $x = a \cosh y$
$f[x, \sqrt{x^2+a^2}] dx$	Let $x = a \tan y$ or $x = a \sinh y$

10.2 Definite Integrals

The *definite integral* of $f(x)$ from a to b is

$$\int_a^b f(x) \, dx = \lim_{\substack{n \rightarrow \infty \\ \max \Delta x_v \rightarrow 0}} \sum_{v=1}^n f(\xi_v) \Delta x_v \quad (218)$$

in which the interval $a \leq x \leq b$ is divided into n arbitrary parts Δx_v , $v = 1, 2, \dots, n$, and ξ_v is an arbitrary point in Δx_v (Fig. 140). A sufficient condition that this integral exists is that $f(x)$ be continuous. However, it is necessary and sufficient only that $f(x)$ be bounded and that its points of discontinuity form a set of Lebesgue measure 0. A set of points is of Lebesgue measure 0 if the points can be enclosed in a set of intervals I_v , $v = 1, 2, 3, \dots$, finite or infinite in number, such that, for any $\epsilon > 0$, the sum of the lengths of the I_v is $< \epsilon$.

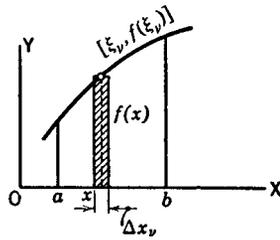

Fig. 140

A definite integral of a given function over a given interval is a number. The geometric interpretation of the definite integral of $f(x)$, $f(x) \geq 0$, is the area bounded by the curve $y = f(x)$, the x axis, and the ordinates at $x = a$ and $x = b$.

To evaluate a definite integral, if $F(x) = \int f(x) dx$, then $\int_a^b f(x) dx = F(b) - F(a)$.

Example 64

$$\int_3^5 x^2 dx = \frac{x^3}{3} \Big|_3^5 = \frac{125}{3} - 9 = \frac{98}{3}$$

Some Fundamental Theorems

$$\begin{aligned} \frac{d}{dx} \int_a^x f(\xi) d\xi &= f(x) \\ \int_a^b cf(x) dx &= c \int_a^b f(x) dx \\ \int_a^b [f_1(x) + f_2(x) + \dots + f_n(x)] dx \\ &= \int_a^b f_1(x) dx + \int_a^b f_2(x) dx \\ &\quad + \dots + \int_a^b f_n(x) dx \\ \int_a^b f(x) dx &= - \int_b^a f(x) dx \\ \int_a^b f(x) dx &= \int_a^c f(x) dx + \int_c^b f(x) dx \\ &\quad a \leq c \leq b \\ \int_a^b f(x) dx &= (b - a) f(\xi) \end{aligned}$$

for some ξ such that $a \leq \xi \leq b$ (mean value theorem).

Simpson's Rule for Approximate Integration.

To evaluate $\int_a^b f(x) dx$ approximately, divide the interval from a to b into an even number n of equal

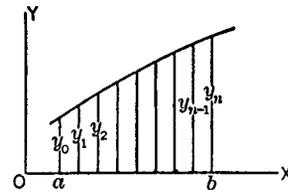

Fig. 141

parts with endpoints $x_0 = a, x_1, \dots, x_n = b$ and let $y_i = f(x_i)$ (Fig. 141). Then

$$\begin{aligned} \int_a^b f(x) dx \approx \frac{b-a}{3n} (y_0 + 4y_1 + 2y_2 + 4y_3 + 2y_4 \\ + \dots + 4y_{n-1} + y_n) \end{aligned} \tag{219}$$

Improper Integrals. If one limit is infinite,

$$\int_a^\infty f(x) dx = \lim_{b \rightarrow \infty} \int_a^b f(x) dx \tag{220}$$

The integral exists, or converges, if there is a number $k > 1$ and a number M independent of x such that $x^k |f(x)| < M$ for arbitrarily large values of x . If $x |f(x)| > m$, an arbitrary positive number, for sufficiently large values of x , the interval diverges.

Example 65. The integral $\int_0^\infty x dx / (x + x^2)^{3/2}$ exists, since, for $k = 2$ and $M = 1$,

$$x^2 \left| \frac{x}{(x + x^2)^{3/2}} \right| = \left(\frac{x^2}{x + x^2} \right)^{3/2} < 1$$

no matter how large the value of x .

If the integrand is infinite at the upper limit

$$\int_a^b f(x) dx = \lim_{\epsilon \rightarrow 0} \int_a^{b-\epsilon} f(x) dx \quad 0 < \epsilon < (b - a) \tag{221}$$

The integral exists if there is a number $k < 1$ and a number M independent of x such that $(b - x)^k |f(x)| < M$ for $a \leq x < b$. If there is a number $k \geq 1$ and a number m such that $(b - x)^k |f(x)| > m$ for $a \leq x < b$, the integral diverges.

Example 66. The integral $\int_0^1 dx / (1 - x)$ diverges, since, for $k = 1$ and $m = \frac{1}{2}$, $(1 - x) / (1 - x) = 1 > \frac{1}{2}$.

If the integrand is infinite at the lower limit, the tests are analogous. If the integrand is infinite at an intermediate point, use the point to divide the interval into two subintervals and apply the preceding tests.

Multiple Integrals. Let $f(x, y)$ be defined in the region R of the xy plane. Divide R into subregions $\Delta R_1, \Delta R_2, \dots, \Delta R_n$ of areas $\Delta A_1, \Delta A_2, \dots, \Delta A_n$. Let (ξ_i, η_i) be any point in ΔR_i . If the sum $\sum_{i=1}^n f(\xi_i, \eta_i) \Delta A_i$ has a limit as $n \rightarrow \infty$ and the maximum diameter of the subregions ΔR_i approaches zero, then

$$\int_R f(x, y) dA = \lim_{n \rightarrow \infty} \sum_{i=1}^n f(\xi_i, \eta_i) \Delta A_i \quad (222)$$

The double integral is evaluated by two successive single integrations, first with respect to y holding x constant between variable limits of integration and then with respect to x between constant limits (Fig. 142). If $f(x, y)$ is continuous, the order of integration can be reversed,

$$\begin{aligned} \int_R f(x, y) dA &= \int_a^b \int_{y_1(x)}^{y_2(x)} f(x, y) dy dx \\ &= \int_c^d \int_{x_1(y)}^{x_2(y)} f(x, y) dx dy \quad (223a) \end{aligned}$$

In polar coordinates,

$$\begin{aligned} \int_R F(r, \theta) dA &= \int_\alpha^\beta \int_{r_1(\theta)}^{r_2(\theta)} F(r, \theta) r dr d\theta \\ &= \int_k^l \int_{\theta_1(r)}^{\theta_2(r)} F(r, \theta) r d\theta dr \quad (223b) \end{aligned}$$

The analogous triple integrals are evaluated by three single integrations. In rectangular coordinates,

$$\int_R f(x, y, z) dV = \int \int \int f(x, y, z) dx dy dz \quad (224)$$

In spherical coordinates,

$$\int_R F(r, \theta, \phi) dV = \int \int \int F(r, \theta, \phi) r^2 \sin \theta dr d\theta d\phi \quad (225)$$

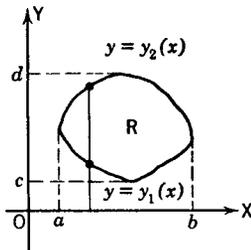

Fig. 142

In cylindrical coordinates,

$$\int_R G(\rho, \phi, z) dV = \int \int \int G(\rho, \phi, z) \rho d\rho d\phi dz \quad (226)$$

Integrals Containing a Parameter. If $f(x, y)$ is a continuous function of x and y in the closed rectangle $x_0 \leq x \leq x_1, y_0 \leq y \leq y_1$, and if $f(x, y)$ is integrated with respect to x , with y regarded as fixed and called a *parameter*, then

$$\int_{x_0}^{x_1} f(x, y) dx = \phi(y) \quad (227)$$

is a continuous function of y . Geometrically, the function $f(x, y)$ may be plotted as a surface $z = f(x, y)$. Then the value of $\phi(y_i)$ is the area of the section under the surface made by the plane $y = y_i$ (Fig. 143). If the limits of integration are continuous functions of y instead of constants, then $\phi(y)$ is continuous.

Differentiation under the Integral Sign. If $\partial f/\partial y$ is a continuous function of x and y in a closed rectangle, then

$$\frac{d\phi}{dy} = \int_{x_0}^{x_1} \frac{\partial f(x, y)}{\partial y} dx \quad (228)$$

If $\partial f/\partial y$ is continuous and the limits of integration are differentiable functions of y , then

$$\begin{aligned} \frac{d\phi}{dy} &= \frac{d}{dy} \int_{x_0=g_0(y)}^{x_1=g_1(y)} f(x, y) dx \\ &= \int_{g_0(y)}^{g_1(y)} \frac{\partial f(x, y)}{\partial y} dx - f(g_0, y) \frac{dg_0}{dy} \\ &\quad + f(g_1, y) \frac{dg_1}{dy} \quad (229) \end{aligned}$$

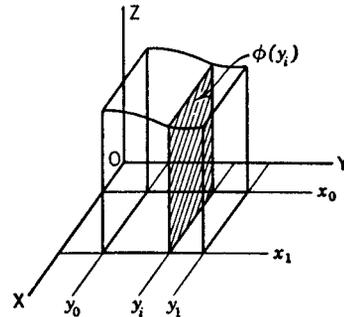

Fig. 143

If $f(x)$ is integrable in the interval $a \leq x \leq b$ and continuous at a point within the interval, then at that point the function $F(x) = \int_a^x f(\xi) d\xi$ has a derivative $F'(x) = f(x)$.

Uniform Convergence and Change of Order of Integration. The improper integral

$$\phi(y) = \int_{x_0}^{\infty} f(x, y) dx \quad (230)$$

converges uniformly in y in the interval $y_0 \leq y \leq y_1$ if for any $\varepsilon > 0$ there exists an L dependent on ε but not on y such that

$$\left| \int_l^{\infty} f(x_1 y) dx \right| < \varepsilon \quad \text{for } l \geq L \quad (231)$$

If $\int_{x_0}^{\infty} f(x, y) dx$ is uniformly convergent for $y_0 \leq y \leq y_1$, then

$$\int_{y_0}^{y_1} \int_{x_0}^{\infty} f(x, y) dx dy = \int_{x_0}^{\infty} \int_{y_0}^{y_1} f(x, y) dy dx \quad (232)$$

Stieltjes Integral. If $f(x)$ and $\phi(x)$ are define in the interval (a, b) , the Stieltjes integral of $f(x)$ with respect to $\phi(x)$ is

$$\begin{aligned} & \int_a^b f(x) d\phi(x) \\ &= \lim_{\substack{n \rightarrow \infty \\ \max \Delta x_v \rightarrow 0}} \sum_{v=1}^n f(\xi_v) [\phi(x_v) - \phi(x_{v-1})] \quad (233) \end{aligned}$$

in which the interval (a, b) is divided into n arbitrary parts $\Delta x_v = x_v - x_{v-1}$ by the points $x_0 = a, x_1, \dots, x_n = b$, and ξ_v is an arbitrary point in Δx_v . This limit exists if $f(x)$ is continuous and $\phi(x)$ is of bounded variation, that is, can be expressed as the difference of two nonincreasing or two nondecreasing bounded functions. However, it is not necessary that $f(x)$ be continuous, but only that the variation of $\phi(x)$ over the set of points of discontinuity of $f(x)$ be zero.

Lebesgue Integral. Let S be a set of points in the interval (a, b) , and $C(S)$ the complement of S , that is, the set of all the points of (a, b) that do not belong to S . Enclose the points of S in a set of intervals $I_v, v = 1, 2, 3, \dots$, finite or infinite in number, and let the sum of the lengths of the I_v be L . The greatest lower bound of all possible values of L is the exterior measure $\bar{m}(S)$ of S . The interior measure of S is $m(S) = (b - a) - \bar{m}[C(S)]$. If $\bar{m}(S) = m(S)$, the set S is measurable and its *measure* is $m(S) = \bar{m}(S)$.

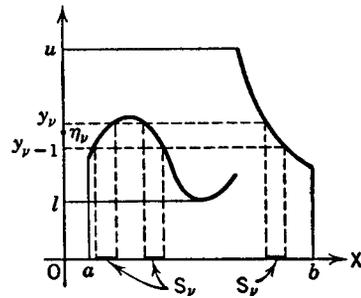

Fig. 144

A function $f(x)$ defined in the interval (a, b) is *measurable* if the set of points x for which $y_0 \leq f(x) < y_1$ is measurable for any values of y_0 and y_1 .

Let u and l be the upper and lower bounds of a measurable function $f(x)$ defined in the interval (a, b) (Fig. 144). Divide the interval (u, l) into n arbitrary subintervals Δy_v by the points $y_0 = l, y_1, \dots, y_n = u$. Let S_v be the set of points for which $y_{v-1} \leq f(x) < y_v$ and η_v any point in the interval Δy_v . Then the Lebesgue integral of $f(x)$ in the interval (a, b) is

$$\int_a^b f(x) dx = \lim_{\substack{n \rightarrow \infty \\ \max \Delta y_v \rightarrow 0}} \sum_{v=1}^n \eta_v \cdot m(S_v) \quad (234)$$

If the Riemann integral in the interval (a, b) , defined on p. 250, exists, the Lebesgue integral does also, and the two are equal, but not conversely.

10.3 Line, Surface, and Volume Integrals

Line Integrals. Let $P(x, y)$ and $Q(x, y)$ be functions continuous at all points of a continuous curve C joining the points A and B in the xy plane. Divide the curve C into n arbitrary parts ΔS_v by the points (x_v, y_v) , let (ξ_v, η_v) be an arbitrary point on ΔS_v , and let Δx_v and Δy_v be the projections of ΔS_v on the x and the y axes (Fig. 145). The line integral is

$$\begin{aligned} & \int_A^B [P(x, y) dx + Q(x, y) dy] = \lim_{\substack{n \rightarrow \infty \\ \max \Delta x_v, \Delta y_v \rightarrow 0}} \\ & \times \sum_{v=1}^n [P(\xi_v, \eta_v) \Delta x_v + Q(\xi_v, \eta_v) \Delta y_v] \quad (235) \end{aligned}$$

If the equation of the curve C is $y = f(x), x = \phi(y)$, or the parametric equations $x = x(t), y = y(t)$, the line integral can be evaluated as a definite integral in the one variable x, y , or t , respectively.

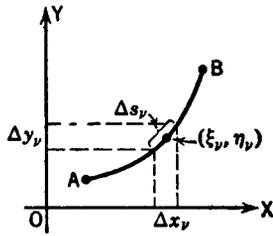

Fig. 145

Example 67. Find the value of $\int_{0,0}^{1,3} [y^2 dx + (xy - x^2) dy]$ along the paths (a) $y = 3x$, (b) $y^2 = 9x$.

(a) Substitute $y = 3x$, $dy = 3 dx$ and obtain

$$\begin{aligned} & \int_0^1 [9x^2 + (3x^2 - x^2)3] dx \\ &= \int_0^1 15x^2 dx = 5 \end{aligned}$$

(b) Substitute $y^2 = 9x$, $2y dy = 9 dx$, and obtain

$$\begin{aligned} & \int_0^3 \left[\frac{2}{9}y^3 + \left(\frac{y^3}{9} - \frac{y^4}{81} \right) \right] dy \\ &= \left[\frac{1}{12}y^4 - \frac{y^5}{405} \right]_0^3 = 6 \frac{3}{20} \end{aligned}$$

A line integral in the xyz space

$$\int_A^B [P(x, y, z) dx + Q(x, y, z) dy + R(x, y, z) dz] \quad (236)$$

is define similarly.

Applications

Work. The work done by a constant force F acting on a particle that moves a distance s along a straight line inclined at an angle θ to the force is $W = Fs \cos \theta$. If the path is a curve C and the force variable, the differential of work is $dW = F \cos \theta ds$, where ds is the differential of the path. Then

$$W = \int dW = \int_C F \cos \theta ds = \int_C (X dx + Y dy) \quad (237)$$

where X and Y are the x and y components of F (Fig. 146).

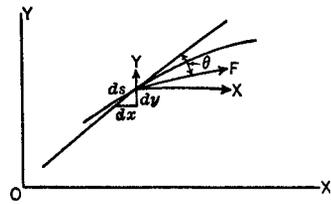

Fig. 146

Area. The area of a region bounded by a closed curve C such that a line parallel to the x or y axis meets C in no more than two points is

$$A = \frac{1}{2} \int_C (x dy - y dx) \quad (238)$$

The formula can be applied to any region that can be divided by a finit number of lines into regions satisfying the preceding condition.

Surface Integrals. Let $P(x, y, z)$ be a function continuous at all points of a region S (bounded by a simple closed curve) of a surface $z = f(x, y)$ which has a continuously turning tangent plane except possibly at isolated points or lines. Let A be the projection of S on the xy plane. Divide S into arbitrary subregions ΔS_v and let (ξ_v, η_v, ζ_v) be an arbitrary point in ΔS_v (Fig. 147). The surface integral is

$$\begin{aligned} & \lim_{\substack{n \rightarrow \infty \\ \max \text{ diam} \Delta S_v \rightarrow 0}} \sum_{v=1}^n P(\xi_v, \eta_v, \zeta_v) \Delta S_v \\ &= \int_S P(x, y, z) dS \\ &= \iint_A P(x, y, z) \sqrt{1 + \left(\frac{\partial z}{\partial x} \right)^2 + \left(\frac{\partial z}{\partial y} \right)^2} dx dy \quad (239) \end{aligned}$$

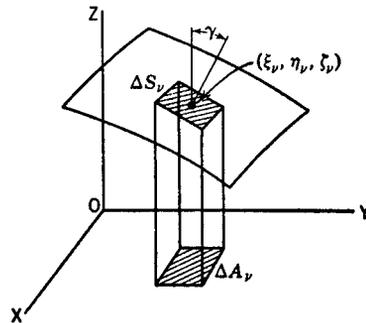

Fig. 147

If α, β, γ are the direction angles of the normal to S , the form of the surface integral analogous to the line integral (235) is

$$\iint_A (P \, dy \, dz + Q \, dz \, dx + R \, dx \, dy) = \int_S (P \cos \alpha + Q \cos \beta + R \cos \gamma) \, dS \quad (240)$$

Green's Theorem. Let $P(x, y)$ and $Q(x, y)$ be continuous functions with continuous partial derivatives $\partial P/\partial y$ and $\partial Q/\partial x$ in a simply connected region R bounded by a simple closed curve C . Then

$$\iint_R \left(\frac{\partial Q}{\partial x} - \frac{\partial P}{\partial y} \right) \, dx \, dy = \int_C (P \, dx + Q \, dy) \quad (241)$$

A region is *simply connected* if any closed curve in the region can be shrunk to a point without passing outside the region.

Stokes's Theorem. Let $P(x, y, z), Q(x, y, z), R(x, y, z)$ be continuous functions with continuous first partial derivatives, S a region (bounded by a simple closed curve C) of a surface $z = f(x, y)$, continuous with continuous first partial derivatives. Then

$$\begin{aligned} \iint_S \left[\left(\frac{\partial R}{\partial y} - \frac{\partial Q}{\partial z} \right) \, dy \, dz + \left(\frac{\partial P}{\partial z} - \frac{\partial R}{\partial x} \right) \, dz \, dx + \left(\frac{\partial Q}{\partial x} - \frac{\partial P}{\partial y} \right) \, dx \, dy \right] \\ = \int_C (P \, dx + Q \, dy + R \, dz) \end{aligned} \quad (242)$$

The signs are such that an observer standing on the surface with head in the direction of the normal will see the integration around C taken in the positive direction.

Divergence, or Gauss's, Theorem. Let $P(x, y, z), Q(x, y, z), R(x, y, z)$ be continuous functions with continuous first partial derivatives. Let V be a region in the xyz space bounded by a closed surface S with a continuously turning tangent plane except possibly at isolated points or lines. Then

$$\begin{aligned} \iiint_V \left(\frac{\partial P}{\partial x} + \frac{\partial Q}{\partial y} + \frac{\partial R}{\partial z} \right) \, dx \, dy \, dz \\ = \iint_S (P \, dy \, dz + Q \, dz \, dx + R \, dx \, dy) \end{aligned} \quad (243)$$

Example 68. Evaluate $\iint (x \, dy \, dz + y \, dz \, dx + z \, dx \, dy)$ over the cylinder

$$x^2 + y^2 = a^2 \quad z = \pm b$$

Since

$$\begin{aligned} P &= x & Q &= y & R &= z \\ \frac{\partial P}{\partial x} &= 1 & \frac{\partial Q}{\partial y} &= 1 & \frac{\partial R}{\partial z} &= 1 \end{aligned}$$

and

$$\int_{-a}^a \int_{-\sqrt{a^2-x^2}}^{\sqrt{a^2-x^2}} \int_{-b}^{+b} 3 \, dz \, dy \, dx = 6\pi a^2 b$$

Independence of Path and Exact Differential.

Under the conditions of Green's theorem, the following statements are equivalent:

1. $\int_C (P \, dx + Q \, dy) = 0$ for any closed curve C in the region R .
2. The value of $\int_{(a,b)}^{(\xi,\eta)} (P \, dx + Q \, dy)$ is independent of the curve connecting (a, b) and (ξ, η) , any points in R .
3. $\partial P/\partial y = \partial Q/\partial x$ at all points of R .
4. There exists a function $F(x, y)$ such that $dF = P \, dx + Q \, dy$.

Under the conditions of Stokes's theorem, the corresponding statements for three dimensions are:

1. $\int_C (P \, dx + Q \, dy + R \, dz) = 0$ for any closed curve C in the region S .
2. The value of $\int_{(a,b,c)}^{(\xi,\eta,\zeta)} (P \, dx + Q \, dy + R \, dz)$ is independent of the curve connecting (a, b, c) and (ξ, η, ζ) , any points in S .
3. $\partial P/\partial y = \partial Q/\partial x, \partial Q/\partial z = \partial R/\partial y, \partial R/\partial x = \partial P/\partial z$ at all points of S .
4. There exists a function $F(x, y, z)$ such that $dF = P \, dx + Q \, dy + R \, dz$.

10.4 Applications of Integration

Length of Arc of a Curve. The length s of the arc of a plane curve $y = f(x)$ from the point (a, b) to the point (c, d) is

$$s = \int_a^c \sqrt{1 + \left(\frac{dy}{dx} \right)^2} \, dx = \int_b^d \sqrt{1 + \left(\frac{dx}{dy} \right)^2} \, dy \quad (244)$$

If the equation of the curve is in polar coordinates, $r = f(\theta)$, then the length of the arc from the point (r_1, θ_1) to the point (r_2, θ_2) is

$$s = \int_{\theta_1}^{\theta_2} \sqrt{r^2 + \left(\frac{dr}{d\theta} \right)^2} \, d\theta = \int_{r_1}^{r_2} \sqrt{1 + r^2 \left(\frac{d\theta}{dr} \right)^2} \, dr \quad (245)$$

If the curve is in three dimensions, represented by the equations $y = f_1(x)$, $z = f_2(x)$, the length of arc from $x_1 = a$ to $x_2 = b$ is

$$s = \int_a^b \sqrt{1 + \left(\frac{dy}{dx}\right)^2 + \left(\frac{dz}{dx}\right)^2} dx \quad (246)$$

Plane Area. The area bounded by the curve $y = f(x)$, the x axis, and the ordinates at $x = a$, $x = b$ is

$$A = \int_a^b f(x) dx \quad (247)$$

where y has the same sign for all values of x between a and b .

In polar coordinates, the area bounded by the curve $r = f(\theta)$ and the two radii $\theta = \alpha$, $\theta = \beta$ (Fig. 148) is

$$A = \frac{1}{2} \int_{\alpha}^{\beta} r^2 d\theta \quad (248)$$

In rectangular coordinates, if the area is bounded by the two curves $y_2 = f(x)$, $y_1 = \phi(x)$ and the lines $x_2 = b$, $x_1 = a$ (Fig. 149), then

$$A = \int_a^b dx \int_{\phi(x)}^{f(x)} dy \quad (249)$$

If the area is bounded by the two curves $x_2 = \psi(y)$, $x_1 = \xi(y)$ and the lines $y_2 = d$, $y_1 = c$, then

$$A = \int_c^d dy \int_{\xi(y)}^{\psi(y)} dx \quad (250)$$

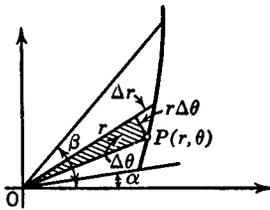

Fig. 148

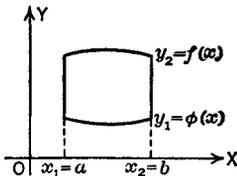

Fig. 149

If expressed in polar coordinates, the area by double integration is

$$A = \int_{\theta_1}^{\theta_2} d\theta \int_{r_1=f_1(\theta)}^{r_2=f_2(\theta)} r dr \quad \text{or} \quad \int_{r_1}^{r_2} r dr \int_{\theta_1=\phi_1(r)}^{\theta_2=\phi_2(r)} d\theta \quad (251)$$

Area of a Surface Revolution. The area of the surface of a solid of revolution generated by revolving the curve $y = f(x)$ between $x = a$ and $x = b$ is given as

$$2\pi \int_a^b y \sqrt{1 + \left(\frac{dy}{dx}\right)^2} dx \quad \text{about the } x \text{ axis} \quad (252)$$

$$2\pi \int_c^d x \sqrt{1 + \left(\frac{dx}{dy}\right)^2} dy \quad \text{about the } y \text{ axis} \quad (253)$$

where $c = f(a)$ and $d = f(b)$.

Volume. By triple integration,

$$V = \begin{cases} \iiint dx dy dz & \text{(rectangular coordinates)} \\ \iiint r^2 \sin \theta d\theta d\phi dr & \text{(spherical coordinates)} \\ \iiint \rho d\rho d\phi dz & \text{(cylindrical coordinates)} \end{cases} \quad (254) \quad (255) \quad (256)$$

(the limits of integration to be supplied).

Volume of a Solid of Revolution. The volume of a solid of revolution generated by revolving the region bounded by the x axis and the curve $y = f(x)$ between $x = a$ and $x = b$ is

$$\pi \int_a^b y^2 dx \quad \text{about the } x \text{ axis} \quad (257a)$$

$$\pi \int_c^d x^2 dy \quad \text{about the } y \text{ axis} \quad (257b)$$

where $c = f(a)$ and $d = f(b)$.

Surfaces. If the equation of a surface is written in the parametric form $x = f_1(u, v)$, $y = f_2(u, v)$, $z = f_3(u, v)$, the length of arc of a curve $u = u(t)$, $v = v(t)$ on the surface is

$$s = \int \sqrt{E \left(\frac{du}{dt}\right)^2 + 2F \frac{du}{dt} \frac{dv}{dt} + G \left(\frac{dv}{dt}\right)^2} dt \quad (258)$$

The area S of a region on the surface is

$$S = \int \int \sqrt{EG - F^2} du dv \quad (259)$$

where

$$E = \left(\frac{\partial x}{\partial u}\right)^2 + \left(\frac{\partial y}{\partial u}\right)^2 + \left(\frac{\partial z}{\partial u}\right)^2$$

$$F = \frac{\partial x}{\partial u} \frac{\partial x}{\partial v} + \frac{\partial y}{\partial u} \frac{\partial y}{\partial v} + \frac{\partial z}{\partial u} \frac{\partial z}{\partial v}$$

$$G = \left(\frac{\partial x}{\partial v}\right)^2 + \left(\frac{\partial y}{\partial v}\right)^2 + \left(\frac{\partial z}{\partial v}\right)^2$$

If the equation of the surface is written as $x = u, y = v, z = f(u, v) = f(x, y)$, the arc length is given as

$$s = \int \sqrt{(1+p^2)\left(\frac{dx}{dt}\right)^2 + 2pq\frac{dx}{dt}\frac{dy}{dt} + (1+q^2)\left(\frac{dy}{dt}\right)^2} dt \quad (260)$$

and the area as

$$S = \int \int \sqrt{1+p^2+q^2} dx dy \quad \text{where}$$

$$p = \frac{\partial z}{\partial x} \quad q = \frac{\partial z}{\partial y} \quad (261)$$

(the limits of integration to be supplied).

Moment. The moments of a mass m about the yz , xz , and xy planes are respectively

$$M_{yz} = \int x dm \quad M_{xz} = \int y dm \quad M_{xy} = \int z dm \quad (262)$$

(the limits of integration to be supplied).

Center of Gravity. The coordinates of the center of gravity of a mass m are

$$x = \frac{\int x dm}{\int dm} \quad y = \frac{\int y dm}{\int dm} \quad z = \frac{\int z dm}{\int dm} \quad (263)$$

(the limits of integration to be supplied).

Moment of Inertia. The moments of inertia I are

$$I_x = \int y^2 ds \quad I_y = \int x^2 ds \quad I_0 = \int (x^2 + y^2) ds \quad (264)$$

for a plane curve about the x and y axis and about the origin, respectively;

$$I_x = \int y^2 dA \quad I_y = \int x^2 dA \quad I_0 = \int (x^2 + y^2) dA \quad (265)$$

for a plane area about the x and y axis and about the origin, respectively; and

$$I_{yz} = \int x^2 dm$$

$$I_{xz} = \int y^2 dm \quad (266)$$

$$I_{xy} = \int z^2 dm$$

$$I_x = I_{xz} + I_{xy}, \text{ etc.}$$

for a solid of mass m about the yz , xz , and xy plane and about the x axis, respectively (the limits of integration to be supplied).

Fluid Pressure. The total force F against a plane surface perpendicular to the surface of the liquid and between the depths a and b is

$$F = \int_{y=a}^{y=b} \rho y dA = \int_a^b \rho y x dy \quad (267)$$

where ρ is the weight of the liquid per unit volume and y is the depth beneath the surface of the liquid of a horizontal element of area dA . Usually, $dA = x dy$, where x is the width of the vertical surface expressed as a function of y .

Center of Pressure. The depth \bar{y} of the center of pressure against a surface perpendicular to the surface of the liquid and between the depths a and b is

$$\bar{y} = \frac{\int_{y=a}^{y=b} \rho y^2 dA}{\int_{y=a}^{y=b} \rho y dA} \quad (268)$$

Work. The work W done in moving a particle from $s = a$ to $s = b$ against a force whose component expressed as a function of s in the direction of motion is $F(s)$ is

$$W = \int_{s=a}^{s=b} F(s) ds \quad (269)$$

11 DIFFERENTIAL EQUATIONS

11.1 Definitions

A *differential equation* is an equation containing an unknown function of a set of variables and its derivatives. If the equation has derivatives with respect to one variable only, it is an *ordinary differential equation*, otherwise it is a *partial differential equation*.

Example 69

$$\frac{d^2y}{dx^2} + k^2y = 0 \quad (270)$$

$$\frac{d^2y}{dx^2} = \sqrt{1 + y^2 + \frac{dy}{dx}} \quad (271)$$

$$y \frac{\partial^2 z}{\partial x^2} + zx \frac{\partial^2 z}{\partial x \partial y} - \frac{\partial z}{\partial y} = xyz \quad (272)$$

$$y - x \frac{dy}{dx} + 3 \frac{dx}{dy} = 0 \quad (273)$$

Equations (270), (271), and (273) are ordinary differential equations and (272) is a partial differential equation.

The *order* of a differential equation is the order of the highest derivative involved. Thus in Eqs. (270)–(272), the order is 2; in (273), the order is 1.

The *degree* of a differential equation is the exponent of the highest order appearing in the equation after it is rationalized and cleared of fractions with respect to the derivatives. The degree of (270), (272), and (273) is 1; that of (271) is 2.

A *solution* or *integral* of a differential equation is a relation among the variables that satisfies the equation identically.

A *general solution* of an ordinary differential equation of the n th order is one that contains n independent constants. Thus, $y = \sin x + c$ is a general solution of the equation $dy/dx = \cos x$.

A *particular solution* is one that is derivable from a general solution by assigning fixed values to the arbitrary constants. Thus, $y_1 = \sin x$, $y_2 = \sin x + 4$ are two particular solutions of the preceding equation.

11.2 First-Order Equations

Separation of Variables. A differential equation of the *first order*,

$$f\left(x, y, \frac{dy}{dx}\right) = 0 \quad (274)$$

can be brought into the form

$$P(x, y) dx + Q(x, y) dy = 0 \quad (275)$$

For the special case where P is a function of x only and Q a function of y only,

$$P(x) dx + Q(y) dy = 0 \quad (276)$$

the variables are separated. The solution is

$$\int P(x) dx + \int Q(y) dy = c \quad (277)$$

Example 70. Solve

$$\frac{dy}{dx} = -\frac{x}{y}$$

This can be written as $x dx + y dy = 0$ and has the solution

$$\int x dx + \int y dy = \frac{1}{2}x^2 + \frac{1}{2}y^2 = c$$

If $c = r^2/2$, then $x^2 + y^2 = r^2$, a set of concentric circles. There are an infinite number of solutions depending on the value of r . Through each point in the plane there passes one circle and only one.

Homogeneous Equations. A function $f(x, y)$ is homogeneous of the n th degree in x and y if $f(kx, ky) = k^n f(x, y)$. An equation

$$P(x, y) dx + Q(x, y) dy = 0 \quad (278)$$

is homogeneous if the functions $P(x, y)$ and $Q(x, y)$ are homogeneous in x and y . By substituting $y = vx$, the variables can be separated.

Example 71. Solve $(x^2 + y^2) dx - 2xy dy = 0$.

This is of the form $P(x, y) dx + Q(x, y) dy = 0$, where P and Q are homogeneous functions of the second degree. Making the substitution $y = vx$, the equation becomes $(1 + v^2) dx - 2v(x dv + v dx) = 0$.

Separating variables,

$$\frac{dx}{x} - \frac{2v}{1 - v^2} dv = 0$$

Integrating, $\log_e x(1 - v^2) = \log_e c$; replacing $v = y/x$, $\log(1 - y^2/x^2)x = \log_e c$; and taking exponentials, $x^2 - y^2 = cx$.

Linear Differential Equation. The differential equation

$$\frac{dy}{dx} + P(x)y = Q(x) \quad (279)$$

in which y and dy/dx appear only in the first degree and P and Q are functions of x is a *linear equation of the first order*. This has the general solution

$$y = e^{-\int P(x) dx} \left[\int Q(x) e^{\int P(x) dx} dx + c \right] \quad (280)$$

Example 72. An equation in the theory of electric networks is

$$L \frac{di}{dt} + Ri = E$$

where i is the current, L the inductance (a constant), R the resistance (a constant), and E the electromotive force, a function of time or constant. If $E = E(t)$,

$$i = e^{-(R/L)t} \left[\int \frac{E}{L} e^{(R/L)t} dt + c \right]$$

If E is constant and if $i = 0$ at $t = 0$, then

$$i = \frac{E}{R} (1 - e^{-(R/L)t})$$

Bernoulli Equation. This is

$$\frac{dy}{dx} + P(x)Y = Q(x)y^n \quad (281)$$

in which $n \neq 1$. By making the substitution $z = y^{1-n}$, a linear equation is obtained and the general solution is

$$y = e^{-\int P(x) dx} \left[(1-n) \int e^{(1-n)\int P(x) dx} Q(x) dx + c \right]^{1/(1-n)} \quad (282)$$

Example 73. Solve the equation

$$\frac{dy}{dx} - xy = xy^2$$

Substitute $z = y^{-1}$ and obtain $dz/dx + xz = -x$. The general integral is

$$z = ce^{-x^2/2} - 1 \quad \text{or} \quad y = \frac{1}{ce^{-x^2/2} - 1}$$

Exact Differential Equation. The equation

$$P(x, y) dx + Q(x, y) dy = 0 \quad (283)$$

is an *exact differential equation* if its left side is an exact differential

$$du = P dx + Q dy \quad (284)$$

that is, if $\partial P/\partial y = \partial Q/\partial x$. Then,

$$\int P dx + \int \left[Q - \frac{\partial \int P dx}{\partial y} \right] dy = c \quad (285)$$

is a solution.

Example 74. Solve $(x^2 - 4xy - y^2) dx + (y^2 - 2xy - 2x^2) dy = 0$.

This is an exact equation because $\partial P/\partial y = -4x - 2y = \partial Q/\partial x$,

$$\begin{aligned} \int (x^2 - 4xy - y^2) dx &= \frac{1}{3}x^3 - 2x^2y - xy^2 \\ \int [(y^2 - 2xy - 2x^2) - (-2x^2 - 2xy)] dy &= \frac{1}{3}y^3 \end{aligned}$$

The general solution is

$$\frac{1}{3}x^3 - 2x^2y - xy^2 + \frac{1}{3}y^3 = c$$

Integrating Factor. If the left member of the differential equation $P(x, y) dx + Q(x, y) dy = 0$ is not an exact differential, look for a factor $v(x, y)$ such that $du = v(P dx + Q dy)$ is an exact differential. Such an *integrating factor* satisfies the equation

$$Q \frac{\partial v}{\partial x} - P \frac{\partial v}{\partial y} + \left(\frac{\partial Q}{\partial x} - \frac{\partial P}{\partial y} \right) v = 0 \quad (286)$$

Example 75. The equation $(xy^2 - y^3) dx + (1 - xy^2) dy = 0$ when multiplied by $v = 1/y^2$ becomes $(x - y) dx + (1/y^2 - x) dy = 0$, of which the left side $du = (x - y) dx + (1/y^2 - x) dy$ is an exact differential since $\partial P/\partial y = \partial Q/\partial x$. The integration gives $u = x^2/2 - xy - 1/y$. The general solution is $u = c$ or $x^2y - 2xy^2 - 2cy - 2 = 0$.

Riccati's Equation. This is

$$\frac{dy}{dx} + P(x)y^2 + Q(x)y + R(x) = 0 \quad (287)$$

If a particular integral y_1 is known, place $y = y_1 + 1/z$ and obtain a linear equation in z .

11.3 Second-Order Equations

The differential equation

$$F\left(x, y, \frac{dy}{dx}, \frac{d^2y}{dx^2}\right) = 0 \quad (288)$$

is of the *second order*. If some of these variables are missing, there is a straightforward method of solution.

CASE 1: With y and dy/dx missing,

$$\frac{d^2y}{dx^2} = f(x) \quad (289)$$

This has the solution

$$y = \int dx \int f(x) dx + cx + c_1 \quad (290)$$

CASE 2: With x and dy/dx missing,

$$\frac{d^2y}{dx^2} = f(y) \quad (291)$$

Multiply both sides by $2 dy/dx$ and obtain

$$x = \int \frac{dy}{\sqrt{c + 2 \int f(y) dy}} + c_1 \quad (292)$$

as a solution.

CASE 3: With x and y missing,

$$\frac{d^2y}{dx^2} = f\left(\frac{dy}{dx}\right) \quad (293)$$

Place

$$\frac{dy}{dx} = p \quad \frac{d^2y}{dx^2} = \frac{dp}{dx} \quad (294)$$

Then

$$x = \int \frac{dp}{f(p)} + c$$

Solve for p , replace p by dy/dx , and solve the resulting first-order equation.

Example 76. The differential equation of the catenary is

$$a \frac{d^2y}{dx^2} = \sqrt{1 + \left(\frac{dy}{dx}\right)^2}$$

Let $p = dy/dx$. Then

$$a \frac{dp}{dx} = \sqrt{1 + p^2}$$

By separating variables,

$$\frac{dp}{\sqrt{1 + p^2}} = \frac{dx}{a}$$

which has the solution

$$\sinh^{-1} p = \frac{x + c}{a} \quad \text{or} \quad p = \frac{dy}{dx} = \sinh \frac{x + c}{a}$$

Integrating this latter,

$$y = a \cosh \frac{x + c}{a} + c_1$$

CASE 4: With y missing,

$$\frac{d^2y}{dx^2} = f\left(\frac{dy}{dx}, x\right) \quad (295)$$

Place $dy/dx = p$ and obtain the first-order equation $dp/dx = f(p, x)$. If this can be solved for p , then

$$y = \int p(x) dx + c \quad (296)$$

CASE 5: With x missing,

$$\frac{d^2y}{dx^2} = f\left(\frac{dy}{dx}, y\right) \quad (297)$$

Place $dy/dx = p$ and obtain the first-order equation $p dp/dy = f(p, y)$. If this can be solved for p , then

$$x = \int \frac{dy}{p(y)} + c \quad (298)$$

11.4 Bessel Functions

Wherever the mathematics of problems having circular or cylindrical symmetry appears, it is usually appropriate to consider the solutions of Bessel's differential equation (299). Such applications include radiation from a cylindrical antenna, eddy current losses in a cylindrical wire, and sinusoidal angle modulations including phase and frequency modulation,

$$x^2 \frac{d^2y}{dx^2} + x \frac{dy}{dx} + (x^2 - n^2)y = 0 \quad (299)$$

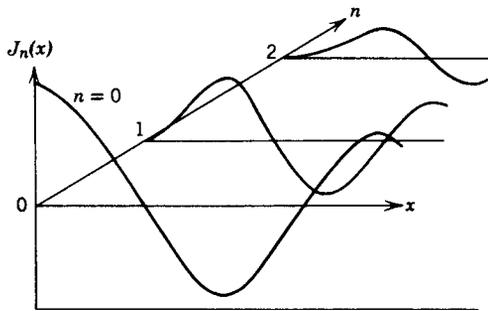

Fig. 150 Bessel functions of first kind.

where n is real, possibly integral or fractional, or complex, and the solution $y(x)$ is said to be of the *first kind* and denoted $J_n(x)$ for $0 \leq n$ an integer. Tables of $J_0(x)$ and $J_1(x)$ are available in Table 22 in Chapter 1. Graphs of these are shown in Fig. 150.

Bessel functions $J_n(x)$ are *almost periodic functions* that for increasing x have a zero-crossing half “period” approaching π from below. A sequence of these functions can be used to construct an orthogonal series much in the same way that periodic functions, sine, and cosine waves make up a Fourier series.

For an extensive set of tables of Bessel functions of many types, *Essentials of Mathematical Methods in Science and Engineering*, by S. S. Bayin (Wiley, Hoboken, New Jersey, 2008).

11.5 Linear Equations

General Theorem. The differential equation

$$\frac{d^n y}{dx^n} + P_1(x) \frac{d^{n-1} y}{dx^{n-1}} + \cdots + P_{n-1}(x) \frac{dy}{dx} + P_n(x)y = F(x) \quad (300)$$

is called the general n th-order linear differential equation. If $F(x) = 0$, the equation is *homogeneous*; otherwise it is *nonhomogeneous*. If $\phi(x)$ is a solution of the nonhomogeneous equation and y_1, y_2, \dots, y_n are linearly independent solutions of the homogeneous equation, then the *general solution* of (300) is

$$y = c_1 y_1 + c_2 y_2 + \cdots + c_n y_n + \phi(x) \quad (301)$$

The part $\phi(x)$ is called the *particular integral*, and the part $c_1 y_1 + \cdots + c_n y_n$ is the *complementary function*.

Homogeneous Differential Equation with Constant Coefficients

$$\frac{d^n y}{dx^n} + a_1 \frac{d^{n-1} y}{dx^{n-1}} + \cdots + a_{n-1} \frac{dy}{dx} + a_n y = 0 \quad (302)$$

A solution of this equation is

$$y_k = c e^{r_k x} \quad (303)$$

if r_k is a root of the algebraic equation,

$$r^n + a_1 r^{n-1} + \cdots + a_{n-1} r + a_n = 0 \quad (304)$$

If all the n roots r_1, r_2, \dots, r_n of (304) are different, then

$$y = c_1 e^{r_1 x} + c_2 e^{r_2 x} + \cdots + c_n e^{r_n x} \quad (305)$$

is a general solution of (302). If k of the roots are equal, $r_1 = r_2 = \cdots = r_k$ while r_{k+1}, \dots, r_n are different, then

$$y = (c_1 + c_2 x + \cdots + c_k x^{k-1}) e^{r_1 x} + c_{k+1} e^{r_{k+1} x} + \cdots + c_n e^{r_n x} \quad (306)$$

is a general solution. If $r_1 = p + iq, r_2 = p - iq$ are conjugate complex roots of (304), then

$$c_1 e^{r_1 x} + c_2 e^{r_2 x} = e^{px} (C_1 \cos qx + C_2 \sin qx) \quad (307)$$

Example 77

$$\frac{d^2 y}{dx^2} + 13 \frac{dy}{dx} + 40y = 0$$

has the solution $y = c_1 e^{-5x} + c_2 e^{-8x}$.

Example 78

$$\frac{d^2 y}{dx^2} + 6 \frac{dy}{dx} + 34y = 0$$

has the solution $y = (c_1 \cos 5x + c_2 \sin 5x) e^{-3x}$.

Nonhomogeneous Differential Equation with Constant Coefficients

$$\frac{d^n y}{dx^n} + a_1 \frac{d^{n-1} y}{dx^{n-1}} + \cdots + a_{n-1} \frac{dy}{dx} + a_n y = F(x) \quad (308)$$

The complementary function is found as previously. To find the particular integral, replace

$$\frac{dy}{dx} \text{ by } D, \quad \frac{d^2 y}{dx^2} \text{ by } D^2, \dots, \quad \frac{d^n y}{dx^n} \text{ by } D^n \quad (309)$$

$$P(D)y = (D^n + a_1 D^{n-1} + \cdots + a_{n-1} D + a_n)y = F(x) \quad (310)$$

Particular integrals y_p , in which B_i , A , B are undetermined coefficients, to be determined by substituting y_p in (310) and equating coefficients of like terms, are:

- If $F(x) = x^n + b_1x^{n-1} + \dots + b_{n-1}x + b_n$, then $y_p = x^n + B_1x^{n-1} + \dots + B_{n-1}x + B_n$. If D^m is a factor of $P(D)$, then $y_p = (x^n + B_1x^{n-1} + \dots + B_{n-1}x + B_n)x^m$.
- If $F(x) = b \sin ax$ or $b \cos ax$, then $y_p = A \sin ax + B \cos ax$. If $(D^2 + a^2)^m$ is a factor of $P(D)$, then $y_p = (A \sin ax + B \cos ax)x^m$.
- If $F(x) = ce^{ax}$ then $y_p = Ae^{ax}$. If $(D - a)^m$ is a factor of $P(D)$, then $y_p = x^m Ae^{ax}$.
- If $F(x) = g(x)e^{ax}$, place $y_p = e^{ax}w$ in (308), divide out e^{ax} , and solve the equation for w_p as a function of x .
- If $F(x)$ is the sum of a number of these functions, then y_p is the sum of the particular integrals corresponding to each of the functions.
- If $F(x)$ is not of the type (e), try the method of Laplace transformation (Section 13).

Example 79. $d^2y/dx^2 + 4y = x^2 + \cos x$ can be written as $(D^2 + 4)y = (D + 2i)(D - 2i) = x^2 + \cos x$. By (307), the complementary function is $y = c_1 \cos 2x + c_2 \sin 2x$. For a particular integral take $y_p = ax^2 + bx + c + f \sin x + g \cos x$ [by (a), (b), (e)].

Then

$$\frac{d^2y_p}{dx^2} = 2a - f \sin x - g \cos x$$

and substituting in the original equation

$$\begin{aligned} \frac{d^2y_p}{dx^2} + 4y_p &= 2a - f \sin x - g \cos x + 4ax^2 \\ &\quad + 4bx + 4c + 4f \sin x + 4g \cos x \\ &= x^2 + \cos x \end{aligned}$$

Equating coefficients, $a = \frac{1}{4}$, $b = 0$, $c = -\frac{1}{8}$, $f = 0$, $g = \frac{1}{3}$ and the general solution is $y = c_1 \cos 2x + c_2 \sin 2x + x^2/4 - \frac{1}{8} + \frac{1}{3} \cos x$.

Euler's Homogeneous Equation

$$x^n \frac{d^n y}{dx^n} + ax^{n-1} \frac{d^{n-1} y}{dx^{n-1}} + \dots + a_{n-1}x \frac{dy}{dx} + a_n y = 0 \quad (311)$$

Place $x = e^t$, and since

$$x \frac{dy}{dx} = \frac{dy}{dt} \quad x^2 \frac{d^2 y}{dx^2} = \left[\frac{d}{dt} \left(\frac{d}{dt} - 1 \right) \right] y$$

$$x^3 \frac{d^3 y}{dx^3} = \left[\frac{d}{dt} \left(\frac{d}{dt} - 1 \right) \left(\frac{d}{dt} - 2 \right) \right] y, \dots \quad (312)$$

(311) is transformed into a linear homogeneous differential equation with constant coefficients

Depression of Order. If a particular integral of a linear homogeneous differential equation is known, the order of the equation can be lowered. If y_1 is a particular integral of

$$\frac{d^n y}{dx^n} + P_1(x) \frac{d^{n-1} y}{dx^{n-1}} + \dots + P_{n-1}(x) \frac{dy}{dx} + P_n(x) = 0 \quad (313)$$

substitute $y = y_1 z$. The coefficient of z will be zero, and then by placing $dz/dx = u$, the equation is reduced to the $(n-1)$ st order.

Example 80. Given

$$\frac{d^2 y}{dx^2} + p(x) \frac{dy}{dx} + q(x)y = 0$$

and y_1 , a particular integral of this equation.

Let $y = y_1 z$. Then

$$\begin{aligned} \frac{dy}{dx} &= y_1 \frac{dz}{dx} + z \frac{dy_1}{dx} \\ \frac{d^2 y}{dx^2} &= y_1 \frac{d^2 z}{dx^2} + 2 \frac{dy_1}{dx} \frac{dz}{dx} + z \frac{d^2 y_1}{dx^2} \end{aligned}$$

Substituting in the original equation

$$\begin{aligned} y_1 \frac{d^2 z}{dx^2} + 2 \frac{dy_1}{dx} \frac{dz}{dx} + z \frac{d^2 y_1}{dx^2} \\ + p \left[y_1 \frac{dz}{dx} + z \frac{dy_1}{dx} \right] + q y_1 z = 0 \end{aligned}$$

and since the coefficient of z is zero, this reduces to

$$y_1 \frac{d^2 z}{dx^2} + \left(2 \frac{dy_1}{dx} + p y_1 \right) \frac{dz}{dx} = 0$$

Writing

$$\frac{dz}{dx} = u \quad \frac{du}{u} + \left(2 \frac{dy_1}{dx} + p y_1 \right) \frac{dx}{y_1} = 0$$

By integrating,

$$\log_e u + \int p dx + \log_e y_1^2 = \log_e c \quad \text{or}$$

$$u = \frac{c}{y_1^2} \exp \left(- \int P dx \right)$$

Another integration gives z . Then

$$y = y_1 \int \frac{c}{y_1^2} \exp\left(-\int P dx\right) dx + c_1$$

Systems of Linear Differential Equations with Constant Coefficients. For a system of n linear equations with constant coefficient in n dependent variables and one independent variable t , the symbolic algebraic method of solution may be used. If $n = 2$,

$$\begin{aligned} (D^n + a_1 D^{n-1} + \dots + a_n)x \\ + (D^m + b_1 D^{m-1} + \dots + b_m)y = R(t) \\ (D^p + c_1 D^{p-1} + \dots + c_p)x \\ + (D^q + d_1 D^{q-1} + \dots + d_q)y = S(t) \end{aligned} \tag{314}$$

where $D = d/dt$. The equations may be written as

$$P_1(D)x + Q_1(D)y = R \quad P_2(D)x + Q_2(D)y = S \tag{315}$$

Treating these as algebraic equations, eliminate either x or y and solve the equation thus obtained.

Example 81. Solve the system,

$$\begin{aligned} (a) \quad \frac{dx}{dt} + \frac{dy}{dt} + 2x + y &= 0 \\ (b) \quad \frac{dy}{dt} + 5x + 3y &= 0 \end{aligned}$$

By using the symbol D these equations can be written

$$(D + 2)x + (D + 1)y = 0 \quad 5x + (D + 3)y = 0$$

Eliminating x , $(D^2 + 1)y = 0$. From (307) (a) this has the solution $y = c_1 \cos t + c_2 \sin t$. Substituting this in (b),

$$x = -\frac{3c_1 + c_2}{5} \cos t + \frac{c_1 - 3c_2}{5} \sin t$$

11.6 Linear Algebraic Equations

Consider the set of linear algebraic equations

$$\sum_{i=1}^n a_{ki} \alpha_i = f_k \quad (k = 1, 2, \dots, m) \tag{316}$$

Equation (316) contains m linear algebraic equations in n unknowns, α_i .

Any system of linear equations in which all f_k are zero is called *homogeneous*. Consider the following equations associated with the matrix operator A :

$$A\alpha = 0 \quad (\text{homogeneous equation}) \tag{317}$$

$$A^* \beta = 0 \quad (\text{adjoint homogeneous equation}) \tag{318}$$

where A^* is the adjoint of A . For the linear algebraic equations, $A^* = A^T$, the transpose of A .

The homogeneous adjoint equations can also be written in the form

$$(A_i, \beta) = 0 \quad (i = 1, 2, \dots, n) \tag{319}$$

where (\cdot, \cdot) denotes the inner product in Euclidean space and A_i are the column vectors of the matrix $[A]$. From Eqs. (316) and (319), we deduce the following result, known as the *solvability condition*: The non-homogeneous equation $A\alpha = \mathbf{f}$ possesses a solution α if and only if the vector \mathbf{f} is orthogonal to all vectors β that are the solutions of the homogeneous adjoint equation, $A^* \beta = \mathbf{0}$. In analytical form this statement can be expressed as

$$(\mathbf{f}, \beta) = 0 \tag{320}$$

We now consider two cases of linear equations and discuss the existence and uniqueness of solutions of linear equations.

1. If (317) has only the trivial (i.e., zero) solution, it follows that $\det A \neq 0$ (otherwise, the trivial solution cannot be determined) and hence $\det A^* \neq 0$. Therefore, the adjoint homogeneous equation (318) also has only the trivial solution. Moreover, the solvability conditions are automatically satisfied for any \mathbf{f} [since the only solution of (318) is $\beta = \mathbf{0}$], and the nonhomogeneous equation 316 has one and only one solution, $\alpha = A^{-1}\mathbf{f}$, where A^{-1} is the inverse of the matrix A .

2. If (317) has nontrivial solutions, then $\det A = 0$. This in turn implies that the rows (or columns) of A are linearly dependent. If these linear dependencies are also reflected in the column vector \mathbf{f} (e.g., if the third row of A is the sum of the first and second rows, we must have $f_3 = f_1 + f_2$ in order to have any solutions), then there is a hope of having a solution to the system. If there are r ($\geq n$) number of independent solutions to (316), A is said to have a *r-dimensional null space* (i.e., nullity of A is r). It can be shown that A^* also has a r -dimensional null space, which is in general different from that of A . A necessary and sufficient condition for (316) to have solutions is provided by the solvability condition

$$(\mathbf{f}, \beta) \equiv \sum_{i=1}^n f_i \beta_i = 0$$

where β is the solution of Eq. (318).

Example 82. This example has three cases:

1. Consider the following pair of equations in two unknowns α_1 and α_2 :

$$3\alpha_1 - 2\alpha_2 = 4 \quad 2\alpha_1 + \alpha_2 = 5$$

or

$$\begin{bmatrix} 3 & -2 \\ 2 & 1 \end{bmatrix} \begin{Bmatrix} \alpha_1 \\ \alpha_2 \end{Bmatrix} = \begin{Bmatrix} 4 \\ 5 \end{Bmatrix} \quad (A\alpha = \mathbf{f})$$

We note that $\det A = 3 + 4 = 7 \neq 0$. The solution is then given by

$$\begin{Bmatrix} \alpha_1 \\ \alpha_2 \end{Bmatrix} = \begin{bmatrix} \frac{1}{7} & \frac{2}{7} \\ -\frac{2}{7} & \frac{3}{7} \end{bmatrix} \begin{Bmatrix} 4 \\ 5 \end{Bmatrix} = \begin{Bmatrix} 2 \\ 1 \end{Bmatrix}$$

The solution of the adjoint equations is trivial, $\beta = 0$, and therefore, the solvability condition is identically satisfied

2. Next consider the pair of equations

$$6\alpha_1 + 4\alpha_2 = 4 \quad 3\alpha_1 + 2\alpha_2 = 2$$

or

$$\begin{bmatrix} 6 & 4 \\ 3 & 2 \end{bmatrix} \begin{Bmatrix} \alpha_1 \\ \alpha_2 \end{Bmatrix} = \begin{Bmatrix} 4 \\ 2 \end{Bmatrix} \quad A\alpha = \mathbf{f}$$

We have $\det A = 0$, because row 1 (R_1) is equal to 2 times row 2 (R_2). However, we also have $2f_2 = f_1$. Consequently, we have one linearly independent solution, say $\alpha^{(1)}$, and the other depends on $\alpha^{(1)}$:

$$\alpha^{(1)} = (2, -2)$$

Note that there are many dependent solutions to the pair. For example, $(2, -2)$, $(4, -5)$, $(-2, 4)$, and so on, are solutions of $A\alpha = \mathbf{f}$. The solution to the adjoint homogeneous equation

$$\begin{bmatrix} 6 & 3 \\ 4 & 2 \end{bmatrix} \begin{Bmatrix} \beta_1 \\ \beta_2 \end{Bmatrix} = \begin{Bmatrix} 0 \\ 0 \end{Bmatrix}$$

is given by $\beta_2 = -2\beta_1$. Note that $(f, \beta) \equiv f_1\beta_1 + f_2\beta_2 = 4(-\frac{1}{2}\beta_2) + 2\beta_2 = 0$; hence the solvability condition is satisfied

3. Finally, consider the pair of equations

$$6\alpha_1 + 4\alpha_2 = 3 \quad 3\alpha_1 + 2\alpha_2 = 2$$

or

$$\begin{bmatrix} 6 & 4 \\ 3 & 2 \end{bmatrix} \begin{Bmatrix} \alpha_1 \\ \alpha_2 \end{Bmatrix} = \begin{Bmatrix} 3 \\ 2 \end{Bmatrix}$$

We note that $\det A = 0$, because $2R_2 = R_1$. However, $2f_2 \neq f_1$. Hence the pair of equations is inconsistent, and therefore no solutions exist.

Geometrically, we can interpret these three pairs of equations as pairs of straight lines in R^2 with $\alpha_i = x_i$, $i = 1, 2$ (see Fig. 151). In part 1, the lines represented by the two equations intersect at the point $(x_1, x_2) = (2, 1)$. In part 2, the lines coincide, or intersect, at an infinite number of points, and hence many solutions exist. In part 3, the lines do not intersect at all showing that no solutions exist. From this geometric interpretation, one can see that the lines are nearly parallel (i.e., the angle θ is nearly zero), the determinant of A is nearly zero [because $\tan \theta = (a_{11}a_{22} - a_{12}a_{21}) / (a_{11}a_{21} + a_{12}a_{22})$], and therefore it is difficult to obtain an accurate numerical solution. In such cases the system of equations is said to be *ill conditioned*. While these observations can be generalized to a system of n equations, the geometric interpretation becomes complicated.

Example 83. This example has two cases:

1. Consider the following set of three equations in three unknowns:

$$\alpha_1 + \alpha_2 + \alpha_3 = 2$$

$$\alpha_1 - \alpha_2 - 3\alpha_3 = 3 \quad \text{or} \quad A\alpha = \mathbf{f}$$

$$3\alpha_1 + \alpha_2 - \alpha_3 = 1$$

The adjoint homogeneous equations become

$$\beta_1 + \beta_2 + 3\beta_3 = 0$$

$$\beta_1 - \beta_2 + \beta_3 = 0 \quad \text{or} \quad A^*\beta = 0$$

$$\beta_1 - 3\beta_2 - \beta_3 = 0$$

Solving for β , we obtain $\beta_1 = 2\beta_2 = -2\beta_3$. Hence, the null space of A^* is defined by

$$\mathcal{N}(A^*) = \{(2a, a, -a), a \text{ is a real number}\}$$

Clearly $\mathcal{N}(A^*)$ is one dimensional. The null space of A is given by

$$\mathcal{N}(A) = \{(a, -2a, a), a \text{ is a real number}\}$$

Note that $\mathcal{N}(A^*) \neq \mathcal{N}(A)$, but their dimension is the same. Clearly $(2, 1, -1)$ is a solution of $A^*\beta = 0$ while $(1, -2, 1)$ is a solution of $A\alpha = 0$. The solvability condition gives

$$(f, \beta) = 2 \times 2 + 3 \times 1 + 1 \times (-1) \neq 0$$

and therefore $A\alpha = \mathbf{f}$ has no solution.

2. Reconsider the preceding linear equations with $\mathbf{f} = \{-1, 3, 1\}^T$. Then the solvability condition

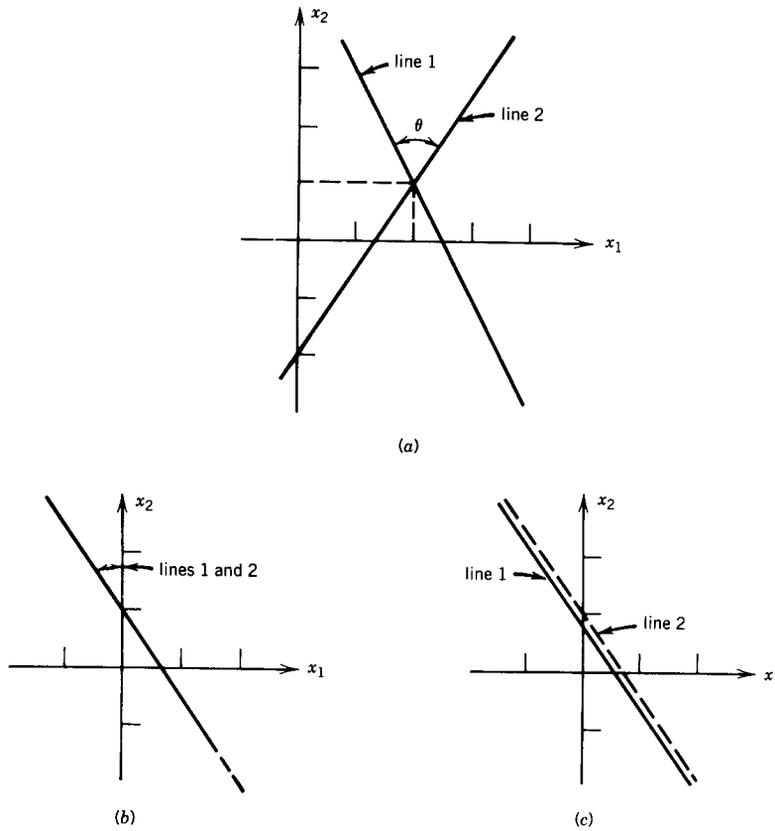

Fig. 151 Geometric interpretation of the solution of two simultaneous algebraic equations in a plane: (a) unique solution; (b) many solutions; (c) no solution.

is clearly satisfied. Hence there is one linearly independent solution to $A\alpha = f$ (note that $-2R_1 + R_3 = R_2$ and $-2f_1 + f_3 = f_2$).

$$\alpha \equiv (\alpha_1, \alpha_2, \alpha_3) = (1, -2, 0)$$

Only one of the three α 's is arbitrary (not determined), and the remaining two α 's are given in terms of the arbitrary α . For example, if α_1 is arbitrary, we have

$$\begin{aligned} \alpha_1 + \alpha_2 + \alpha_3 &= 1 \\ \alpha_1 + \alpha_2 - 3\alpha_3 &= 2 \quad \text{or} \quad A\alpha = f \\ 3\alpha_1 + \alpha_2 - \alpha_3 &= 3 \end{aligned}$$

We have $\det A \neq 0$. It can be easily verified that $(A) = (A^*) = \{(0, 0, 0)\}$. The unique solution to $A\alpha = f$ is given by

$$\alpha_1 = \frac{3}{4} \quad \alpha_2 = \frac{1}{2} \quad \alpha_3 = -\frac{1}{4}.$$

11.7 Partial Differential Equations

First Order

Definition. If x_1, x_2, \dots, x_n are n independent variables, $z = z(x_1, x_2, \dots, x_n)$ the dependent variable, and

$$\frac{\partial z}{\partial x_1} = p_1, \dots, \frac{\partial z}{\partial x_n} = p_n \quad (321)$$

then

$$F(x_1, x_2, \dots, x_n, z, p_1, p_2, \dots, p_n) = 0 \quad (322)$$

is a partial differential equation of the first order. An equation

$$f(x_1, x_2, \dots, x_n, z, c_1, \dots, c_n) = 0 \quad (323)$$

with n independent constants is a *complete integral* of (322) if the elimination of the constants by partial differentiation gives the differential equation (322).

Example 84

$$F = z^2 \left[\left(\frac{\partial z}{\partial x} \right)^2 + \left(\frac{\partial z}{\partial y} \right)^2 + 1 \right] - c^2 = 0$$

Then

$$f = (x - h)^2 + (y - k)^2 + z^2 - c^2 = 0$$

is a solution, since by differentiating it with respect to x and y ,

$$(x - h) + z \frac{\partial z}{\partial x} = 0 \quad (y - k) + z \frac{\partial z}{\partial y} = 0$$

and substituting the values of $x - h$, $y - k$ from the last two equations in f , expression F is obtained.

If the eliminant obtained by eliminating c_1, \dots, c_n from the equations $f = 0$, $\partial f / \partial c_1 = 0, \dots, \partial f / \partial c_n = 0$ satisfies the differential equation, it is a *singular solution*. This differs from a particular integral in that it is usually not obtainable from the complete integral by giving particular values to the constants.

Suppose that the equation

$$F \left(x, y, z, \frac{\partial z}{\partial x}, \frac{\partial z}{\partial y} \right) = 0$$

has the complete integral $f(x, y, z, a, b) = 0$. Let one of the constants $b = \phi(a)$; then $f[x, y, z, a, \phi(a)] = 0$. The *general integral* is the set of solutions found by eliminating a between $f[x, y, z, a, \phi(a)] = 0$ and $d\phi/da = 0$ for all choices of ϕ .

Linear Differential Equations

$$P(x, y, z)p + Q(x, y, z)q = R(x, y, z) \quad \text{where}$$

$$p = \frac{\partial z}{\partial x} \quad q = \frac{\partial z}{\partial y} \quad (324)$$

is a linear partial differential equation. From the system of ordinary equations

$$\frac{dx}{P} = \frac{dy}{Q} = \frac{dz}{R}$$

the two independent solutions $u(x, y, z) = c_1$, $v(x, y, z) = c_2$ are obtained. Then $\Phi(u, v) = 0$, where Φ is an arbitrary function, is the *general solution* of $Pp + Qq = R$.

Example 85. Given $xp + yq = z$. The system $dx/x = dy/y = dz/z$ has the solution $u = y/x = c_1$, $v = z/x = c_2$. Then the general solution is

$$\Phi(u, v) = \Phi \left(\frac{y}{x}, \frac{z}{x} \right) = 0$$

Example 86. Given $(ny - mz)p + (lz - nx)q = mx - ly$. From

$$\frac{dx}{ny - mz} = \frac{dy}{lz - nx} = \frac{dz}{mx - ly}$$

by using the multipliers l , m , n and adding the fraction $(l dx + m dy + n dz)/0$ is obtained. Therefore $l dx + m dy + n dz = 0$. This has the solution $lx + my + nz = c_1$. Similarly, $x dx + y dy + z dz = 0$, or $x^2 + y^2 + z^2 = c_2$. Then the general solution is $\Phi(x^2 + y^2 + z^2, lx + my + nz) = 0$.

General Method of Solution. Given $F(x, y, z, p, q) = 0$, the partial differential equation to be solved. Since z is a function of x and y , it follows that $dz = p dx + q dy$. If another relation can be found among x, y, z, p, q , such as $f(x, y, z, p, q) = 0$, then p and q can be eliminated. The solution of the ordinary differential equation thus formed involving x, y, z will satisfy the given equation, $F(x, y, z, p, q) = 0$. The unknown function f must satisfy the following linear partial differential equation:

$$\begin{aligned} \frac{\partial F}{\partial p} \frac{\partial f}{\partial x} + \frac{\partial F}{\partial q} \frac{\partial f}{\partial y} + \left(p \frac{\partial F}{\partial p} + q \frac{\partial F}{\partial q} \right) \frac{\partial f}{\partial z} \\ - \left(\frac{\partial F}{\partial x} + p \frac{\partial F}{\partial z} \right) \frac{\partial f}{\partial p} - \left(\frac{\partial F}{\partial y} + q \frac{\partial F}{\partial z} \right) \frac{\partial f}{\partial q} = 0 \end{aligned} \quad (325)$$

which is satisfied by any of the solutions of the system

$$\begin{aligned} \frac{\partial x}{\partial F / \partial p} = \frac{\partial y}{\partial F / \partial q} = \frac{dz}{p \partial F / \partial p + q \partial F / \partial q} \\ = \frac{-dp}{\partial F / \partial x + p \partial F / \partial z} = \frac{-dq}{\partial F / \partial y + q \partial F / \partial z} \end{aligned} \quad (326)$$

Example 87. Solve $p(q^2 + 1) + (b - z)q = 0$. Here Eqs. (326) reduce to

$$\begin{aligned} \frac{dp}{pq} = \frac{dp}{q^2} = \frac{dz}{3pq^2 + p + (b - z)q} = \frac{dx}{q^2 + 1} \\ = \frac{dy}{-z + b + 2pq} \end{aligned}$$

The third fraction, by virtue of the given equation, reduces to $dz/2pq^2$. From the first two fractions, by integration, $q = cp$. This and the original equation determine the values of p and q , namely,

$$p = \frac{\sqrt{c_1(z - b) - 1}}{c_1} \quad q = \sqrt{c_1(z - b) - 1}$$

Substitution of these values in $dz = p dx + q dy$ gives

$$dz = \left(\frac{dx}{c_1} + dy \right) \sqrt{c_1(z-b) - 1}$$

In this equation the variables are separable; this on integration gives the complete integral $2\sqrt{c_1(z-b) - 1} = x + c_1y + c_2$. There is no singular solution. In this work, had another pair of ratios been chosen, say $dq/q^2 = dx/(q^2 + 1)$, another complete integral would have been obtained, namely,

$$(z-b) \left\{ \frac{1}{2}(x+k_1) - \sqrt{\left[\frac{1}{2}(x+k_1) \right]^2 + 1} \right\} + y + k_2 = 0$$

Second Order

Definitions. A linear partial differential equation of the second order with two independent variables is of the form

$$L = Ar + 2Bs + Ct + Dp + Eq + Fz = f(x, y) \tag{327}$$

where

$$r = \frac{\partial^2 z}{\partial x^2} \quad s = \partial^2 z / (\partial x \partial y) \quad t = \partial^2 z / \partial y^2$$

$$p = \partial z / \partial x \quad q = \partial z / \partial y$$

The coefficients A, \dots, F are real continuous functions of the real variables x and y . Let $\xi = \xi(x, y)$, $\eta = \eta(x, y)$ be two solutions of the following homogeneous partial differential equation of the first order:

$$Ap^2 + 2Bpq + Cq^2 = 0 \tag{328}$$

If $B^2 - AC = 0$, the homogeneous form of (327), $L = 0$, is called the *parabolic* type and has the normal form

$$\frac{\partial^2 z}{\partial \xi^2} + a \frac{\partial z}{\partial \xi} + b \frac{\partial z}{\partial \eta} + cz = 0 \tag{329}$$

where a, b, c are functions of ξ and η . An example is the equation of heat flow $\partial u / \partial t = a^2 \partial^2 u / \partial t^2$, where $u = u(x, t)$ is the temperature, t is the time, a^2 is constant. If $B^2 - AC > 0$ in (328), the homogeneous form of (327) is the *hyperbolic* type that has as its two normal forms

$$\frac{\partial^2 z}{\partial \xi \partial \eta} + a \frac{\partial z}{\partial \xi} + b \frac{\partial z}{\partial \eta} + cz = 0 \tag{330}$$

$$\frac{\partial^2 z}{\partial \xi^2} - \frac{\partial^2 z}{\partial \eta^2} + a \frac{\partial z}{\partial \xi} + b \frac{\partial z}{\partial \eta} + cz = 0 \tag{331}$$

An example is the equation of a vibrating string,

$$\frac{\partial^2 z}{\partial t^2} = a^2 \frac{\partial^2 z}{\partial x^2}$$

where z is the transverse displacement of a point on the string, with abscissa x at time t and a^2 is constant. If $B^2 - AC < 0$, the equation is of the *elliptic* type that has the normal form

$$\frac{\partial^2 z}{\partial \xi^2} + \frac{\partial^2 z}{\partial \eta^2} + a \frac{\partial z}{\partial \xi} + b \frac{\partial z}{\partial \eta} + cz = 0 \tag{332}$$

An example is Laplace's equation

$$\frac{\partial^2 z}{\partial \xi^2} + \frac{\partial^2 z}{\partial \eta^2} = 0$$

usually written $\nabla^2 z = 0$. The two solutions of (328) are real in the hyperbolic case and conjugate complex in the elliptic case. That is, in the latter case, $\xi = \frac{1}{2}(\alpha + i\beta)$, $\eta = \frac{1}{2}(\alpha - i\beta)$, where α and β are real, and

$$\frac{\partial^2 z}{\partial \xi \partial \eta} = \frac{1}{4} \left(\frac{\partial^2 z}{\partial \alpha^2} + \frac{\partial^2 z}{\partial \beta^2} \right)$$

As in ordinary linear equations, the whole solution consists of the complementary function and the particular integral. Also, if $z = z_1, z = z_2, \dots, z = z_n$ are solutions of the homogeneous equation (327), $L = 0$, then $z = c_1 z_1 + c_2 z_2 + \dots + c_n z_n$ is again a solution.

Equations Linear in the Second Derivatives.

The general type of second-order equation linear in the second derivatives may be written in the form

$$Ar + Bs + Ct = V \tag{333}$$

where A, B, C, V are functions of x, y, z, p, q . From the equations

$$A dy^2 - B dx dy + C dx^2 = 0 \tag{334}$$

$$A dp dy + C dq dx - V dx dy = 0 \tag{335}$$

$$p dx + q dy = dz \tag{336}$$

it may be possible to derive either one or two relations between x, y, z, p, q , called intermediary integrals, and from these to deduce the solution of (333). To obtain an intermediary integral, resolve (334), supposing the left member is not a perfect square, into the two equations $dy - n_1 dx = 0, dy - n_2 dx = 0$. From the first of these and from (335) combined, if necessary, with (336), obtain the two integrals $u_1(x, y, z, p, q) = a, v_1(x, y, z, p, q) = b$; then $u_1 = f_1(v_1)$, where f_1 is an arbitrary function, is now an intermediary integral.

In the same way, from $dy - n_2 dx = 0$, obtain another pair of integrals $u_2 = a_1, v_2 = b_1$; then $u_2 = f_2(v_2)$ is an intermediary integral. For the final integral, if $n_1 = n_2$, the intermediary integral may be integrated. If $n_1 \neq n_2$, solve the two intermediary integrals for p and q , substitute in $p dx + q dy = dz$, and integrate for the solution.

Example 88. Solve

$$r^2 - a^2 t = 0 \quad (337)$$

the equation for a vibrating string.

The auxiliary equations are

$$\begin{aligned} dy - a dx &= 0 & dy + a dx &= 0 \\ dp dy - a^2 dx dq &= 0 \end{aligned} \quad (338)$$

Hence $y + ax = c_1, y - ax = c_2$. Combining $y + ax = c_1$ with (338), $dp + a dq = 0$ is obtained, whereupon $p + aq = c_3 = f_1(y + ax)$. Combining $y - ax = c_2$ with (338), $dp - a dq = 0$ is obtained, whereupon $p - aq = c_4 = f_2(y - ax)$.

Solving for p and q ,

$$\begin{aligned} p &= \frac{1}{2}[f_1(y + ax) + f_2(y - ax)] \\ q &= \frac{1}{2a}[f_1(y + ax) - f_2(y - ax)] \end{aligned}$$

Substituting these in $p dx + q dy = dz$,

$$\begin{aligned} dz &= \frac{1}{2a}[f_1(y + a)(dy + a dx) \\ &\quad - f_2(y - ax)(dy - a dx)] \end{aligned}$$

which is an exact differential. Integration gives $z = \phi(y + ax) + \psi(y - ax)$.

Homogeneous Equation with Constant Coefficients

$$\frac{\partial^2 z}{\partial x^2} + A_1 \frac{\partial^2 z}{\partial x \partial y} + A_2 \frac{\partial^2 z}{\partial y^2} = 0 \quad (339)$$

This equation is equivalent to

$$\left(\frac{\partial}{\partial x} - m_1 \frac{\partial}{\partial y}\right) \left(\frac{\partial}{\partial x} - m_2 \frac{\partial}{\partial y}\right) z = 0 \quad (340)$$

where m_1 and m_2 are roots of the auxiliary equation $X^2 + A_1 X + A_2 = 0$. The general solution of (340) is

$$z = f_1(y + m_1 x) + f_2(y + m_2 x) \quad (341)$$

Example 89. Solve

$$8 \frac{\partial^2 z}{\partial x^2} + 2 \frac{\partial^2 z}{\partial x \partial y} - 15 \frac{\partial^2 z}{\partial y^2} = 0$$

The auxiliary equation is $8X^2 + 2X - 15 = (2X + 3)(4X - 5) = 0$. Hence $m_1 = -\frac{3}{2}, m_2 = \frac{5}{4}$. The general solution is $z = f_1(2y - 3x) + f_2(4y + 5x)$.

If the auxiliary equation has multiple factors, the general solution is $z = f_1(y + m_1 x) + x f_2(y + m_1 x)$.

Example 90. Solve

$$\frac{\partial^2 z}{\partial x^2} + 6 \frac{\partial^2 z}{\partial x \partial y} + 9 \frac{\partial^2 z}{\partial y^2} = 0$$

The auxiliary equation is $X^2 + 6X + 9 = (X + 3)(X + 3) = 0$. The general solution is $z = f_1(y - 3x) + x f_2(y - 3x)$.

If the coefficients in Eq. (339) are real, the complex roots of the auxiliary equation occur in conjugate pairs. Then the general solution will have the form

$$z = f(y + \alpha x + i\beta x) + g(y + \alpha x - i\beta x)$$

Example 91. Solve

$$\frac{\partial^2 z}{\partial x^2} - 2 \frac{\partial^2 z}{\partial x \partial y} + 2 \frac{\partial^2 z}{\partial y^2} = 0$$

The auxiliary equation is $X^2 - 2X + 2 = 0$ and $m = 1 \pm i$. The general solution is $z = f(y + x + ix) + g(y + x - ix)$, which can be written as $z = f_1(y + x + ix) + f_1(y + x - ix) + i[g_1(y + x + ix) - g_1(y + x - ix)]$, where f_1 and g_1 are any twice-differentiable real functions. If, in particular, $f_1 = \cos u$ and $g_1 = e^u$, it can be shown that $z = 2 \cos(x + y) \cosh x - 2e^{x+y} \sin x$.

Method of Separation of Variables. As an example of this method, the solution will be given to Laplace's equation

$$\nabla^2 u = \frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} = 0 \quad (342)$$

Assume that

$$u = X(x) \cdot Y(y) \quad (343)$$

where X is a function of x only and Y a function of y only. By substitution and dividing by $X \cdot Y$, (342) becomes

$$\frac{1}{X} \frac{d^2 X}{dx^2} = -\frac{1}{Y} \frac{d^2 Y}{dy^2} \quad (344)$$

Since the left side does not contain y , the right side does not contain x , and the two sides are equal, they must equal a constant, say $-k^2$:

$$\frac{1}{X} \frac{d^2X}{dx^2} = -k^2 \quad \frac{1}{Y} \frac{d^2Y}{dy^2} = k^2 \quad (345)$$

The solutions of these homogeneous linear differential equations with constant coefficient are

$$X = c_1 \cos kx + c_2 \sin kx \quad Y = c_3 e^{ky} + c_4 e^{-ky} \quad (346)$$

Hence, from (343),

$$\begin{aligned} u &= (c_1 \cos kx + c_2 \sin kx)(c_3 e^{ky} + c_4 e^{-ky}) \\ &= e^{ky}(k_1 \cos kx + k_2 \sin kx) \\ &\quad + e^{-ky}(k_3 \cos kx + k_4 \sin kx) \end{aligned} \quad (347)$$

Since (342) is linear, the sum of any number of solutions is again a solution. An infinite number of solutions may be taken provided the series converges and may be differentiated term by term. Then

$$\begin{aligned} u &= \sum_{n=0}^{\infty} [e^{ky}(A_n \cos kx + B_n \sin kx) \\ &\quad + e^{-ky}(D_n \cos kx + E_n \sin kx)] \end{aligned} \quad (348)$$

is a solution of (342). The coefficient of (348) are determined by using the series as a Fourier series to fit the boundary conditions.

Functions that satisfy Laplace's equation are *harmonic*. In polar coordinates (342) becomes

$$\nabla^2 u = \frac{\partial^2 u}{\partial r^2} + \frac{1}{r^2} \frac{\partial^2 u}{\partial \theta^2} + \frac{1}{r} \frac{\partial u}{\partial r} = 0 \quad (349)$$

In three dimensions, Laplace's equation in rectangular coordinates is

$$\nabla^2 u = \frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} + \frac{\partial^2 u}{\partial z^2} = 0 \quad (350)$$

In cylindrical coordinates,

$$\nabla^2 u = \frac{\partial^2 u}{\partial \rho^2} + \frac{1}{\rho} \frac{\partial u}{\partial \rho} + \frac{1}{\rho^2} \frac{\partial^2 u}{\partial \phi^2} + \frac{\partial^2 u}{\partial z^2} = 0 \quad (351)$$

In spherical coordinates,

$$\begin{aligned} \nabla^2 u &= \frac{1}{r^2} \frac{\partial}{\partial r} \left(r^2 \frac{\partial u}{\partial r} \right) + \frac{1}{r^2 \sin^2 \theta} \frac{\partial^2 u}{\partial \phi^2} \\ &\quad + \frac{1}{r^2 \sin \theta} \frac{\partial}{\partial \theta} \left(\sin \theta \frac{\partial u}{\partial \theta} \right) \end{aligned} \quad (352)$$

12 FINITE-ELEMENT METHOD

12.1 Introduction

The finite-element method is a powerful numerical technique that uses variational methods and interpolation theory for solving differential and integral equations of initial and boundary-value problems. The method is so general that it can be applied to a wide variety of engineering problems, including heat transfer, fluid mechanics, solid mechanics, chemical processing, electrical systems, and a host of other fields. The method is also so systematic and modular that it can be implemented on a digital computer and can be utilized to solve a wide range of practical engineering problems by merely changing the data input to the program. The method is naturally suited for the description of complicated geometries and the modeling and simulation of most physical phenomena.

Basic Features The finite-element method is characterized by two distinct features: First, the *domain* of the problem is viewed as a collection of simple subdomains, called *finite elements*. By the word domain we refer to a physical structure, system, or region over which the governing equations are to be solved. The collection of the elements is called the *finite-element mesh*. Second, over each element, the solution of the equations being solved is approximated by interpolation polynomials. The first feature, dividing a whole into parts, called *discretization of the domain*, allows the analyst to represent any complex system as one of numerous smaller connected elements, each element being of a simpler shape that permits approximation of the solution by a linear combination of algebraic polynomials. The second feature, *elementwise polynomial approximation*, enables the analyst to represent the solution on an element by polynomials so that the numerical evaluation of integrals becomes easy. The polynomials are typically interpolants of the solution at a preselected number of points, called *nodes*, in the element. The number and location of the nodes in an element depends on the geometry of the element and the degree of the polynomial, which in turn depends on the equation being solved. Since the solution is represented by polynomials on each element, a continuous approximation of the solution of the whole can only be obtained by imposing the continuity of the finite-element solution, and possibly its derivatives, at element interfaces (i.e., at the nodes common to two elements). The procedure of putting the elements together is called the *connectivity* or *assembly*.

Finite-Element Approximation Beyond the two features already described, the finite-element method is a variational method, like the Ritz, Galerkin, and weighted-residual methods, in which the approximate solution is sought in the form

$$u \approx U_N = \sum_{j=1}^N c_j \phi_j$$

where ϕ_j are preselected functions and c_j are parameters that are determined using a *variational statement* of the equation governing u . However, the finite element method typically entails the solution of a very large number of equations for the nodal values of the function being sought. The number of equations is equal to the number of unknown nodal values. In most practical problems the number of unknown nodal values are so large that it is practical only if the calculations are carried on an electronic computer.

12.2 One-Dimensional Problems

The finite-element analysis consists of dividing a domain into simple parts (i.e., elements) that are easier to work with. Over each element the method involves representing the solution in terms of its nodal values and the development of a relationship between the nodal values and their counterparts by means of a variational method. Assembly of these relations and solution of the equations after imposing known boundary and initial conditions completes the analysis.

Evaluation of an Integral Consider the evaluation of the integral

$$I = \int_a^b f(x) dx \tag{353}$$

where $f(x)$ is a complicated function whose integration by conventional methods (e.g., exact integration) is not possible. A step-by-step procedure of the numerical evaluation of the integral I by the finite-element method is given later.

Discretization of Domain. The area can be approximated by representing the interval (domain) $\Omega = (a, b)$ as a finite set of subintervals (see Fig. 152). A typical subinterval (element), $\Omega^e = (x_e, x_{e+1})$, is of length $h_e \equiv x_{e+1} - x_e$, with $x_1 = a$, and $x_{N+1} = b$, where N is the number of elements.

Approximation of Solution. Over each element, the function $f(x)$ is approximated using polynomials of a desired degree. The accuracy increases with increasing N and degree of the approximating polynomial. Over each element Ω^e , the function $f(x)$ can be approximated by a linear polynomial (see Fig. 153)

$$f(x) \approx F_e(x) = c_1^e + c_2^e x \tag{354}$$

where c_1^e and c_2^e are constants that can be determined in terms of the values of the function f at the endpoints, x_e and x_{e+1} , called the nodes. Let F_1^e and F_2^e denote the values of $F_e(x)$ at nodes 1 and 2 of element Ω^e :

$$F_1^e = F_e(x_e) \quad F_2^e = F_e(x_{e+1}) \tag{355}$$

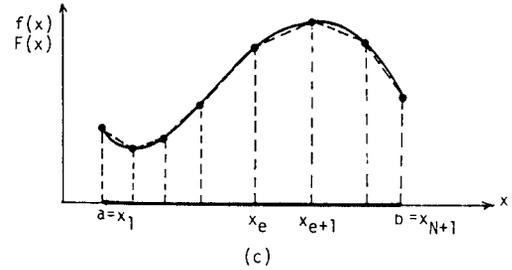

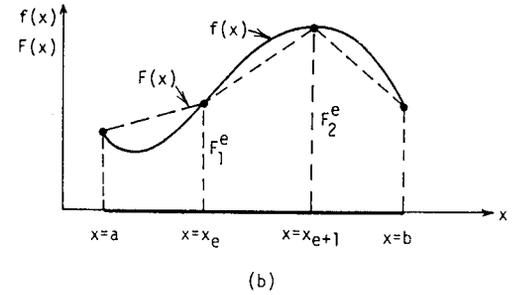

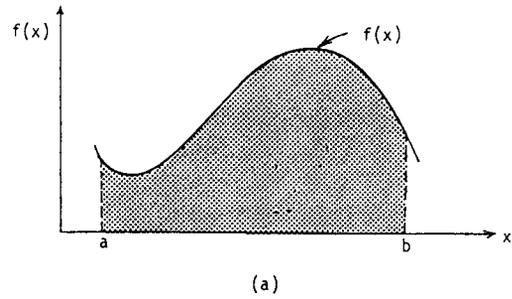

Fig. 152 Piecewise approximation of integral of function by polynomials.

Now $F_e(x)$ can be expressed in terms of its values at the nodes as

$$F_e(x) = \frac{x_{e+1} - x}{h_e} F_1^e + \frac{x - x_e}{h_e} F_2^e = \sum_{j=1}^2 F_j^e \psi_j^e \tag{356}$$

where ψ_j^e are called the *element interpolation functions* (see Fig. 153),

$$\psi_1^e = \frac{x_{e+1} - x}{h_e} \quad \psi_2^e = \frac{x - x_e}{h_e} \tag{357}$$

Let the approximation of the area I over a typical element Ω^e be denoted by I_e ,

$$I_e = \int_{x_e}^{x_{e+1}} F_e(x) dx \tag{358}$$

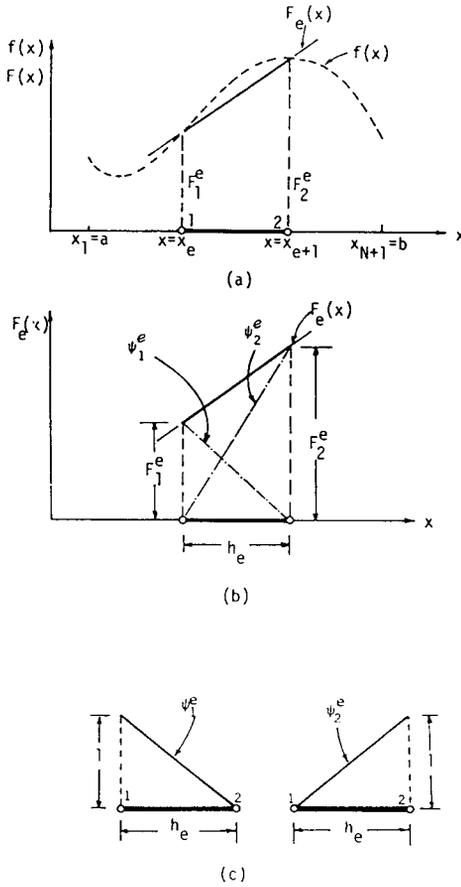

Fig. 153 Finite-element approximation of function $f(x)$ over typical element.

Substituting Eq. (356) into (358) and integrating, one obtains

$$\begin{aligned}
 I_e &= \sum_{j=1}^2 F_j^e \int_{x_e}^{x_{e+1}} \psi_j^e dx \\
 &= \frac{1}{h_e} \left\{ F_1^e \left[h_e x_{e+1} - \frac{h_e}{2} (x_{e+1} + x_e) \right] \right. \\
 &\quad \left. + F_2^e \left[\frac{h_e}{2} (x_{e+1} + x_e) - h_e x_e \right] \right\} \\
 &= \frac{h_e}{2} (F_1^e + F_2^e) \tag{359}
 \end{aligned}$$

Thus, the area under the function $F_e(x)$ over the element Ω^e is given by the area of the trapezoid of sides F_1^e and F_2^e and width h_e (see Fig. 153b).

Assembly of Equations. An approximation of the total area I is given by the sum of the areas I_e , $e = 1, 2, \dots, N$:

$$\begin{aligned}
 I &= \sum_{e=1}^N \int_{x_e}^{x_{e+1}} f(x) dx \\
 &\approx \sum_{e=1}^N \int_{x_e}^{x_{e+1}} F_e(x) dx \\
 &= \sum_{e=1}^N I_e = \sum_{e=1}^N \frac{h_e}{2} (F_1^e + F_2^e) \tag{360}
 \end{aligned}$$

Incidentally, Eq. (360) is known as the *trapezoidal rule*.

The accuracy of the approximation can be improved by increasing the number of elements N (see Fig. 152c) or by using higher order approximation of $f(x)$ over each element. Note that the accuracy can also be improved by using unequal intervals, with smaller elements in areas where function $f(x)$ varies rapidly.

The quadratic interpolation of $f(x)$ over Ω^e is given by

$$\begin{aligned}
 f(x) \approx F_e(x) &= F_1^e \psi_1^e + F_2^e \psi_2^e + F_3^e \psi_3^e \\
 &= \sum_{j=1}^3 F_j^e \psi_j^e \tag{361}
 \end{aligned}$$

where ψ_j^e are the quadratic interpolation functions

$$\begin{aligned}
 \psi_1^e &= \frac{(x - \xi_2)(x - \xi_3)}{(\xi_1 - \xi_2)(\xi_1 - \xi_3)} \\
 \psi_2^e &= \frac{(x - \xi_1)(x - \xi_3)}{(\xi_2 - \xi_1)(\xi_2 - \xi_3)} \\
 \psi_3^e &= \frac{(x - \xi_1)(x - \xi_2)}{(\xi_3 - \xi_1)(\xi_3 - \xi_2)} \tag{362}
 \end{aligned}$$

and ξ_1, ξ_2 , and ξ_3 are the coordinates of the three nodes in Ω^e . If nodes are equally spaced within each element (see Fig. 154), (ξ_1, ξ_2, ξ_3) take the values

$$\begin{aligned}
 \xi_1 &= x_{2e-1} & \xi_2 &= x_{2e} & \xi_3 &= x_{2e+1} \\
 & & & & & (e = 1, 2, \dots, N)
 \end{aligned}$$

Then Eqs. (362) become

$$\begin{aligned}
 \psi_1^e &= \left(\frac{2\bar{x}}{h_e} - 1 \right) \left(\frac{\bar{x}}{h_e} - 1 \right) & \psi_2^e &= -\frac{4\bar{x}}{h_e} \left(\frac{\bar{x}}{h_e} - 1 \right) \\
 \psi_3^e &= \frac{\bar{x}}{h_e} \left(\frac{2\bar{x}}{h_e} - 1 \right) \tag{363}
 \end{aligned}$$

where $\bar{x} = x - x_{2e-1}$ and h_e is the length of the element Ω^e .

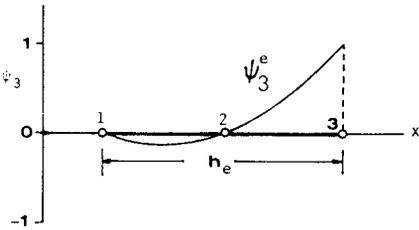

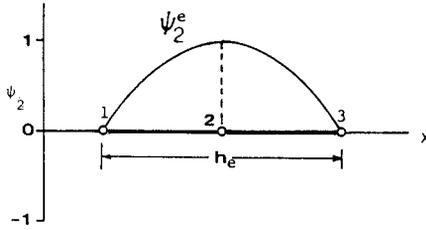

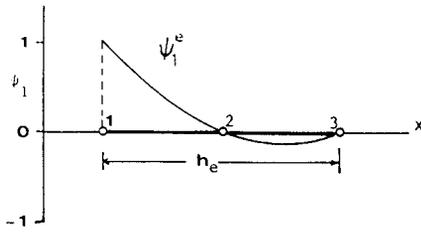

Fig. 154 One-dimensional quadratic interpolation functions.

In general, the interpolation functions ψ_j^e satisfy the properties

$$\psi_j^e(\xi_i) = \begin{cases} 0 & \text{if } i \neq j \\ 1 & \text{if } i = j \end{cases} \quad (364)$$

Substituting Eq. (361) into (358) and integrating, one obtains

$$\begin{aligned} I_e &= \sum_{j=1}^3 F_j^e \int_{x_{2e-1}}^{x_{2e+1}} \psi_j^e(x) dx \\ &= \sum_{j=1}^3 F_j^e \int_0^{h_e} \psi_j^e(\bar{x}) d\bar{x} \\ &= \frac{1}{6} h_e (F_1^e + 4F_2^e + F_3^e) \end{aligned}$$

The total area is given by

$$I \approx \sum_{e=1}^N I_e = \sum_{e=1}^N \frac{h_e}{6} (F_1^e + 4F_2^e + F_3^e)$$

This equation is known as the *one-third Simpson's rule*.

Example 92. Consider the integral of the function

$$f(x) = \sin(2 \cos x) \sin^2 x$$

over the domain $\Omega = (0, \pi/2)$. Table 12 contains the finite-element solutions obtained using linear and quadratic interpolation. It is clear that the accuracy improves as the number of elements or the degree of polynomial is increased.

Solution of a Differential Equation

Model Equation. Consider the differential equation

$$-\frac{d}{dx} \left[a(x) \frac{du}{dx} \right] - f(x) = 0 \quad 0 < x < L \quad (365)$$

which arises in connection with heat transfer in a heat exchanger fin, where $a(x) = kA$, k is the thermal conductivity, A is the cross-sectional area of the fin, $f(x)$ is the heat source, and $u = u(x)$ is temperature to be determined. Equation (365) also arises in many fields of engineering. In addition to Eq. (365), the function u is required to satisfy certain boundary conditions (i.e., conditions at points $x = 0$ and $x = L$). Equation (365), in general, has the following types of boundary conditions:

Specify either u or $(a du/dx)$ at a boundary point

Discretization. The domain $\Omega = (0, L)$ is represented as a collection of line elements, each element having at least two end nodes so that it can be connected to adjacent elements. A two-node element with one unknown per node requires, uniquely, a linear polynomial approximation of the variable over the element (see Fig. 155).

Approximation. Over a typical element $\Omega^e = (x_e, x_{e+1})$, the function $u(x)$ is approximated by $U_e(x)$, which is assumed to be of the form

$$U_e(x) = \sum_{j=1}^n U_j^e \psi_j^e(x) \quad (366)$$

where U_j^e denotes the value of $U_e(x)$ at the j th node and ψ_j^e are the linear [see Eq. (357)], quadratic [see Eq. (363)], or higher order interpolation functions. The values U_j^e are to be determined such that Eq. (365), with appropriate boundary conditions, is satisfied in integral sense.

Table 12 Finite-Element Solutions Using Linear and Quadratic Interpolation

Number of Elements	Linear Interpolation		Quadratic Interpolation		Exact
	\bar{I}	Error ^a (%)	\bar{I}	Error (%)	
2 (1) ^b	0.38790	23.6	0.51719	-1.8	0.50797
4 (2)	0.48149	5.2	0.51268	-0.9	0.50797
6 (3)	0.49640	2.3	0.50865	-0.1	0.50797

10 (5)	0.50384	0.8	0.50805	-0.02	0.50797

^a $(1 - \bar{I})/I(100)$.

^bNumbers in parentheses indicate number of equivalent quadratic elements.

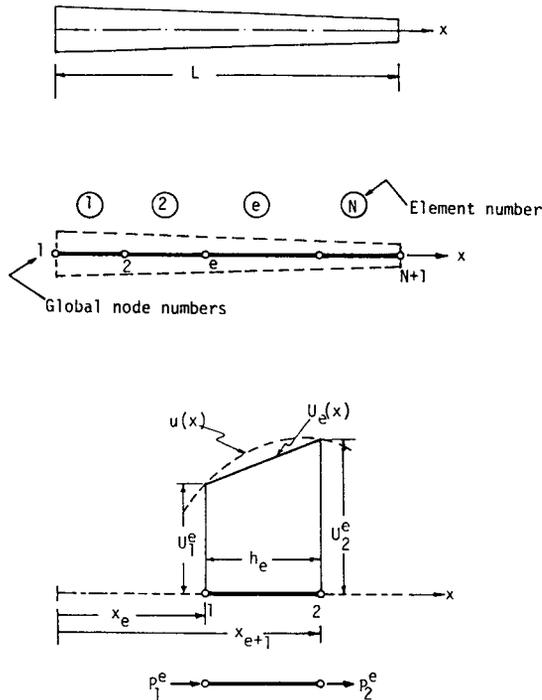

Fig. 155 One-dimensional domain, finite-element discretization, and finite-element approximation over an element.

Need for a Variational Statement. The difference between the numerical evaluation of an integral and the numerical solution of a differential equation is that in the case of a differential equation one is required to determine a function that satisfies a given differential equation and boundary conditions. It is possible to recast the differential equation as an integral statement, called a *variational statement*. The variational statement of Eq. (333), with the aid of a variational method of approximation, gives the same number of algebraic equations as the number of unknowns (n) in the approximation (334).

Variational Formulation. The variational statement of Eq. (333) over an element $\Omega^e = (x_e, x_{e+1})$ (see Fig. 155) is constructed as follows. Multiply Eq. (333) with an arbitrary but continuous function W and integrate over the domain of the element to obtain

$$0 = \int_{x_A}^{x_B} W \left[-\frac{d}{dx} \left(a \frac{dU}{dx} \right) - f \right] dx \quad (367)$$

The (Ritz) finite-element model uses a *weak form* that can be obtained from Eq. (367) by trading differentiation between the weight function W and the variable of approximation U equally:

$$0 = \int_{x_A}^{x_B} \left(a \frac{dW}{dx} \frac{dU}{dx} - Wf \right) dx - \left[W \left(a \frac{dU}{dx} \right) \right]_{x_A}^{x_B} \quad (368)$$

which is obtained by integrating the first term in Eq. (367) by parts. The term weak form is appropriate because the solution U of Eq. (368) requires weaker continuity conditions on ψ_i than U of Eq. (367). Also, the weak formulation allows the incorporation of the boundary conditions of the “flux type, dU/dx (the coefficient of the weight function W in the boundary term, called the *natural boundary condition*), into the variational statement (368). Boundary conditions on U in the same form as the weight function in the boundary terms are called the *essential boundary conditions*.

Identifying the coefficients of the weight function in the boundary terms (i.e., fluxes) as the *dual variables*,

$$\left(a \frac{dU}{dx} \right) \Big|_{x=x_e} = -P_1^e \quad \left(a \frac{dU}{dx} \right) \Big|_{x=x_{e+1}} = P_2^e$$

Eq. (368) can be written as

$$0 = \int_{x_e}^{x_{e+1}} \left(a \frac{dW}{dx} \frac{dU}{dx} - Wf \right) dx - W(x_e)P_1^e - W(x_{e+1})P_2^e \quad (369)$$

Equation (369) represents the variational statement of Eq. (365) for the (Ritz) finite-element model.

As a general rule, the essential boundary conditions of the variational form of a problem indicate what interelement continuity conditions are to be imposed on the function U and its derivatives. This in turn dictates the type and degree of approximation and hence the element type. For example, Eq. (369) indicates that U must be continuous in the interval (x_e, x_{e+1}) . A complete continuous polynomial in x is a linear polynomial

$$U_e(x) = c_1^e + c_2^e x$$

The constants c_1^e and c_2^e are expressed in terms of the values of U_e at nodes 1 and 2,

$$U_e = \sum_{j=1}^2 U_j^e \psi_j^e(x)$$

For the $(n-1)$ st-degree polynomial approximation, U_e is of the form

$$U_e(x) = \sum_{j=1}^n U_j^e \psi_j^e(x)$$

(Ritz) Finite-Element Model. In the Ritz model U_j^e Eq. (369) is satisfied for each $W = \psi_j^e$ ($i = 1, 2, \dots, n$). For each choice of W , an algebraic equation can be obtained:

$$\begin{aligned} 0 &= \int_{x_e}^{x_{e+1}} \left[a \frac{d\psi_i^e}{dx} \left(\sum_{j=1}^n U_j^e \frac{d\psi_j^e}{dx} \right) - \psi_1^e f \right] dx \\ &\quad - \psi_1^e(x_e) P_1^e - \psi_1^e(x_{e+1}) P_2^e \\ 0 &= \int_{x_e}^{x_{e+1}} \left[a \frac{d\psi_2^e}{dx} \left(\sum_{j=1}^n U_j^e \frac{d\psi_j^e}{dx} \right) - \psi_2^e f \right] dx \\ &\quad - \psi_2^e(x_e) P_1^e - \psi_2^e(x_{e+1}) P_2^e \\ &\quad \vdots \\ 0 &= \int_{x_e}^{x_{e+1}} \left[a \frac{d\psi_n^e}{dx} \left(\sum_{j=1}^n U_j^e \frac{d\psi_j^e}{dx} \right) - \psi_n^e f \right] dx \\ &\quad - \psi_n^e(x_e) P_1^e - \psi_n^e(x_{e+1}) P_2^e \end{aligned}$$

The i th equation can be written in compact form as

$$0 = \sum_{j=1}^n K_{ij}^e U_j^e - F_i^e \quad (370a)$$

where

$$K_{ij}^e = \int_{x_e}^{x_{e+1}} a \frac{d\psi_i^e}{dx} \frac{d\psi_j^e}{dx} dx$$

$$F_i^e = \int_{x_e}^{x_{e+1}} f \psi_i^e dx + \psi_i^e(x_e) P_1^e + \psi_i^e(x_{e+1}) P_2^e \quad (370b)$$

To be more specific let ψ_j^e be the linear interpolation functions of Eq. (357). Because of the interpolation property (364) of ψ_j^e , the F_i^e of Eq. (371) can be written as

$$F_i^e = \int_{x_e}^{x_{e+1}} f \psi_j^e dx + P_i^e \equiv f_i^e + P_i^e$$

For elementwise constant values of a and f , the element coefficient matrix $[K^e]$ and source vector $\{f^e\}$ become

$$[K^e] = \frac{ae}{he} \begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix} \quad \{f^e\} = \frac{hefe}{2} \begin{Bmatrix} 1 \\ 1 \end{Bmatrix}$$

Assembly of Elements. The element equations (370) must be put together to obtain the equations of the whole domain. Geometrically, the elements are connected together by noting that the second node of element Ω^e is the same as the first node of element Ω^{e+1} . Since the solution and hence its approximation are single valued throughout the domain, the geometric continuity also implies the continuity of the approximate solution (see Fig. 156):

$$U_2^e = U_1^{e+1} \quad e = 1, 2, \dots, N$$

In addition to the continuity of U_e , the balance of the dual variables P_i at interelement nodes is also enforced:

$$P_2^e + P_1^{e+1} = 0 \quad e = 1, 2, \dots, N$$

Note that this *does not* guarantee the continuity of $a dU_e/dx$ at interelement nodes.

The finite-element approximation on the entire domain $\Omega = \sum_{e=1}^N \Omega^e$ is given by

$$U = \sum_{e=1}^N U_e = \sum_{e=1}^N \sum_{j=1}^2 U_j^e \psi_j^e(x)$$

In view of the continuity conditions and the elementwise definition of the interpolation functions ψ_j^e , the finite-element approximation can be written as

$$U = \sum_{J=1}^{N+1} U_J \Phi_J(x) \quad (371)$$

where U_J denotes the value of $U(x)$ at the J th (global) node of the mesh and Φ_J are the *global interpolation*

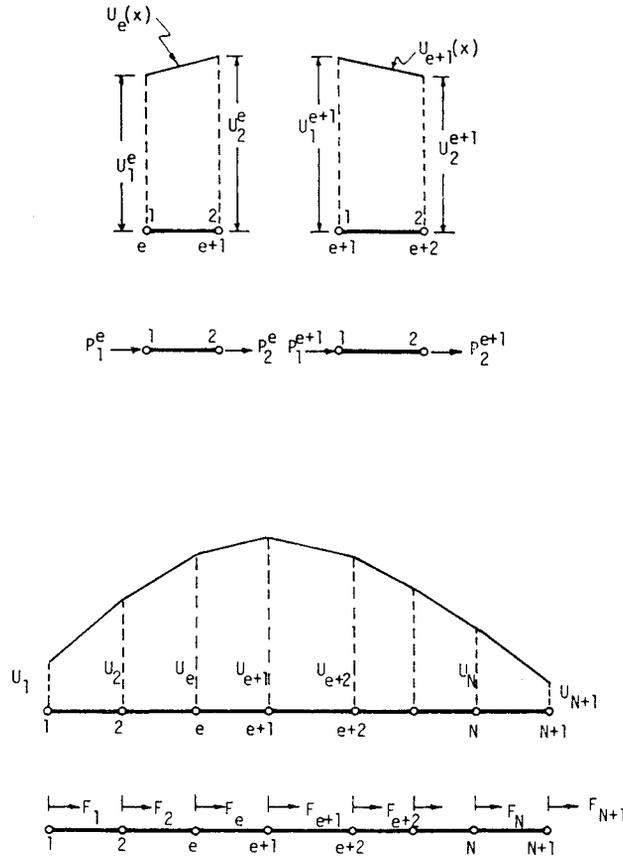

Fig. 156 Assembly of finite elements using continuity of finite-element approximation between elements.

functions, related to the local (or element) interpolation functions by

$$\begin{aligned} \Phi_1 &= \psi_1^1 & 0 = x_1 \leq x \leq x_2 \\ \Phi_J &= \begin{cases} \psi_2^{J-1} & x_{J-1} \leq x \leq x_J \\ \psi_1^J & x_J \leq x \leq x_{J+1} \end{cases} \\ & & (J = 2, 3, \dots, N) \end{aligned}$$

$$\Phi_{N+1} = \psi_2^N \quad x_N \leq x \leq x_{N+1} = L$$

Note that Φ_J are continuous and define only on the two elements connected at the global node J .

Analogous to the variational form (369) for an element Ω^e , a variational form for the entire domain can be derived as

$$0 = \int_0^L \left(a \frac{dW}{dx} \frac{dU}{dx} - Wf \right) dx - \left[W \left(a \frac{dU}{dx} \right) \right]_{x=0}^{x=L} \quad (372)$$

Substitution of Eq. (371) for U and $W = \Phi_I (I = 1, 2, \dots, N + 1)$ into Eq. (372) gives

$$\begin{aligned} 0 &= \int_0^L \left[a \frac{d\Phi_I}{dx} \left(\sum_{j=1}^{N+1} U_j \frac{d\Phi_j}{dx} \right) \right. \\ &\quad \left. - \Phi_I f \right] dx - \left[\Phi_I \sum_{e=1}^N a \frac{dU_e}{dx} \right]_{x=0}^{x=L} \end{aligned}$$

Since each Φ_I is define on two neighboring elements, this equation becomes

$$\begin{aligned} 0 &= \int_{x_{I-1}}^{x_I} \left[a \frac{d\psi_2^{I-1}}{dx} \left(U_{I-1} \frac{d\psi_1^{I-1}}{dx} + U_I \frac{d\psi_2^{I-1}}{dx} \right) \right. \\ &\quad \left. - \psi_2^{I-1} f \right] dx - \psi_2^{I-1}(L) P_2^{I-1} \end{aligned}$$

$$\begin{aligned}
& + \int_{x_I}^{x_{I+1}} \left[a \frac{d\psi_I^I}{dx} \left(U_I \frac{d\psi_I^I}{dx} + U_{I+1} \frac{d\psi_I^I}{dx} \right) \right. \\
& \left. - \psi_I^I f \right] dx - \psi_I^I(a) P_1^I \\
& = K_{21}^{I-1} U_{I-1} + (K_{22}^{I-1} + K_{11}^I) U_I + K_{12}^I U_{I+1} \\
& \quad - (f_2^{I-1} + f_1^I) - \psi_2^{I-1}(L) P_2^{I-1} - \psi_1^I(0) P_1^I \quad (373)
\end{aligned}$$

Thus, the equations of the connected elements (i.e., the finite-element equations of the entire domain) are given by setting $I = 1, 2, \dots, N + 1$ in Eq. (373) (set $K_{IJ}^0 = F_I^0 = P_I^0 = 0$):

$$\begin{aligned}
K_{11}^1 U_1 + K_{12}^1 U_2 &= f_1^1 + P_1^1 \\
K_{21}^1 U_1 + (K_{22}^1 + K_{11}^2) U_2 + K_{12}^2 U_3 &= f_2^1 + f_1^2 + \cancel{(P_2^1 + P_1^2)} \rightarrow 0 \\
K_{21}^2 U_2 + (K_{22}^2 + K_{11}^3) U_3 + K_{12}^3 U_4 &= f_2^2 + f_1^3 + \cancel{(P_2^2 + P_1^3)} \rightarrow 0 \\
&\vdots \\
K_{21}^N U_N + K_{22}^N U_{N+1} &= f_2^N + P_2^N
\end{aligned}$$

or, in matrix form,

$$\begin{bmatrix}
K_{11}^1 & K_{12}^1 & 0 & 0 & 0 \\
K_{21}^1 & K_{22}^1 + K_{11}^2 & K_{12}^2 & 0 & 0 \\
0 & K_{21}^2 & K_{22}^2 + K_{11}^3 & K_{12}^3 & 0 \\
\vdots & \vdots & \vdots & \vdots & \vdots \\
0 & 0 & 0 & K_{21}^N & K_{22}^N
\end{bmatrix}
\times \begin{Bmatrix} U_1 \\ U_2 \\ U_3 \\ \vdots \\ U_{N+1} \end{Bmatrix}
= \begin{Bmatrix} f_1^1 + P_1^1 \\ f_2^1 + f_1^2 \\ f_2^2 + f_1^3 \\ \vdots \\ f_2^N + P_2^N \end{Bmatrix} \quad (374)$$

One does not repeat the connectivity procedure described in Eqs. (371)–(374) for every problem but uses the pattern implied in the final equations (374) for all problems described by Eq. (365).

Example 93. Heat conduction in a long radially symmetric coaxial cylindrical cable can be described by

$$-\frac{d}{dr} \left[a(r) \frac{du}{dr} \right] = 0 \quad (375)$$

where u denotes the temperature and $a = 2\pi r k$, k being the thermal conductivity of the medium.

Equation (375) is in the same form as Eq. (365). Therefore, Eqs. (370) and (374) describe the element and global finite-element models of Eq. (375). For the choice of linear interpolation functions, we have

$$K_{ij}^e = \int_{r_e}^{r_{e+1}} 2\pi k_e r \frac{d\psi_i^e}{dr} \frac{d\psi_j^e}{dr} dr$$

where

$$\begin{aligned}
\psi_i^e &= \frac{r_{e+1} - r}{r_{e+1} - r_e} & \psi_2^e &= \frac{r - r_e}{r_{e+1} - r_e} \\
h_e &= r_{e+1} - r_e
\end{aligned}$$

For example, K_{11}^e is given by

$$\begin{aligned}
K_{11}^e &= 2\pi k_e \int_{r_e}^{r_{e+1}} r \left(-\frac{1}{h_e} \right)^2 dr \\
&= \frac{\pi k_e}{h_e} (r_{e+1} + r_e)
\end{aligned}$$

We have

$$\frac{\pi k_e}{h_e} (r_{e+1} + r_e) \begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix} \begin{Bmatrix} u_1^e \\ u_2^e \end{Bmatrix} = \begin{Bmatrix} P_1^e \\ P_2^e \end{Bmatrix}$$

where P_i^e denote the internal heats,

$$\begin{aligned}
P_1^e &= -2\pi k_e \left(r \frac{dU}{dr} \right) \Big|_{r=r_e} \\
P_2^e &= 2\pi k_e \left(r \frac{dU}{dr} \right) \Big|_{r=r_{e+1}}
\end{aligned}$$

The assembled equations for an N -element case are shown in the tabulation at the top of page 277.

We now impose the boundary conditions of the problem. Suppose that the domain is the cross section of a coaxial cylinder with two materials (i.e., with different thermal conductivities), as shown in Fig. 157. Let the internal and external radii be $r_1 = 20$ mm and $r_{N+1} = 50$ mm and let the thickness of the first material be 11.6 mm and that of the second material be 18.4 mm and the associated material constants (k) be 5 and 1. We assume the boundary conditions to be $u(20) = 100^\circ\text{C}$ and $u(50) = 0.0$. These conditions translate to

$$\begin{aligned}
U_1 &= 100.0 & U_{N+1} &= 0.0 \\
P_2^1 + P_1^2 &= 0, \dots & P_2^{N-1} + P_1^N &= 0
\end{aligned}$$

For a nonuniform mesh of four elements ($h_1 = 5.1, h_2 = 6.5, h_3 = 8.2, h_4 = 10.2$; equivalently, $r_1 = 20, r_2 = 25.1, r_3 = 31.6, r_4 = 39.8$, and $r_5 = 50.0$),

Table 13 Finite-Element Solutions Obtained by Various Nonuniform Meshes

r	Two Elements	Four Elements	Eight Elements	Analytical Solution

44.9	—	—	19.551	19.549
50.0	0.000	0.000	0.000	0.000

Equation (376) arises in the study of a number of engineering problems, including heat transfer, irrotational flow of a fluid, transverse deflection of a membrane, and torsion of a cylindrical member. Also, the Stokes flow and plane elasticity problems are described by a pair of equations of the same form as the model equation. Thus, the finite-element procedure to be described for Eq. (376) is applicable to *any* problem that can be formulated as one of solving equations of the form of (376).

While the basic ideas are the same as described before, the mathematical complexity for two-dimensional problems increases because of the partial differential equations on two-dimensional domains with possibly curved boundaries. It is necessary to approximate not only the solution of a partial differential equation but also the domain by a suitable finite-element mesh. This latter property is what made the finite-element method a more attractive practical analysis tool over other competing methods.

Discretization of a Domain Two-dimensional domains can be represented by more than one type of geometric shape. For example, a plane curved domain can be represented by triangular elements or rectangular elements. Without reference to a specific geometric shape, we simply denote a typical element by Ω^e and proceed to discuss the approximation of Eq. (376).

The choice of the finite-element mesh depends both on the element characteristics (convergence, computational simplicity, etc.) and the ability to represent the domain accurately. The concept of so-called *isoparametric formulations* allows the representation of the element geometry by the same interpolation as that used in the approximation of the dependent variables. Thus, by identifying nodes on the boundary of the domain, one can approximate the domain by suitable collection of elements to a desired accuracy.

Element Equations

Variational Formulation. Consider a typical finite element Ω^e from the finite-element mesh of the domain Ω (see Fig. 158). Let ψ_i^e ($i = 1, 2, \dots, n$) denote the interpolation functions used to approximate u on Ω^e . Multiply Eq. (376) with a weight function W , integrate

over the element domain Ω^e , and use the Green–Gauss theorem to trade differentiation to W to obtain the weak variational form

$$0 = \int_{\Omega^e} \left[\frac{\partial W}{\partial x} \left(a_{11}^e \frac{\partial U}{\partial x} \right) + \frac{\partial W}{\partial y} \left(a_{22}^e \frac{\partial U}{\partial y} \right) + a_{00}^e W U - W f_e \right] dx dy - \int_{\Gamma^e} W \left[n_x \left(a_{11}^e \frac{\partial U}{\partial x} \right) + n_y \left(a_{22}^e \frac{\partial U}{\partial y} \right) \right] ds \quad (377)$$

where n_x and n_y are the components (i.e., direction cosines) of the unit normal \hat{n} ,

$$\hat{n} = n_x \hat{i} + n_y \hat{j} = \cos \alpha \hat{i} + \sin \alpha \hat{j}$$

on the boundary Γ^e and ds is the elemental arc length along the boundary of the element. From an inspection of the boundary term in Eq. (377), it follows that the specification of the coefficient of W ,

$$q_n^e \equiv n_x \left(a_{11}^e \frac{\partial U}{\partial x} \right) + n_y \left(a_{22}^e \frac{\partial U}{\partial y} \right) \quad (378)$$

constitutes the natural boundary condition. The variable q_n is of physical interest in most problems. For example, in the case of the heat transfer through an anisotropic medium (where a_{ij} denotes the conductivities of the medium), q_n denotes the heat flux across the boundary of the element (see Fig. 158). The variable U is called the *primary variable* and q_n (heat flux) is termed the *secondary variable*.

The variational form in Eq. (377) now becomes

$$0 = \int_{\Omega^e} \left[\frac{\partial W}{\partial x} \left(a_{11}^e \frac{\partial U}{\partial x} \right) + \frac{\partial W}{\partial y} \left(a_{22}^e \frac{\partial U}{\partial y} \right) + a_{00}^e W U - W f_e \right] dx dy - \int_{\Gamma^e} W q_n^e ds \quad (379)$$

This variational equation forms the basis of the Ritz finite-element model. The boundary term indicates that W should be continuous at interelement boundaries.

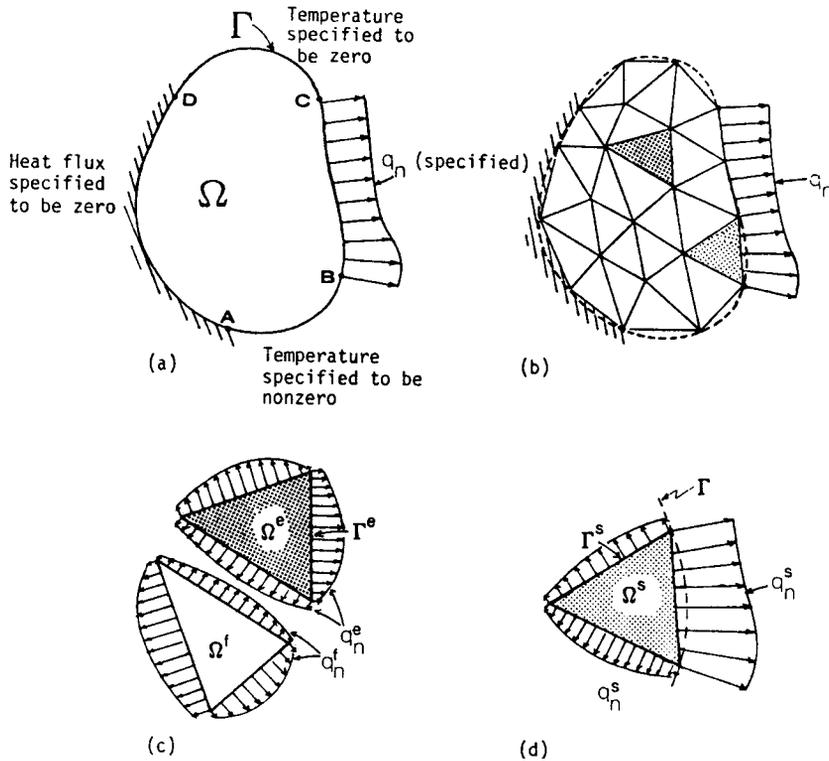

Fig. 158 Finite-element representation of two-dimensional domain with various types of boundary conditions.

Finite-Element Formulation. The variational form in (379) indicates that the approximation chosen for u should be at least bilinear in x and y so that $\partial u/\partial x$ and $\partial u/\partial y$ are nonzero and the interelement continuity of u can be imposed. Suppose that the temperature is approximated by the expression

$$u \approx U_e = \sum_{j=1}^n U_j^e \psi_j^e \quad (380)$$

where U_j^e are the values of U_e at the point (x_j, y_j) in Ω^e and ψ_j^e are the interpolation functions with the property

$$\psi_i^e(x_j, y_j) = \delta_{ij}$$

The specific form of ψ_i^e will be derived later for linear triangular and rectangular elements.

Substituting Eq. (380) for U_e and ψ_j^e for W into the variational form (379), the i th algebraic equation of the model is obtained,

$$\sum_{j=1}^n K_{ij}^e U_j^e = F_i^e \quad (i = 1, 2, \dots, n) \quad (381)$$

where

$$K_{ij}^e = \int_{\Omega^e} \left[\frac{\partial \psi_i^e}{\partial x} \left(a_{11}^e \frac{\partial \psi_j^e}{\partial x} \right) + \frac{\partial \psi_i^e}{\partial y} \left(a_{22}^e \frac{\partial \psi_j^e}{\partial y} \right) + a_0^e \psi_i^e \psi_j^e \right] dx dy$$

$$F_i^e = \int_{\Omega^e} f_e \psi_i^e dx dy + \int_{\Gamma^e} q_n^e \psi_i^e ds \equiv f_i^e + P_i^e \quad (382)$$

Note that $K_{ij}^e = K_{ji}^e$ (i.e., $[K^e]$ is symmetric). Equation (381) is called the finite-element model of Eq. (376).

Assembly of Elements The assembly of finite element equations is based on the same principle as that employed in one-dimensional problems. We illustrate the procedure by considering a finite-element mesh consisting of two triangular elements (see Fig. 159). Let K_{ij}^e and K_{ij}^f ($i, j = 1, 2, 3$) denote the coefficient matrices and $\{F^e\}$ and $\{F^f\}$ denote the column vectors of three-node triangular elements Ω^e and Ω^f . From the finite-element mesh shown in Fig. 159, the following correspondence between the global and

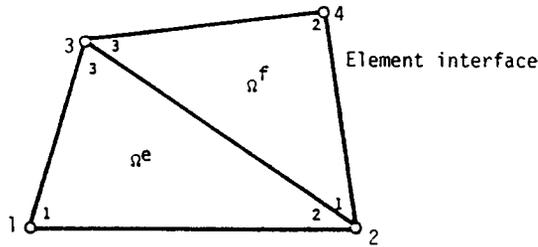

Fig. 159 Assembly (or connectivity) of linear triangular elements.

element nodal values of the temperature is noted:

$$\begin{aligned} U_1 &= U_1^e & U_2 &= U_2^e = U_1^f \\ U_3 &= U_3^e = U_e^f & U_4 &= U_2^f \end{aligned}$$

The continuity of U at the interelement nodes guarantees its continuity along the *entire* interelement boundary. To see this, consider two linear triangular elements (see Fig. 159). The finite-element solution for U is linear along the boundaries of the elements. The interelement boundary is along the line connecting global nodes 2 and 3. Since U_e is linear along side 2–3 of element Ω^e , it is uniquely determined by the two values U_2^e and U_3^e . Similarly, U_f is uniquely determined along side 1–3 of element Ω^f by the two values U_1^f and U_3^f . Since $U_2^e = U_1^f$ and $U_3^e = U_3^f$, it follows that $U_e = U_f$ along the interface. Similar arguments can be presented for higher order elements.

The coefficient K_{ij}^e is a representation of a physical property of node i with respect to node j of element Ω^e . The assembled coefficient matrix also represents the same property among the global nodes. But the global property comes from the element nodes shared by the global nodes. For example, the coefficient K_{23} of the global coefficient matrix is the sum of the contributions from nodes 2 and 3 of Ω^e and nodes 1 and 3 of Ω^f (see Fig. 159):

$$K_{23} = K_{23}^e + K_{13}^f \quad K_{32} = K_{32}^e + K_{31}^f$$

Similarly,

$$K_{22} = K_{22}^e + K_{11}^f \quad K_{33} = K_{33}^e + K_{33}^f, \dots$$

If the global nodes I and J do not correspond to nodes in the same element, then $K_{IJ} = 0$. For example, K_{14} is zero because global nodes 1 and 4 do not belong to the same element. The column vectors can be assembled using the same logic:

$$F_2 = F_2^e + F_1^f \quad F_3 = F_3^e + F_3^f, \dots$$

The complete assembled equations for the two-element mesh is given by

$$\begin{bmatrix} K_{11}^e & K_{12}^e & K_{13}^e & 0 \\ K_{21}^e & K_{22}^e + K_{11}^f & K_{23}^e + K_{13}^f & K_{12}^f \\ K_{31}^e & K_{32}^e + K_{31}^f & K_{33}^e + K_{33}^f & K_{32}^f \\ 0 & K_{21}^f & K_{23}^f & K_{32}^f \end{bmatrix} \begin{Bmatrix} U_1 \\ U_2 \\ U_3 \\ U_4 \end{Bmatrix} = \begin{Bmatrix} F_1^e \\ F_2^e + F_1^f \\ F_3^e + F_3^f \\ F_2^f \end{Bmatrix}$$

Imposition of Boundary Conditions The boundary conditions on the primary variables (temperatures) and secondary variables (heats) are imposed on the assembled equations in the same way as in the one-dimensional problems. To understand the physical significance of the P 's [see Eq. (382)], take a closer look at the definition

$$P_i^e \equiv \int_{\Gamma^e} q_n^e \psi_i^e(s) ds \quad (383)$$

where $\psi_i^e(s)$ is the value of $\psi_i^e(x, y)$ on the boundary Γ^e . The heat flu q_n^e [see Eq. (378)] is an unknown when Ω^e is an interior element of the mesh (see Fig. 158a). However, when the element equations are assembled, the contribution of the heat flu q_n^e to the nodes (namely, P_i^e) of Ω^e get canceled by similar contributions from the adjoining elements (see Fig. 158b). If the element Ω^r has any of its sides on the boundary Γ of the domain Ω (see Fig. 158c), then on that side the heat flu q_n^r is either specified or unspecified. If q_n^r is specified then the heat P_i^r at the nodes on that side can be computed using Eq. (383). If q_n^r is not specified then the primary variable U_r is known on that portion of the boundary.

The remaining steps of the analysis do not differ from those of one-dimensional problems.

Interpolation Functions

Linear Triangular Element. The simplest finite element in two dimensions is the triangular element. Since a triangle is defined uniquely by three points that form its vertices, the vertex points are chosen as the nodes (see Fig. 160a). These nodes will be connected to the nodes of adjoining elements in a finite-element mesh.

A polynomial in x and y that is uniquely defined by three constants is of the form $p(x, y) = c_0 + c_1x + c_2y$. Hence, assume approximation of u_e in the form

$$U_e = c_0^e + c_1^e x + c_2^e y \quad (384)$$

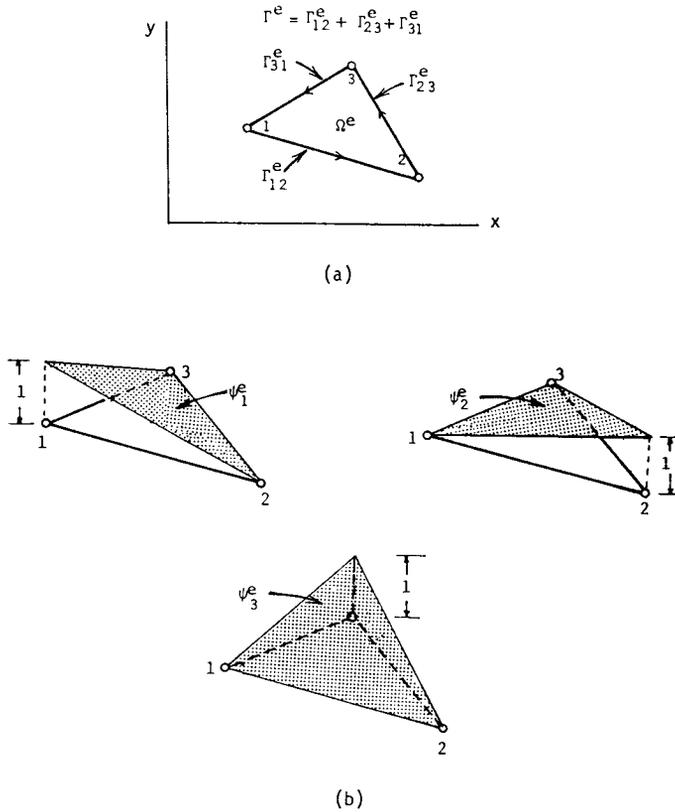

Fig. 160 Typical linear triangular element and associated finite-element interpolations function.

Proceeding as in the case of one-dimensional elements, write

$$U_i^e \equiv U_e(x_i, y_i) = c_0^e + c_1^e x_i + c_2^e y_i \quad i = 1, 2, 3$$

where (x_i, y_i) denote the global coordinates of the element node i in Ω^e . In explicit form this equation becomes

$$\begin{Bmatrix} U_1^e \\ U_2^e \\ U_3^e \end{Bmatrix} = \begin{bmatrix} 1 & x_1 & y_1 \\ 1 & x_2 & y_2 \\ 1 & x_3 & y_3 \end{bmatrix} \begin{Bmatrix} c_0^e \\ c_1^e \\ c_2^e \end{Bmatrix}$$

Note that the element nodes are numbered counter-clockwise. Upon solving for c 's and substituting back into Eq. (384), one obtains

$$U_e = \sum_{i=1}^3 U_i^e \psi_i^e(x, y)$$

$$\psi_i^e = \frac{1}{2A_e} (\alpha_i^e + \beta_i^e x + \gamma_i^e y)$$

where A_e represents the area of the triangle, and

$$\alpha_i^e = x_j y_k - x_k y_j \quad \beta_i^e = y_j - y_k \quad \gamma_i^e = x_k - x_j$$

$$i \neq j \neq k \quad i, j, k = 1, 2, 3$$

and the indices on α_i^e , β_i^e , and γ_i^e permute in a natural order. For example, α_1^e is given by setting $i = 1$, $j = 2$, and $k = 3$:

$$\alpha_1^e = x_2 y_3 - x_3 y_2$$

The sign of the determinant changes if the node numbering is changed to clockwise. The interpolation functions ψ_i^e satisfy the interpolation properties listed in Eq. (364). The shape of these functions is shown in Fig. 160b.

Note that the derivative of ψ_i^e with respect to x or y is a constant. Hence, the derivatives of the solution evaluated in the postcomputation would be elementwise constant. Also, the coefficient matrix

$$K_{ij}^e = \int_{\Omega^e} \left(a_{11}^e \frac{\partial \psi_i^e}{\partial x} \frac{\partial \psi_j^e}{\partial x} + a_{22}^e \frac{\partial \psi_i^e}{\partial y} \frac{\partial \psi_j^e}{\partial y} \right) dx dy \quad (385)$$

can be easily evaluated for the linear interpolation functions for a triangle. We have

$$\frac{\partial \psi_i^e}{\partial x} = \frac{\beta_i^e}{2A_e} \quad \frac{\partial \psi_i^e}{\partial y} = \frac{\gamma_i^e}{2A_e}$$

and, for elementwise constant values of a_{11}^e and a_{22}^e , the coefficients of K_{ij}^e become

$$K_{ij}^e = \frac{1}{4A_e^2} (a_{11}^e \beta_i^e \beta_j^e + a_{22}^e \gamma_i^e \gamma_j^e) \left(\int_{\Omega^e} dx dy \right) \\ = \frac{1}{4A_e} (a_{11}^e \beta_i^e \beta_j^e + a_{22}^e \gamma_i^e \gamma_j^e)$$

Linear Rectangular Element. A rectangular element is uniquely defined by the four corner points (see Fig. 161). Therefore, the four-term polynomial can be used to derive the interpolation functions. Express u_e in the form

$$u_e = c_0^e + c_1^e x + c_2^e y + c_3^e xy \quad (386)$$

and obtain

$$\begin{Bmatrix} U_1^e \\ U_2^e \\ U_3^e \\ U_4^e \end{Bmatrix} = \begin{bmatrix} 1 & x_1 & y_1 & x_1 y_1 \\ 1 & x_2 & y_2 & x_2 y_2 \\ 1 & x_3 & y_3 & x_3 y_3 \\ 1 & x_4 & y_4 & x_4 y_4 \end{bmatrix} \begin{Bmatrix} c_0^e \\ c_1^e \\ c_2^e \\ c_3^e \end{Bmatrix}$$

By inverting the equations for c 's and substituting into Eq. (386), one obtains

$$\psi_1^e = \left(1 - \frac{\xi}{a}\right) \left(1 - \frac{\eta}{b}\right) \quad \psi_2^e = \frac{\xi}{a} \left(1 - \frac{\eta}{b}\right) \\ \psi_3^e = \frac{\xi}{a} \frac{\eta}{b} \quad \psi_4^e = \left(1 - \frac{\xi}{a}\right) \frac{\eta}{b}$$

where (ξ, η) are the element coordinates,

$$\xi = x - x_1 \quad \eta = y - y_1$$

The functions are geometrically represented in Fig. 161. In calculating element matrices, one finds that the use

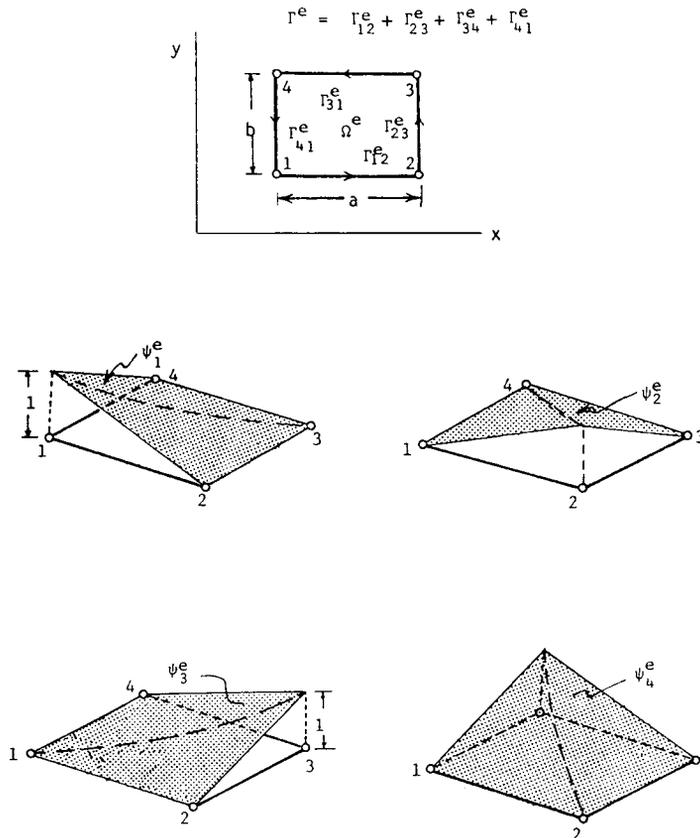

Fig. 161 Typical linear rectangular element and associated finite-element interpolation functions.

of the local coordinate system (ξ, η) is more convenient than using the global coordinates (x, y) .

For the linear rectangular element, the derivatives of the shape functions are not constant within the element:

$$\frac{\partial \psi_i^e}{\partial x} = \text{linear in } y \quad \frac{\partial \psi_i^e}{\partial y} = \text{linear in } x$$

The integration of polynomial expressions over a rectangular element is made simple by the fact that $\Omega^e = (0, a) \times (0, b)$:

$$\int_{\Omega^e} f(x, y) dx dy = \int_b^a \int_0^b f(x, y) dx dy$$

The coefficients in Eq. (385) can be easily evaluated over a linear rectangular element for elementwise constant values of a_{11}^e and a_{22}^e :

$$[K^e] = \frac{b}{6a} \begin{bmatrix} 2 & -2 & -1 & 1 \\ -2 & 2 & 1 & -1 \\ -1 & 1 & 2 & -2 \\ 1 & -1 & -2 & 2 \end{bmatrix}$$

$$+ \frac{a}{6b} \begin{bmatrix} 2 & 1 & -1 & -2 \\ 1 & 2 & -2 & -1 \\ -1 & -2 & 2 & 1 \\ -2 & -1 & 1 & 2 \end{bmatrix}$$

Example 94. Consider a computational example of Eq. (376) for the case where $a_{11} = a_{22} = 1$, $f = 0$, and Ω is a unit square. Let the boundary conditions be as follows (see Fig. 162a):

$$u(0, y) = u(1, y) = 0 \quad u(x, 0) = 0$$

$$\frac{\partial u}{\partial y}(x, 1) = x$$

The finite-element model is given by Eq. (381), with

$$K_{ij}^e = \int_{\Omega^e} \left(\frac{\partial \psi_i^e}{\partial x} \frac{\partial \psi_j^e}{\partial x} + \frac{\partial \psi_i^e}{\partial y} \frac{\partial \psi_j^e}{\partial y} \right) dx dy \quad f_i^e = 0$$

Triangular Elements. The 2×2 mesh of triangular elements is shown in Fig. 162b. The element

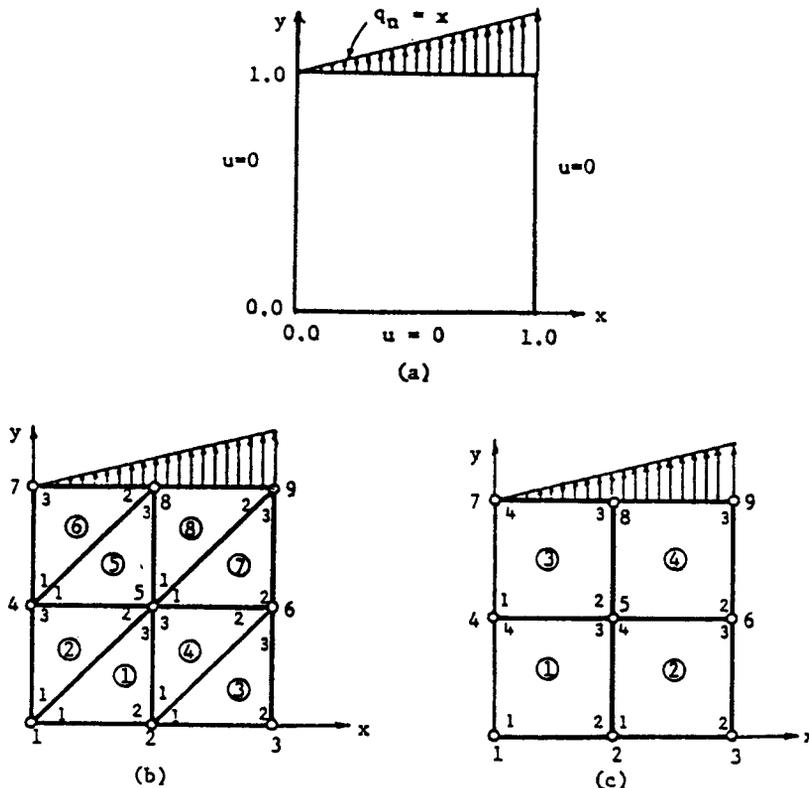

Fig. 162 Domain, boundary conditions, and finite-element meshes.

coefficient matrices are given by

$$[K^1] = [K^3] = [K^5] = [K^7] = \frac{1}{2} \begin{bmatrix} 1 & -1 & 0 \\ -1 & 2 & -1 \\ 0 & -1 & 1 \end{bmatrix}$$

$$[K^2] = [K^4] = [K^6] = [K^8] = \frac{1}{2} \begin{bmatrix} 1 & 0 & -1 \\ 0 & 1 & -1 \\ -1 & -1 & 2 \end{bmatrix}$$

The assembled equations are given by (refer to Fig. 162b) the tabulation below where \times denotes a zero due to disconnectivity (e.g., $K_{13} = 0$ because global nodes 1 and 3 do not belong to the same element).

The boundary conditions on the primary variables (i.e., U 's) are

$$U_1 = U_2 = U_3 = U_4 = U_6 = U_7 = U_9 = 0$$

The known secondary variables are (correspond to nodes 5 and 8)

$$P_3^1 + P_2^2 + P_3^4 + P_2^5 + P_1^7 + P_1^8 = 0$$

(because no flux is specified at node 5)

$$P_3^5 + P_2^6 + P_3^8 = \int_0^{0.5} q\psi_2^6(x, 1) dx + \int_{0.5}^{1.0} q\psi_3^8(x, 1) dx \quad (387)$$

Note that the individual fluxes P_i^e in Eqs. (387) are not zero, but their sum is equal to the values indicated. For example, consider P_2^6 :

$$P_2^6 = \int_{S_6} q\psi_2^6 ds = \int_{0.5}^{1.0} q\psi_2^6(y - 0.5, y) \left(\frac{1}{\sqrt{2}} dy\right) + \int_0^{0.5} q\psi_2^6(x, 1)(-dx) + \int_{1.0}^{0.5} q\psi_2^6(0, y)(-dy)$$

where $\psi_2^6(x, y) = 2x$. The first integral is nonzero but gets canceled by a similar but negative contribution from P_3^5 , the second integral is nonzero and can be evaluated since $q = x$ is known, and the third integral is zero because $\psi_2^6(0, y) = 0$.

Evaluating the integral in Eq. (387) [with $\psi_2^6(x, y) = 2x$ and $\psi_3^8 = 2(y - x)$], we obtain

$$P_3^5 + P_2^6 + P_3^8 = \int_0^{0.5} x2x dx + \int_{0.5}^{1.0} 2x(1 - x) dx = \frac{2}{3}(0.5)^3 + (1)^2 - (0.5)^2 - \frac{2}{3}[(1)^3 - (0.5)^3] = \frac{1}{12} + \frac{1}{6} = \frac{1}{4}$$

Tabulation for Triangular Elements

	1	2	3	4	5	6	7	8	9

								1 + 1	

$$\times \begin{bmatrix} U_1 \\ U_2 \\ U_3 \\ U_4 \\ U_5 \\ U_6 \\ U_7 \\ U_8 \\ U_9 \end{bmatrix} = \begin{bmatrix} P_1^1 + P_1^2 \\ P_2^1 + P_1^3 + P_1^4 \\ P_2^3 \\ P_3^2 + P_1^5 + P_1^6 \\ (P_3^1 + P_2^2 + P_3^4 + P_2^5 + P_1^7 + P_1^8) \\ P_3^3 + P_2^4 + P_2^7 \\ P_3^6 \\ P_3^5 + P_2^6 + P_3^8 \\ P_3^7 + P_2^8 \end{bmatrix} \begin{matrix} 1 \\ 2 \\ 3 \\ 4 \\ 5 \\ 6 \\ 7 \\ 8 \\ 9 \end{matrix}$$

To solve for the unknowns U_5 and U_8 , equations (5) and (8) of the assembled equations are used. This choice is dictated by the fact that the remaining equations contain additional unknowns in P 's. The solution is given by

$$U_5 = \frac{1}{28} \quad U_8 = \frac{2}{14}$$

The internal heat P_i^e can be determined from either the element equations (381) or by definition (383). In general, the values computed by the two methods are not the same because P_i^e determined from the element equations is the internal heat in equilibrium with the heat from the neighboring elements, whereas P_i^e computed from the gradient of the approximate temperature field is not.

Rectangular Elements. For the 2×2 mesh of rectangular elements shown in Fig. 162c, the element matrices are given by

$$[K^-] = [K^2] = \frac{1}{6} \begin{bmatrix} 4 & -1 & -2 & -1 \\ -1 & 4 & -1 & -2 \\ -2 & -1 & 4 & -1 \\ -1 & -2 & -1 & 4 \end{bmatrix}$$

The assembled equations are shown in the tabulation below.

The boundary conditions are given by

$$P_3^1 + P_4^2 + P_2^3 + P_1^4 = 0 \quad P_3^3 + P_4^4 = 0.25$$

The condensed equations become

$$\frac{1}{6} \begin{bmatrix} 16 & -2 \\ -2 & 8 \end{bmatrix} \begin{Bmatrix} U_5 \\ U_8 \end{Bmatrix} = \begin{Bmatrix} 0 \\ \frac{1}{4} \end{Bmatrix}$$

and the solution is given by

$$U_5 = \frac{3}{124} \quad U_8 = \frac{6}{31}$$

The exact solution of the problem is given by

$$u(x, y) = \frac{2}{\pi^2} \sum_{n=1}^{\infty} \frac{(-1)^{n+1}}{n^2 \cosh n\pi} \sin n\pi x \sinh n\pi y$$

A comparison of the finite-element solutions obtained with 2×2 and 4×4 meshes of linear rectangular and triangular elements with the series solution is presented in Table 14. The finite-element solution improves as the mesh is refined

Table 15 Basic Steps in Finite-Element Analysis of Typical Problem

1. *Discretization of a Domain.* Represent the given domain as a collection of a finite number of simple subdomains, called *finite elements*. The number, shape, and type of element depend on the domain and differential equation being solved. The principal parts of this step include:
 - (a) Number the nodes (see step 2) and elements of the collection, called the *finite-element mesh*.
 - (b) Generate the coordinates of the nodes in the mesh and the relationship between the element nodes to global nodes (called the *connectivity matrix*, which indicates the relative position of each element in the mesh).
2. *Approximation of the Solution*
 - (a) *Derivation of the Approximating Functions.* For each element in the mesh, derive the approximation functions needed in the variational method. These functions are generally algebraic polynomials generated by interpolating the unknown function in terms of its values at preselected points, the *nodes*, of the element.
 - (b) *Variational Approximation of the Equation.* Using the functions derived in step 2a and any appropriate variational method, derive the algebraic equations among the nodal values of the primary and secondary variables.
3. *Connectivity (or Assembly) of Elements.* Combine the algebraic equations of all elements in the mesh by imposing the continuity of the primary nodal variables (i.e., the values of the primary variables at a node shared by two or more elements are the same). This can be viewed as putting the elements (which were isolated in steps 2a and 2b from the mesh to derive the algebraic equations) back into their original places. This gives the algebraic equations governing the whole problem.
4. *Imposition of Boundary Conditions.* Impose the boundary conditions, both on primary and secondary variables of the assembled equations.
5. *Solution of Equations.* Solve the equations for the unknown nodal values of the primary variables.
6. *Computation of Additional Quantities.* Using the nodal values of the primary variables, compute the secondary variables (via constitutive equations).

In summary, the finite-element method is a numerical technique of solving field problems of engineering. It is endowed with two unique features: The domain in which the equations are defined is represented by a collection of simple parts (finite elements), and over each element the problem is approximated using any one of the variational methods with polynomials for the approximation functions. The first feature allows approximate representation of geometrically complicated domains by simple geometric shapes, while the second feature enables the approximation of the field variables, evaluation of the coefficient matrices, and solution of the finite-element equations on a computer. A list of basic steps of the finite-element analysis is presented in Table 15.

13 LAPLACE TRANSFORMATION

13.1 Transformation Principles

The Laplace and Fourier transformation methods and the Heaviside operational calculus are in essence different aspects of the same method. This method simplifies the solving of linear constant-coefficient integrodifferential equations and convolution-type integral equations. For brevity the conditions under which the steps of the method may be validly applied will be omitted. Hence the correctness of a final result should be checked in each case by showing that the formal solution satisfies the given equation and conditions.

1. *Direct Laplace Transformation.* Let t be a real variable, s a complex variable (Section 14.2),

$f(t)$ a real function of t that equals zero for $t < 0$, $F(s)$ a function of s , and e the base of the natural logarithms. If the Lebesgue integral

$$\int_0^{\infty} e^{-st} f(t) dt = F(s) \quad (388)$$

then $F(s)$ is the *direct Laplace transform* of $f(t)$; in simpler notation

$$\mathcal{L}[f(t)] = F(s) \quad (389)$$

2. *Inverse Laplace Transformation.* Under certain conditions the direct transformation can be inverted, giving as one explicit representation

$$\frac{1}{2\pi i} \int_{c-i\infty}^{c+i\infty} e^{ts} F(s) ds (=) f(t) \quad (390)$$

in which c is a real constant chosen so that the path of integration lies to the right of all the singularities of $F(s)$, and $(=)$ means equals except possibly for a set of values of t of measure zero. If this relation holds, then $f(t)$ is the *inverse Laplace transform* of $F(s)$. In simpler notation the transformation is written

$$\mathcal{L}^{-1}[F(s)] (=) f(t) \quad (391)$$

3. *Transformation of nth Derivative.* If $\mathcal{L}[f(t)] = F(s)$, then

$$\mathcal{L}\left[\frac{d^n f(t)}{dt^n}\right] = s^n F(s) - \sum_{k=0}^{n-1} f^{(k)}(0+) \cdot s^{n-1-k} \tag{392}$$

where $f^{(2)}(0+)$ means $d^2 f(t)/dt^2$ evaluated for $t \rightarrow 0$ and $f^{(0)}(0+)$ means $f(0+)$ and $n = 1, 2, 3, \dots$

4. *Transformation of nth Integral.* If $\mathcal{L}[f(t)] = F(s)$, then

$$\mathcal{L}\left[\overbrace{\iint \dots \int}^n f(t) dt\right] = s^{-n} F(s) + \sum_{k=-1}^{-n} f^{(k)}(0+) \cdot s^{-n-1-k} \tag{393}$$

where $n = 1, 2, 3, \dots$. For example, $f^{(-2)}(0+)$ means $\int \int f(t) dt dt$ evaluated for $t \rightarrow 0$.

5. *Inverse Transformation of Product.* If

$$\mathcal{L}^{-1}[F_1(s)] = f_1(t) \quad \mathcal{L}^{-1}[F_2(s)] = f_2(t) \tag{394}$$

then

$$\mathcal{L}^{-1}[F_1(s) \cdot F_2(s)] = \int_0^t f_1(t-\lambda) \cdot f_2(\lambda) d\lambda \tag{395}$$

6. *Linear Transformations \mathcal{L} and \mathcal{L}^{-1} .* Let k_1, k_2 be real constants. Then

$$\mathcal{L}[k_1 f_1(t) + k_2 f_2(t)] = k_1 \mathcal{L}[f_1(t)] + k_2 \mathcal{L}[f_2(t)] \tag{396}$$

and

$$\mathcal{L}^{-1}[k_1 F_1(s) + k_2 F_2(s)] = k_1 \mathcal{L}^{-1}[F_1(s)] + k_2 \mathcal{L}^{-1}[F_2(s)] \tag{397}$$

13.2 Procedure

To illustrate the application of the rules of procedure the following simple initial-value problem will be solved. Given the equation

$$k_1 \frac{dy(t)}{dt} + k_2 y(t) + k_3 \int y(t) dt = u(t)$$

and initial values $y(0), y^{(-1)}(0)$ where $u(t) = 0$ for $t < 0$ and $u(t) = 1$ for $0 < t$ and k_1, k_2, k_3 are real constants. Assume that $y(t)$ has a Laplace transform $Y(s)$, that is, $\mathcal{L}[y(t)] = Y(s)$.

Step A. Find the Laplace transform of the equation to be solved and express it in terms of the transform of the unknown function.

Thus,

$$\mathcal{L}\left[k_1 \frac{dy(t)}{dt} + k_2 y(t) + k_3 \int y(t) dt\right] = \mathcal{L}[u(t)]$$

By (396) this becomes

$$k_1 \mathcal{L}\left[\frac{dy(t)}{dt}\right] + k_2 \mathcal{L}[y(t)] + k_3 \mathcal{L}\left[\int y(t) dt\right] = \mathcal{L}[u(t)]$$

By (392) and (393) and the given initial conditions of the problem the equation becomes

$$k_1[sY(s) - y(0)] + k_2 Y(s) + k_3[s^{-1}Y(s) + y^{(-1)}(0) \cdot s^{-1}] = \mathcal{L}[u(t)]$$

Step B. Solve the resulting equation for the transform of the unknown function. Thus,

$$Y(s) = \frac{\mathcal{L}[u(t)] + k_1 y(0) - y^{(-1)}(0) \cdot s^{-1}}{k_1 s + k_2 + k_3 s^{-1}}$$

Step C. Evaluate the direct transform of the given function (right member) in the original equation.

Since

$$\mathcal{L}[u(t)] = \frac{1}{s}$$

$$Y(s) = \frac{k_1 y(0) \cdot s - y^{(-1)}(0) + 1}{k_1 s^2 + k_2 s + k_3}$$

Step D. Obtain the solution of the problem by evaluating the inverse Laplace transform of the function obtained by the preceding steps.

One way to carry out step D is to find the inverse transform from the table of Laplace transforms in Section 12.3. To use the table, the denominator of the fraction should be factored:

$$y(t) = \mathcal{L}^{-1}[Y(s)] = \mathcal{L}^{-1}\left[\frac{k_1 y(0) \cdot s - y^{(-1)}(0) + 1}{k_1 s^2 + k_2 s + k_3}\right] = \mathcal{L}^{-1}\left[\frac{k_1 y(0) \cdot s - y^{(-1)}(0) + 1}{k_1(s + K_1)(s + K_2)}\right]$$

in which

$$K_1 \equiv \frac{k_2}{2k_1} - \frac{1}{2k_1}(k_2^2 - 4k_1 k_3)^{1/2}$$

$$K_2 \equiv \frac{k_2}{2k_1} + \frac{1}{2k_1}(k_2^2 - 4k_1 k_3)^{1/2}$$

To find the result it is necessary to distinguish between two cases.

CASE 1: If $K_1 \neq K_2$,

$$y(t) = \frac{[k_1 y(0)K_1 + y^{(-1)}(0) - 1]e^{-K_1 t} - [k_1 y(0)K_2 + y^{(-1)}(0) - 1]e^{-K_2 t}}{k_1(K_1 - K_2)}$$

for $0 < t$ and $y(t) = 0$ for $t < 0$.

CASE 2: If $K_1 = K_2 = K$, then $K = k_2/2k_1$, and

$$y(t) = \mathcal{L}^{-1} \left[\frac{k_1 y(0) \cdot s - y^{(-1)}(0) + 1}{k_1(s + K)^2} \right]$$

From Table 16,

$$y(t) = \frac{k_1 y(0)e^{-Kt} - [y^{(-1)}(0) - 1 + k_1 y(0)K]te^{-Kt}}{k_1}$$

for $0 < t$ and $y(t) = 0$ for $t < 0$.

The solutions can be shown to satisfy the original equation and initial conditions.

The use of step C can be avoided by using steps E, F, and G in place of steps C and D in the following way.

Step E. Factor the transform of the unknown function obtained by step B and evaluate the inverse Laplace transform of each factor.

Note. The inverse transform of a rational fraction can be found only if it is a proper fraction.

Thus

$$Y(s) = \frac{k_1 y(0) \cdot s - y^{(-1)}(0)}{k_1 s^2 + k_2 s + k_3} + \frac{s \mathcal{L}[u(t)]}{k_1 s^2 + k_2 s + k_3}$$

Let

$$\begin{aligned} y_1(t) &\equiv \mathcal{L}^{-1} \left[\frac{k_1 y(0) \cdot s - y^{(-1)}(0)}{k_1(s + K_1)(s + K_2)} \right] \\ &= [k_1 y(0)K_1 + y^{(-1)}(0)]e^{-K_1 t} \\ &\quad - \frac{[k_1 y(0)K_2 + y^{(-1)}(0)]e^{-K_2 t}}{k_1(K_1 - K_2)} \end{aligned}$$

for $0 < t$ and $y_1(t) = 0$ for $t < 0$. Also

$$\mathcal{L}^{-1} \left[\frac{s}{k_1(s + K_1)(s + K_2)} \right] = \frac{K_1 e^{-K_1 t} - K_2 e^{-K_2 t}}{k_1(K_1 - K_2)}$$

for $0 < t$ and $y_1(t) = 0$ for $t < 0$. Finally, $\mathcal{L}^{-1} \{ \mathcal{L}[u(t)] \} = u(t)$.

Step F. Use condition 5 to find the inverse transform of the product.

Thus, by condition 6 and step F,

$$\begin{aligned} y(t) &= y_1(t) + [k_1(K_1 - K_2)]^{-1} \\ &\quad \times \int_0^t [K_1 e^{-K_1(t-\tau)} - K_2 e^{-K_2(t-\tau)}]u(\tau) d\tau \end{aligned}$$

Step G. Evaluate the (convolution) integral arising from step F. Thus,

$$y(t) = y_1(t) + [k_1(K_1 - K_2)]^{-1}(e^{-K_2 t} - e^{-K_1 t})$$

for $0 < t$ and $y(t) = 0$ for $t < 0$.

For the particular problem treated it is much simpler to use steps C and D than steps E, F, and G. However, for a more complicated right member of the original equation it could happen that step G would be easier to carry out than step C, in which case the second method (A, B, E, F, G) should be used rather than the first (A, B, C, D).

One physical representation of the initial-value problem that we have used for illustration is the problem of finding the current response of a series electric circuit containing constant lumped inductance, resistance, and capacitance to an applied electromotive force $u(t)$, with an initial current in the inductance and an initial charge on the condenser.

The complete method (of which only a part has been given) is not restricted in its field of application to linear equations with constant coefficients but the solution of this type of equation is most simplified

13.3 Transform Pairs

The Laplace transforms in Table 16 are applicable in the solution of ordinary integrodifferential and difference equations.

14 COMPLEX ANALYSIS

14.1 Complex Numbers

A *complex number* A is a combination of two real numbers a_1, a_2 in the ordered pair $(a_1, a_2) = A = a_1 + ia_2$, where $i = (-1)^{1/2}$. Real and imaginary numbers are special cases of complex numbers obtained by placing $(a_1, 0) = a_1$, $(0, a_2) = ia_2$ (see Fig. 163).

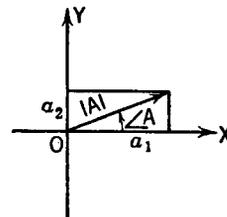

Fig. 163

1. If $a_1 + ia_2 = 0$, then $a_1 = 0, a_2 = 0$.
2. If $a_1 + ia_2 = b_1 + ib_2$, then $a_1 = b_1, a_2 = b_2$.
3. $a_1 + ia_2$ and $a_1 - ia_2$ are *conjugate complex* numbers. The complex conjugate of A is \overline{A} or A^* .
4. $A + B = (a_1 + ia_2) + (b_1 + ib_2) = (a_1 + b_1) + i(a_2 + b_2)$.
5. $a_1 + ia_2 = |A|(\cos \angle A + i \sin \angle A) = |A|e^{i\angle A}$ and $a_1 - ia_2 = |A|(\cos \angle A - i \sin \angle A) = |A|e^{-i\angle A}$, where $|A| = \sqrt{a_1^2 + a_2^2}$, $\sin \angle A = a_2/|A|$, $\cos \angle A = a_1/|A|$, $|A|$ is the *absolute value (modulus)*, and $\angle A$ is the *angle* of A .
6. $AB = (a_1 + ia_2)(b_1 + ib_2) = (a_1b_1 - a_2b_2) + i(a_2b_1 + a_1b_2) = |A||B|e^{i(\angle A + \angle B)}$.
7. $A\overline{A} = (a_1 + ia_2)(a_1 - ia_2) = a_1^2 + a_2^2 = |A|^2$.
8. $\frac{A}{B} = \frac{a_1 + ia_2}{b_1 + ib_2} = \frac{(a_1 + ia_2)(b_1 - ib_2)}{(b_1 + ib_2)(b_1 - ib_2)} = \frac{a_1b_1 + a_2b_2}{b_1^2 + b_2^2} + i\frac{a_2b_1 - a_1b_2}{b_1^2 + b_2^2} = \frac{|A|}{|B|}e^{i(\angle A - \angle B)}$.
9. $A^n = (a_1 + ia_2)^n = [|A|(\cos \angle A + i \sin \angle A)]^n = |A|^n e^{in\angle A} = |A|^n (\cos n\angle A + i \sin n\angle A)$.
 $\overline{A}^n = (a_1 - ia_2)^n = [|A|(\cos \angle A - i \sin \angle A)]^n = |A|^n e^{-in\angle A} = |A|^n (\cos n\angle A - i \sin n\angle A)$.
10. $\sqrt[n]{A} = \sqrt[n]{a_1 + ia_2} = \sqrt[n]{|A|} \left(\cos \frac{\angle A + 2k\pi}{n} + i \sin \frac{\angle A + 2k\pi}{n} \right) = R|A|n e^{i\angle A + 2k\pi/n}$,

where k is an integer. For $k = 0, 1, 2, \dots, n-1$, all of the n roots are obtained.

14.2 Complex Variables

Analytic Functions of a Complex Variable. A function $w = f(z)$, $z = x + iy$, which has a derivative

$$\frac{df}{dz} = f'(z) = \lim_{h \rightarrow 0} \frac{f(z+h) - f(z)}{h}$$

at a point z independent of the manner of approach of $z+h$ to z , is *analytic* at z and may be expanded in a convergent power series there. A function that is analytic at every point of a region is *analytic in the region*. If $f(z) = w = u(x, y) + iv(x, y)$ and $f(z)$ is

analytic at z , then the Cauchy–Riemann differential equations

$$\frac{\partial u}{\partial x} = \frac{\partial v}{\partial y}, \quad \frac{\partial u}{\partial y} = -\frac{\partial v}{\partial x}$$

hold at z . If in a neighborhood of a point z these four partial derivatives exist and are continuous and if the Cauchy–Riemann equations hold, then $f(z)$ is analytic at z . The functions u and v satisfy Laplace's equation

$$\frac{\partial^2 \phi}{\partial x^2} + \frac{\partial^2 \phi}{\partial y^2} = 0$$

Example 95. Examples of analytic functions are $z, 1/z, e^z$, and $\sin z$. An example of a nonanalytic function is $w = x - iy$.

Conformal Mapping. The function $w = f(z)$, analytic in a region R_z of the z plane, *conformally* maps each point in R_z on a point of the w plane in the region R_w if $f'(z) \neq 0$ at all points of R_z . This mapping is also *isogonal*, that is, the angle between two curves starting at z_0 is equal to the angle between their mapped curves starting at w_0 .

Example 96

1. $w = z + b$, b complex, is a *translation* of magnitude $|b|$ in the direction $\angle b$.
2. $w = az$, a complex, is a *rotation* through $\angle a$ and a *magnification* by $|a|$.
3. $w = az + b$, a, b complex, the *integral linear transformation*, is a combination of 1 and 2.
4. $w = 1/z$, the *inversion transformation*, carries the origin of the z plane into the point at infinity in the *enlarged* w plane.
5. $w = (az + b)/(cz + d)$, $ad - bc \neq 0$, the *general linear* or *bilinear transformation*, can be resolved into two linear integral and one inversion transformations.

Integrals of Analytic Functions. If $dF(z)/dz = f(z)$ in a simply connected region R_z , then $F(z) = \int f(z) dz$ is analytic throughout R_z . If $f_1(z), f_2(z)$ are analytic in R_z and the path of integration is in R_z , then:

1. $\int_{z_0}^{z_0} f_1(z) dz = 0$
2. $\int_{z_0}^{z_1} [k_1 f_1(z) + k_2 f_2(z)] dz = k_1 \int_{z_0}^{z_1} f_1(z) dz + k_2 \int_{z_0}^{z_1} f_2(z) dz$
3. $\int_{z_1}^{z_0} f_1(z) dz = -\int_{z_0}^{z_1} f_1(z) dz$
4. $\int_{z_0}^{z_1} f_1(z) dz + \int_{z_1}^{z_2} f_1(z) dz = \int_{z_0}^{z_2} f_1(z) dz$

Cauchy's Integral Theorem. If $f(z)$ is analytic and single valued on and within a simple closed contour C , then $\int_C f(z) dz = 0$.

A *contour* is a continuous curve made up of a finite number of elementary arcs.

If $f(z)$ is continuous on a simple closed contour C and analytic in the region bounded by C , then *Cauchy's integral formula*

$$f(z) = \frac{1}{2\pi i} \int_C \frac{f(\zeta)}{\zeta - z} d\zeta$$

holds; also

$$f^{(n)}(z) = \frac{n!}{2\pi i} \int_C \frac{f(\zeta)}{(\zeta - z)^{n+1}} d\zeta$$

Laurent Series. A function $f(z)$ has a *zero of order n* at z_1 if it can be put in the form $f(z) = (z - z_1)^n f_1(z)$, n a positive integer, $f_1(z_1) \neq 0$. A function $f(z)$ has a *pole of order n* at z_1 if it can be put in the form $f(z) = f_2(z)/(z - z_1)^n$, n a positive integer, $f_2(z_1) \neq 0$.

If $f(z)$ is analytic in a ring between and on two concentric circles C_1 and C_2 with radii R_1 and R_2 , $R_1 < R_2$, and center z_1 , then the *Laurent series*

$$f(z) = \sum_{n=-\infty}^{\infty} c_n(z - z_1)^n \quad R_1 < |z - z_1| < R_2$$

is convergent everywhere in the ring, and

$$c_n = \frac{1}{2\pi i} \int_C \frac{f(z)}{(z - z_1)^{n+1}} dz$$

C is circle $|z - z_1| = r$, $R_1 < r < R_2$.

If a single-valued analytic function $f(z)$ is expanded in a Laurent series in the neighborhood of an isolated singularity z_1 , then the *residue* of $f(z)$ at z_1 is

$$c_{-1} = \frac{1}{2\pi i} \int_C f(z) dz$$

C is any circle with center at z_1 that excludes all other singularities of $f(z)$.

A function is *meromorphic* in a region if it is analytic in the region except for a finite number of poles. If $f(z)$ is analytic on and inside a contour C , except for a finite number of poles, and has no zeros on C , then

$$\frac{1}{2\pi i} \int_C \frac{f'(z)}{f(z)} dz = N - P$$

N the total order of the zeros and P the total order of the poles within the contour.

15 VECTOR ANALYSIS

15.1 Vector Algebra

A *scalar* is a quantity that has magnitude, such as mass, density, and temperature. A *vector* is a quantity

that has magnitude and direction, such as force, velocity, and acceleration. A vector may be represented geometrically by an oriented line segment.

Two vectors \mathbf{A} and \mathbf{B} are equal if they have the same magnitude and direction. A vector may be displaced parallel to itself provided it retains the same magnitude and direction. A vector having the same magnitude but direction opposite to that of \mathbf{A} is the negative of \mathbf{A} and is written $-\mathbf{A}$. If \mathbf{A} is a vector of magnitude, or length, a , then $|\mathbf{A}| = a$. A vector parallel to \mathbf{A} but with magnitude equal to the reciprocal of the magnitude of \mathbf{A} is written $\mathbf{A}^{-1} = 1/\mathbf{A}$. A unit vector $\mathbf{A}/|\mathbf{A}|$ ($\mathbf{A} \neq 0$) has the direction of \mathbf{A} and magnitude 1.

The *sum* of two vectors \mathbf{A} and \mathbf{B} is $\mathbf{A} + \mathbf{B}$ (Fig. 164). Similarly, the sum of three or more vectors can be found by adding them end to end.

The sum of \mathbf{A} and $-\mathbf{B}$ is $\mathbf{A} - \mathbf{B}$ (Fig. 164), the *difference* of two vectors.

Let \mathbf{A} , \mathbf{B} , \mathbf{C} be vectors and p , q scalars.

$p\mathbf{A} = \mathbf{A}p$, a vector p times as long as \mathbf{A} with the same direction as \mathbf{A} if p is positive and opposite if p is negative,

$$(p + q)\mathbf{A} = p\mathbf{A} + q\mathbf{A} \quad p(\mathbf{A} + \mathbf{B}) = p\mathbf{A} + p\mathbf{B}$$

$$\mathbf{A} + \mathbf{B} = \mathbf{B} + \mathbf{A}$$

$$\mathbf{A} + (\mathbf{B} + \mathbf{C}) = (\mathbf{A} + \mathbf{B}) + \mathbf{C}$$

$|\mathbf{A} + \mathbf{B}| \leq |\mathbf{A}| + |\mathbf{B}|$, where the equality sign holds only for \mathbf{A} parallel to \mathbf{B} .

Rectangular Coordinates. Figure 165 shows a right-hand coordinate system. Let \mathbf{i} , \mathbf{j} , \mathbf{k} be unit vectors with the directions OX , OY , OZ , respectively. The vector \mathbf{R} with initial point O and endpoint $P(x, y, z)$ can be expressed as the sum of its components,

$$\mathbf{R} = ix + jy + kz$$

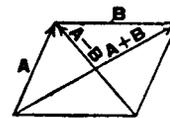

Fig. 164

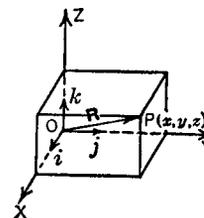

Fig. 165

If $\mathbf{A} = ia_1 + ja_2 + ka_3$ and $\mathbf{B} = ib_1 + jb_2 + kb_3$, then

$$\mathbf{A} + \mathbf{B} = i(a_1 + b_1) + j(a_2 + b_2) + k(a_3 + b_3)$$

The *scalar, inner, or dot product* of two vectors \mathbf{A} and \mathbf{B} is $\mathbf{A} \cdot \mathbf{B} = |\mathbf{A}||\mathbf{B}| \cos \theta$ (Fig. 166),

$$\mathbf{A} \cdot \mathbf{B} = \mathbf{B} \cdot \mathbf{A}$$

$$\mathbf{A} \cdot (\mathbf{B} + \mathbf{C}) = \mathbf{A} \cdot \mathbf{B} + \mathbf{A} \cdot \mathbf{C}$$

$$\mathbf{A} \cdot \mathbf{A} = A^2 = |\mathbf{A}|^2$$

$$\mathbf{i} \cdot \mathbf{i} = \mathbf{j} \cdot \mathbf{j} = \mathbf{k} \cdot \mathbf{k} = 1$$

$$\mathbf{i} \cdot \mathbf{j} = \mathbf{j} \cdot \mathbf{k} = \mathbf{k} \cdot \mathbf{i} = 0$$

If $\mathbf{A} \cdot \mathbf{B} = 0$, then either $\mathbf{A} = 0$, $\mathbf{B} = 0$, or \mathbf{A} is perpendicular to \mathbf{B} .

If $\mathbf{A} = ia_1 + ja_2 + ka_3$ and $\mathbf{B} = ib_1 + jb_2 + kb_3$, then $\mathbf{A} \cdot \mathbf{B} = a_1b_1 + a_2b_2 + a_3b_3$.

The *vector, restricted outer, or cross product* of two vectors \mathbf{A} and \mathbf{B} is $\mathbf{A} \times \mathbf{B} = \mathbf{C}$, where \mathbf{C} is perpendicular to the plane of \mathbf{A} and \mathbf{B} with the magnitude $|\mathbf{C}| = |\mathbf{A}||\mathbf{B}| \sin \theta$ (the area of the parallelogram made by \mathbf{A} and \mathbf{B} , Fig. 167) and so directed that a right-hand rotation of less than 180° carries \mathbf{A} into \mathbf{B} ,

$$\mathbf{A} \times \mathbf{B} = -\mathbf{B} \times \mathbf{A}$$

$$\mathbf{A} \times (\mathbf{B} + \mathbf{C}) = \mathbf{A} \times \mathbf{B} + \mathbf{A} \times \mathbf{C}$$

$$(\mathbf{B} + \mathbf{C}) \times \mathbf{A} = \mathbf{B} \times \mathbf{A} + \mathbf{C} \times \mathbf{A}$$

$$\mathbf{i} \times \mathbf{i} = \mathbf{j} \times \mathbf{j} = \mathbf{k} \times \mathbf{k} = 0$$

$$\mathbf{i} \times \mathbf{j} = \mathbf{k} = -\mathbf{j} \times \mathbf{i}$$

$$\mathbf{j} \times \mathbf{k} = \mathbf{i} = -\mathbf{k} \times \mathbf{j}$$

$$\mathbf{k} \times \mathbf{i} = \mathbf{j} = -\mathbf{i} \times \mathbf{k}$$

If $\mathbf{A} \times \mathbf{B} = 0$, then either $\mathbf{A} = 0$, $\mathbf{B} = 0$, or \mathbf{A} is parallel to \mathbf{B} . If $\mathbf{A} = ia_1 + ja_2 + ka_3$ and $\mathbf{B} = ib_1 + jb_2 +$

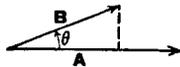

Fig. 166

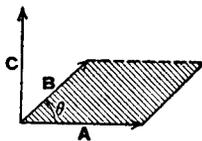

Fig. 167

kb_3 , then

$$\mathbf{A} \times \mathbf{B} = \begin{vmatrix} \mathbf{i} & \mathbf{j} & \mathbf{k} \\ a_1 & a_2 & a_3 \\ b_1 & b_2 & b_3 \end{vmatrix}$$

If $\mathbf{A} = ia_1 + ja_2 + ka_3$, $\mathbf{B} = ib_1 + jb_2 + kb_3$, $\mathbf{C} = ic_1 + jc_2 + kc_3$, then the *scalar triple product*

$$\mathbf{A} \cot(\mathbf{B} \times \mathbf{C}) = (\mathbf{A} \times \mathbf{B}) \cdot \mathbf{C} = \mathbf{B} \cdot (\mathbf{C} \times \mathbf{A})$$

$$= (\mathbf{ABC}) = \begin{vmatrix} a_1 & a_2 & a_3 \\ b_1 & b_2 & b_3 \\ c_1 & c_2 & c_3 \end{vmatrix}$$

and is equal to the volume of a parallelepiped whose three determining edges are \mathbf{A} , \mathbf{B} , \mathbf{C} ,

$$(\mathbf{A} \times \mathbf{B}) \times \mathbf{C} = (\mathbf{A} \cdot \mathbf{C})\mathbf{B} - (\mathbf{B} \cdot \mathbf{C})\mathbf{A}$$

$$= -\mathbf{C} \times (\mathbf{A} \times \mathbf{B})$$

$$(\mathbf{A} \times \mathbf{B}) \cdot (\mathbf{C} \times \mathbf{D}) = (\mathbf{A} \cdot \mathbf{C})(\mathbf{B} \cdot \mathbf{D})$$

$$- (\mathbf{A} \cdot \mathbf{D})(\mathbf{B} \cdot \mathbf{C})$$

15.2 Differentiation and Integration of Vectors

Differentiation. A vector function of one or more scalar variables is called a *variable vector* or *field vector*. The derivative is

$$\begin{aligned} \frac{d\mathbf{F}}{dt} &= \mathbf{F}'(t) = \lim_{\Delta t \rightarrow 0} \frac{\mathbf{F}(t + \Delta t) - \mathbf{F}(t)}{\Delta t} \\ &= \lim_{\Delta t \rightarrow 0} \frac{\Delta \mathbf{F}}{\Delta t} \quad (\text{Fig. 168}) \end{aligned}$$

If the length of \mathbf{F} remains unaltered, then $\mathbf{F} \cdot d\mathbf{F} = 0$. If the direction of \mathbf{F} remains unaltered, then $\mathbf{F} \times d\mathbf{F} = 0$,

$$d(\mathbf{A} + \mathbf{B}) = d\mathbf{A} + d\mathbf{B}$$

$$d(\mathbf{A} \cdot \mathbf{B}) = \mathbf{A} \cdot d\mathbf{B} + \mathbf{B} \cdot d\mathbf{A}$$

$$d(\mathbf{A} \times \mathbf{B}) = d\mathbf{A} \times \mathbf{B} + \mathbf{A} \times d\mathbf{B}$$

$$= \mathbf{A} \times d\mathbf{B} - \mathbf{B} \times d\mathbf{A}$$

$$d(\mathbf{A} \cdot \mathbf{B} \cdot \mathbf{C}) = \mathbf{A} \cdot \mathbf{B} \cdot d\mathbf{C} + \mathbf{B} \cdot \mathbf{C} \cdot d\mathbf{A}$$

$$+ \mathbf{C} \cdot \mathbf{A} \cdot d\mathbf{B}$$

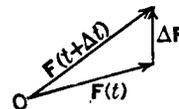

Fig. 168

Derivative Operators

$$\nabla = \text{del} = \mathbf{i} \frac{\partial}{\partial x} + \mathbf{j} \frac{\partial}{\partial y} + \mathbf{k} \frac{\partial}{\partial z}$$

$$\nabla^2 = \text{Laplacian} = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}$$

If V is a scalar function, then

$$\nabla V = \text{grad } V = \mathbf{i} \frac{\partial V}{\partial x} + \mathbf{j} \frac{\partial V}{\partial y} + \mathbf{k} \frac{\partial V}{\partial z}$$

If \mathbf{A} is a vector function with components A_x, A_y, A_z , then

$$\nabla \cdot \mathbf{A} = \text{div } \mathbf{A} = \frac{\partial A_x}{\partial x} + \frac{\partial A_y}{\partial y} + \frac{\partial A_z}{\partial z}$$

$$\nabla \times \mathbf{A} = \text{curl } \mathbf{A} = \text{rot } \mathbf{A} = \begin{vmatrix} \mathbf{i} & \mathbf{j} & \mathbf{k} \\ \frac{\partial}{\partial x} & \frac{\partial}{\partial y} & \frac{\partial}{\partial z} \\ A_x & A_y & A_z \end{vmatrix}$$

Formulas for Differentiation. Let U and V be scalar functions and \mathbf{A} and \mathbf{B} be vector functions of x, y, z . Then (see *Advanced Engineering Analysis* by J. N. Reddy and M. L. Rasmussen, Wiley, New York, 1982)

$$\begin{aligned} \nabla(U + V) &= \nabla U + \nabla V & \nabla \cdot (\mathbf{A} + \mathbf{B}) &= \nabla \cdot \mathbf{A} + \nabla \cdot \mathbf{B} \\ \nabla \times (\mathbf{A} + \mathbf{B}) &= \nabla \times \mathbf{A} + \nabla \times \mathbf{B} \\ \nabla(UV) &= V\nabla U + U\nabla V \\ \nabla \cdot (U\mathbf{A}) &= U\nabla \cdot \mathbf{A} + \mathbf{A} \cdot \nabla U \\ \nabla \times (U\mathbf{A}) &= \nabla U \times \mathbf{A} + U\nabla \times \mathbf{A} \\ \nabla \cdot (\mathbf{A} \times \mathcal{B}) &= \mathbf{B} \cdot \nabla \times \mathcal{A} - \mathcal{A} \cdot \nabla \times \mathcal{B} \\ \nabla(\mathbf{A} \cdot \mathcal{B}) &= \mathbf{A} \cdot \nabla \mathcal{B} + \mathcal{B} \cdot \nabla \mathbf{A} + \mathbf{A} \times (\nabla \times \mathcal{B}) \\ &\quad + \mathcal{B} \times (\nabla \times \mathbf{A}) \\ \nabla \times (\mathbf{A} \times \mathcal{B}) &= \mathcal{B} \cdot \nabla \mathbf{A} - \mathbf{A} \cdot \nabla \mathcal{B} + \mathbf{A}(\nabla \cdot \mathcal{B}) \\ &\quad - \mathcal{B}(\nabla \cdot \mathbf{A}) \\ \nabla \times (\nabla \times \mathbf{A}) &= \nabla(\nabla \cdot \mathbf{A}) - \nabla^2 \mathbf{A} \\ \nabla \cdot (\nabla \times \mathbf{A}) &= 0 \\ \nabla \times (\nabla U) &= 0 \end{aligned}$$

If $\mathbf{R} = ix + jy + kz$ (Fig. 165), then

$$\begin{aligned} \nabla \cdot \mathbf{R} &= 3 & \nabla \times \mathbf{R} &= \mathbf{0} & \mathbf{A} \cdot \nabla |\mathbf{R}| &= |\mathbf{A}| \\ \nabla \cdot \frac{1}{|\mathbf{R}|} &= -\frac{\mathbf{R}}{|\mathbf{R}|^3} & \nabla^2 \frac{1}{|\mathbf{R}|} &= 0 \end{aligned}$$

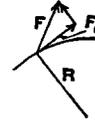

Fig. 169

Integration. The line integral of a vector \mathbf{F} along a curve AB denotes the integral of the tangential component of the vector along the curve; thus

$$\int_A^B \mathbf{F} \cdot d\mathcal{R} = \int_A^B |\mathcal{F}_c| ds \quad (\text{Fig. 169})$$

where $d\mathbf{R} = \mathbf{i} dx + \mathbf{j} dy + \mathbf{k} dz$.

If $\mathbf{F} = \nabla U$ is the gradient of a single-valued continuous function $U(x, y, z)$, the line integral of \mathbf{F} depends only on the endpoints. Conversely, if $\mathbf{F}(x, y, z)$ is continuous and $\int_C \mathbf{F} \cdot d\mathbf{R} = 0$ for any closed path C in a three-dimensional region, there is a function $U(x, y, z)$ such that $\mathbf{F} = \nabla U$.

15.3 Theorems and Formulas

Let \mathbf{n} be the vector of unit length perpendicular to a surface at a point P and extending on the positive side (the outward normal), dS the element of surface, and dv the element of volume.

Divergence (Gauss) Theorem. If a field vector \mathbf{F} and its first derivatives are continuous at all points in a region of volume v bounded by a closed elementary surface S , then

$$\iint_S \mathbf{F} \cdot \mathbf{n} dS = \iiint_v \nabla \cdot \mathcal{F} dv$$

Stokes's Theorem. If a field vector \mathbf{F} and its first derivatives are continuous at all points in a region of area S bounded by a closed curve C , then

$$\iint_S \nabla \times \mathbf{F} \cdot \mathbf{n} dS = \int_C \mathcal{F} \cdot d\mathcal{R}$$

Green's Theorem. Under the conditions of the divergence theorem,

$$\begin{aligned} \iint_S \mathbf{n} \cdot U\nabla V dS &= \iiint_v U\nabla^2 V dv \\ &\quad + \iint_v (\nabla U \cdot \nabla V) dv \\ \iint_S \mathbf{n} \cdot (U\nabla V - V\nabla U) dS &= \iiint_v (U\nabla^2 V \\ &\quad - V\nabla^2 U) dv \end{aligned}$$

Cylindrical Coordinates

$$x = r \cos \theta \quad y = r \sin \theta \quad z = z$$

The element of volume $dv = r dr d\theta dz$. The unit vectors \mathbf{u}_r , \mathbf{u}_θ , \mathbf{u}_z are perpendicular to each other,

$$\begin{aligned} \text{grad } V &= \nabla V = \frac{\partial V}{\partial r} \mathbf{u}_r + \frac{1}{r} \frac{\partial V}{\partial \theta} \mathbf{u}_\theta + \frac{\partial V}{\partial z} \mathbf{u}_z \\ \text{div } \mathbf{F} &= \nabla \cdot \mathbf{F} = \frac{1}{r} \frac{\partial}{\partial r} (r \mathbf{F}_r) + \frac{1}{r} \frac{\partial}{\partial \theta} (\mathbf{F}_\theta) + \frac{\partial}{\partial z} (\mathbf{F}_z) \\ \text{curl } \mathbf{F} &= \nabla \times \mathbf{F} = \begin{vmatrix} \mathbf{u}_r & \mathbf{u}_\theta & \mathbf{u}_z \\ r & r & r \\ \frac{\partial}{\partial r} & \frac{\partial}{\partial \theta} & \frac{\partial}{\partial z} \\ \mathbf{F}_r & r \mathbf{F}_\theta & \mathbf{F}_z \end{vmatrix} \\ \nabla^2 V &= \frac{1}{r} \frac{\partial V}{\partial r} + \frac{\partial^2 V}{\partial r^2} + \frac{1}{r^2} \frac{\partial^2 V}{\partial \theta^2} + \frac{\partial^2 V}{\partial z^2} \end{aligned}$$

Spherical Coordinates

$$x = r \cos \phi \sin \theta \quad y = r \sin \phi \sin \theta \quad z = r \cos \theta$$

The unit vectors \mathbf{u}_r , \mathbf{u}_ϕ , \mathbf{u}_θ are perpendicular to each other,

$$\begin{aligned} \text{grad } V &= \nabla V = \frac{\partial V}{\partial r} \mathbf{u}_r + \frac{1}{r \sin \theta} \frac{\partial V}{\partial \phi} \mathbf{u}_\phi \\ &\quad + \frac{1}{r} \frac{\partial V}{\partial \theta} \mathbf{u}_\theta \\ \text{div } \mathbf{F} &= \nabla \cdot \mathbf{F} = \frac{1}{r^2} \frac{\partial}{\partial r} (r^2 \mathbf{F}_r) \\ &\quad + \frac{1}{r \sin \theta} \frac{\partial \mathbf{F}_\phi}{\partial \phi} + \frac{1}{r \sin \theta} \frac{\partial}{\partial \theta} (\sin \theta \mathbf{F}_\theta) \\ \text{curl } \mathbf{F} &= \nabla \times \mathbf{F} = \begin{vmatrix} \mathbf{u}_r & \mathbf{u}_\theta & \mathbf{u}_\phi \\ r^2 \sin \theta & r \sin \theta & r \\ \frac{\partial}{\partial r} & \frac{\partial}{\partial \theta} & \frac{\partial}{\partial \phi} \\ \mathbf{F}_r & r \mathbf{F}_\theta & r \sin \theta \mathbf{F}_\phi \end{vmatrix} \\ \nabla^2 V &= \frac{1}{r^2} \frac{\partial}{\partial r} \left(r^2 \frac{\partial V}{\partial r} \right) + \frac{1}{r^2 \sin^2 \theta} \frac{\partial^2 V}{\partial \phi^2} \\ &\quad + \frac{1}{r^2 \sin \theta} \frac{\partial}{\partial \theta} \left(\sin \theta \frac{\partial V}{\partial \theta} \right) \end{aligned}$$

Solid Angle. The lines joining the point P to points of a surface S generate a solid angle. If a is the area intercepted by these lines on a sphere of center P with radius r , then

$$\omega = \frac{a}{r^2}$$

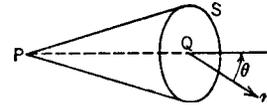

Fig. 170

is the measure of the solid angle (Fig. 170). If S is a surface that does not pass through P , $\cos \theta$ is nowhere zero, and \mathbf{n} is everywhere continuous on the surface, then

$$\omega = \int_S \frac{\mathbf{R} \cdot \mathbf{n} da}{r^3}$$

where $\mathbf{R} = PQ$. If S forms the complete boundary of a three-dimensional region, the total solid angle subtended by S at P is zero if P lies outside the region and 4π if P lies inside the region.

1 DEFINITIONS

Mechanics is that branch of science that treats forces and motion.

Statics is that branch of mechanics that deals with the equilibrium of forces on bodies *at rest* (or moving at a uniform velocity in a straight line).

Kinematics is that branch of mechanics that deals with the motion of bodies without consideration of the character of the bodies or of the influence of forces upon their motion. It considers only concepts of *geometry* and *time*.

Kinetics (or *dynamics*) is that branch of mechanics that deals with the effect of unbalanced external forces in *modifying the motion* of bodies.

Mass and weight, in the *gravitational system of units* employed by English engineers, are related by

the formula $W = Mg$, where W = weight, M = mass, and g = acceleration due to gravity. For a thorough discussion of these terms, see Chapter 1.

Force is that which changes or tends to change the state of rest or motion of a body.

Inertia is that property of a body by virtue of which it tends to continue in the state of rest or motion in which it may be placed until acted on by some force.

Reaction is that *equal and opposite force* exerted by a body in opposing another force acting upon it.

Newton's Laws of Motion

First Law. If a body is at rest, it will remain at rest, or if in motion, it will move uniformly in a straight line until acted on by some force.

Second Law. The time rate of change of the linear momentum of a particle (define as the product of its mass and its acceleration, a vector) is proportional to the force (a vector) acting on the particle.

Third Law. If a force acts to change the state of a body with respect to rest or motion, the body will offer a resistance equal and directly opposed to the force. Or, to every action there is opposed an equal and opposite reaction.

Special terms such as *hydrostatics*, *aerodynamics*, and so on, are used to denote the theory of statics as applied to *liquid bodies*, the theory of dynamics as applied to *gaseous bodies*, and so on. *Mechanics of materials* considers, in addition to *external forces*, the *internal forces*, or *stresses*, between molecules of a body. Subjects of these types are covered in other sections of this handbook. The present chapter on mechanics is confined in general, to the discussion of motion of, and external forces applied to, *rigid bodies*.

2 STATICS

2.1 Graphical Representation and Classification of Forces

Graphical Representation of Force A force is completely specified by its *magnitude*, *direction*, and *point of application*. The word *sense* as applied to a force refers to one of the two directions along the line of action of the force. The effect of any force applied to a rigid body at rest is the same, no matter where in its own line of action the force is applied. This is known as the principle of the *transmissibility of force*. A force may be represented graphically in magnitude and direction by a straight line drawn parallel to its line of action, the length being proportional to the magnitude of the force; its sense is indicated by an arrowhead placed on the line. The English engineers' unit of force is the pound, or the earth's pull on a mass of 1 lb. A drawing that indicates the lines of action of the various forces acting on a machine or structure is called a *space diagram*; one in which vectors are drawn to represent the magnitudes and directions of the forces is a *vector diagram*. A force is indicated on a space diagram by two lowercase letters placed on opposite sides of the line of action of the force; the vector, representing its magnitude and direction, by the same capital letters placed at the ends. Thus, in Fig. 1, AB represents the magnitude and direction of

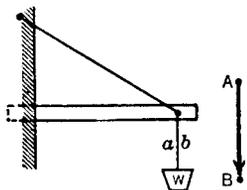

Fig. 1 Space diagram.

the force W and ab its action line. The vector being read as AB indicates a downward sense; read as BA , an upward sense.

Classification of Systems of Forces A system of forces consists of any number of forces taken collectively.

Classification of systems of forces is made according to the arrangement of their *action lines*. If the action lines lie in the same plane, the system is *coplanar*, otherwise *noncoplanar*. If they pass through the same point, the system is *concurrent*, otherwise *nonconcurrent*. If two or more forces have the same action line, they are *collinear*. A system of two equal forces parallel, opposite in sense, and having different action lines is a *couple*. Two or more forces equivalent to a single force are components of the single force. *Resolution* is the operation of replacing a single force by a system of components. The single force is the *resultant* of its components. In general, the resultant of a system of forces is the simplest equivalent system. This may be a *single force*, a *single couple*, or a *noncoplanar force and couple* (or *two skewed forces*). When the resultant is a single force, the equilibrant is a force equal in magnitude, having the same line of action but opposite sense. *Composition* is the operation of replacing a system of forces by its resultant.

2.2 Addition and Resolution of Concurrent Forces

Addition of Two Concurrent Forces*

Parallelogram Law. If magnitudes, lines of action, and senses of two concurrent forces acting on a rigid body are represented by OA and OB (Fig. 2), the magnitude, line of action, and sense of their resultant are represented by the diagonal OC of the parallelogram $OABC$. The points of application of the forces may be anywhere on the body in the lines OA , OB , and OC or their extensions. The arrowheads on the lines OA , OB , and OC all point toward or all away from the point of concurrence O .

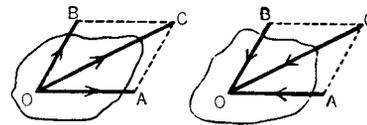

Fig. 2 Concurrent forces.

*It is evident that a pair of concurrent forces and their resultant are necessarily coplanar.

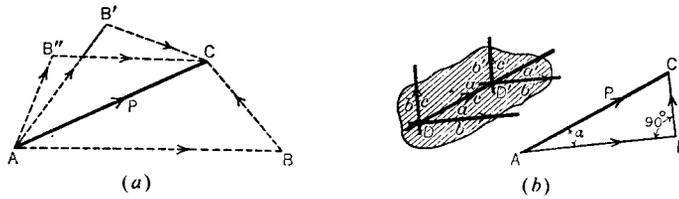

Fig. 3 Force components.

Triangle Law. The triangle law for graphical vector addition of two concurrent forces follows directly from the parallelogram law. In the parallelogram law, vectors are drawn tail to tail and a parallelogram is created. If either half of the parallelogram in Fig. 2 (either above or below line OC , with each "half" containing line OC) is examined, it can be seen that each triangle thus considered contains both of the forces being composed (added) laid out in a head-to-tail sequence.

Resolution into Two Concurrent Forces A force may be resolved into an infinite number of pairs of components by constructing triangles with the given force as one of the sides. In each such triangle, the other two sides of the triangle are the components of the given force in the directions defined by the other two sides of the triangle, as shown in Fig. 3a. Of special interest are those cases in which the given force is the hypotenuse of a right triangle, in which case the sides of the triangle are rectangular components of the given force, as shown in Fig. 3b. Algebraically, the rectangular components of the force P in Fig. 3b in the x and y directions are given by $P_x = P \cos \alpha$ and $P_y = P \sin \alpha$.

Addition of More Than Two Coplanar Concurrent Forces

Graphic Method. In Fig. 4, consider body G acted on by the four forces shown. Construct a force polygon as follows: Plot AB parallel to ab , and scale it to represent 60 lb; from B plot BC parallel to bc , and

scale it to represent 80 lb; in like manner plot CD and DE , so that the arrows lead *confluently* from A to E . The resultant of the system is AE in magnitude and sense and equals 114 lb. Its action line is ae . The resultant will be the same regardless of the order in which the forces are plotted. Note particularly that the resultant is not confluent with the component forces.

Algebraic Method. Choose rectangular axes OX and OY . Referring to Fig. 4 resolve each force into its x and y components, considering components acting upward or to the right as positive and those acting downward or to the left as negative. Arrange the results in tabular form, placing the forces in the first column, the x components in the second, and the y components in the third. $\sum F_x =$ algebraic sum of x components and $\sum F_y =$ algebraic sum of y components.

F (lb)	F_x (lb)	F_y (lb)
$ab = 60$	$-60 \times 0.707 = -42.4$	$+60 \times 0.707 = +42.4$
$bc = 80$	$+80 \times 2/\sqrt{5} = +71.4$	$+80 \times 1/\sqrt{5} = +35.7$
$cd = 120$	$+120 \times 0.866 = +104$	$-120 \times 0.5 = -60$
$de = 40$	$-40 \times 0.5 = -20$	$-40 \times 0.866 = -34.6$
	$\sum F_x = +113$	$\sum F_y = -16.5$

Then $R = \sqrt{\sum F_x^2 + \sum F_y^2} = \sqrt{13,041} = 114$ lb. Sense is downward and to the right (Fig. 5):

$$\tan \theta = \frac{\sum F_y}{\sum F_x} = -0.146 \quad \theta = -8^\circ 20'$$

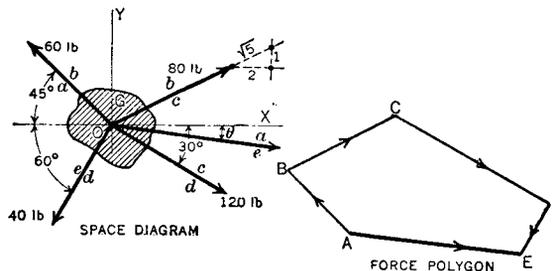

Fig. 4 Force polygon.

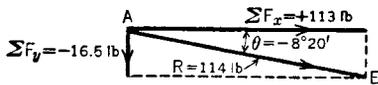

Fig. 5 Rectangular components.

Addition of Noncoplanar Forces

Graphical Methods. Graphical methods for the addition of noncoplanar forces are unnecessarily cumbersome in view of the ease with which the process can be handled algebraically using rectangular components.

Algebraic Method. Consider any number of concurrent forces (e.g., the three forces **F**, **G**, and **H** acting at point *O* as shown in Fig. 6). Each such force can be resolved into its components with respect to a set of rectangular axes by using the direction angles of the line of action of the force (and their cosines, called direction cosines) as shown in Fig. 6. The rectangular components of the force **F** are given by

$$F_x = F \cos \alpha_F \quad F_y = F \cos \beta_F \quad F_z = F \cos \gamma_F$$

and the force **F** can be written as

$$\mathbf{F} = F_x \mathbf{i} + F_y \mathbf{j} + F_z \mathbf{k}$$

where **i**, **j**, and **k** are unit vectors in the *x*, *y*, and *z* directions, respectively. Similar forms can be written for the forces **G** and **H**. The resultant or sum of the three forces **F**, **G**, and **H** is obtained by adding corresponding components of the forces. Thus, the resultant, **R**, is given by

$$\mathbf{R} = R_x \mathbf{i} + R_y \mathbf{j} + R_z \mathbf{k}$$

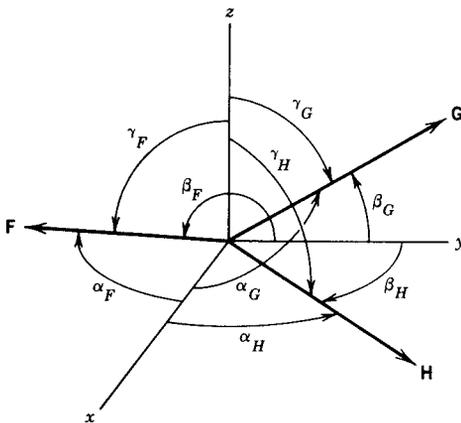

Fig. 6 Direction angles.

where

$$R_x = F_x + G_x + H_x$$

$$R_y = F_y + G_y + H_y$$

$$R_z = F_z + G_z + H_z$$

Nature of Resultant of Concurrent Forces The resultant of any system of concurrent forces that are not in equilibrium is a single force.

2.3 Moments and Couples

Moment (or Torque) of a Force about a Point *Moment*, or *torque*, of a force about a point is the product of the force magnitude and the distance from the point to its action line. This perpendicular distance is called the *arm* of the force, and the point is the *origin* or *center of moments*. The product is the measure of the rotational tendency of the force. The name of the unit of moment is a combination of the names of force and distance units, as foot-pound, inch-ton, and so on. (Some writers use pound-foot as a unit of moment of a force to distinguish from foot-pound as the unit of work or energy, similar distinction being made for the other units.)

The computation of moments is most easily carried out by introducing a coordinate system and then taking the vector cross product,

$$\mathbf{M} = \mathbf{R} \times \mathbf{F}$$

where **R** is the vector from the reference point to the point of action of the force and **F** is the vector representation of the force in the same coordinate system. The moment vector **M** is perpendicular to the plane of **R** and **F**. This vector operation, in effect, takes into account the angle between **R** and **F** and can be used in two- and three-dimensional situations.

Moment (or Torque) of a Force about a Line

The moment of a force **F** about a line is most easily calculated using vectors. Let *O* be any point on the line and let *A* be any other point on the line. Let *P* be the point of application of the force **F**. The moment of the force **F** about the line *OA* measures the torque of the force about the axis *OA*. In order to calculate this torque, it is most convenient to break **F** into two components, with one of the components parallel to *OA*. The component of **F** parallel to *OA* does not exert a torque around the axis *OA*. Thus, the torque of the force **F** around the axis *OA* can be written as

$$\mathbf{M} \text{ (about } OA) = \mathbf{R} \times (\mathbf{F} - \mathbf{F} \cdot \mathbf{U}_{OA})$$

where **R** is the vector from *O* to *P*, **F** is the force vector, and **U**_{*OA*} is a unit vector directed along the axis *OA*. The quantity **F** · **U**_{*OA*} is the component of **F** parallel to the axis *OA*.

Principle of Moments

For a Point. The moment of the resultant of any set of forces about a point is the vector sum of the moments of the individual forces about the point.

For an Axis. The moment of the resultant of any set of forces about an axis is the vector sum of the moments of the individual forces about the axis.

Couples

Nature of Couples. Two equal and parallel forces of opposite sense are called a couple. The tendency of a couple is to produce rotation only. Since a couple has no single resultant, no single force can balance it. To prevent the rotation of a body acted upon by a couple, the application of two other forces is required, forming a second couple.

The arm of a couple is the perpendicular distance between the lines of action of the forces. The moment of a couple is constant and independent of the origin of moments; it is equal to one of the forces times the arm of the couple. Its sense is positive or negative according as rotational tendency is counterclockwise or clockwise. Couples of equal moments, in the same or parallel planes, are *equivalent* and may be replaced one by the other. Further, the *center of rotation* for a couple may be anywhere in its plane. Hence, a couple may be turned about in its own plane or moved to a parallel plane or replaced by another couple (having an arm of any given length but the same moment) without altering its effect on a rigid body.

Resultant of Couples. The resultant of any number of coplanar couples is a couple. Its moment and sense are determined by the algebraic sum of the moments of the individual couples.

In vector form, the moment of a couple can be calculated by choosing a point O on the line of action of one of the forces and determining the moment of the other force of the couple about that point. Thus, the moment of a couple is calculated from

$$\mathbf{M} = \mathbf{R} \times \mathbf{F}$$

The resultant of any number of couples is the vector sum of the moments of the individual forces (each calculated as shown), and this resultant is itself a couple.

Composition of Single Force and Couple. A single force and couple in the *same plane* (or *parallel planes*) may be composed into *another* single force equal and parallel to the original force, at a distance from it equal to the moment of the couple divided by the magnitude of the force and so situated that the moment of the resultant about the point of application of the original force is of the same sign as the moment of the couple. The couple may be brought into the position shown in Fig. 7. The resultant of P , $-Q$, and

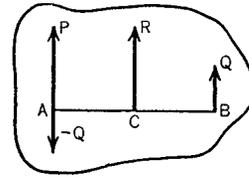

Fig. 7 Composition of a force and a couple.

Q is $R (= P)$ acting in a line through point C so that $(P - Q) \times AC = Q \times BC$. From this it follows that

$$AC = \frac{Q(AC + BC)}{P} = \frac{\text{moment of couple}}{P}$$

Resolution into Single Force through Chosen Point and Couple.

A single force may be resolved into another single force acting through a *chosen point and a couple* (the new force being equal and parallel to the original force). In Fig. 8, P_1 is the given force and O the chosen point. Through O apply a pair of forces, opposite in sense, equal and parallel to P_1 . As P_2 and P_3 balance, no change is produced in the motion of the body due to the addition. P_1 and P_3 constitute a couple of moment $P \times a$, which is the same as moment of P_1 about O ; P_2 is a force just like P_1 but acting through the chosen point O .

2.4 Addition of Nonconcurrent Forces and Moments

The addition of nonconcurrent forces involves the determination of the force and moment resultants of the forces. The procedure requires that a reference point O for the moments be defined and that all position vectors and force vectors be written in terms of vector components. The procedure works for all force and moment sets:

Force Resultant. The force resultant of a set of nonconcurrent forces is the vector sum of the individual forces:

$$\mathbf{R} = \sum_{i=1}^n \mathbf{F}_i = \sum_{i=1}^n (F_{ix})\mathbf{i} + \sum_{i=1}^n (F_{iy})\mathbf{j} + \sum_{i=1}^n (F_{iz})\mathbf{k}$$

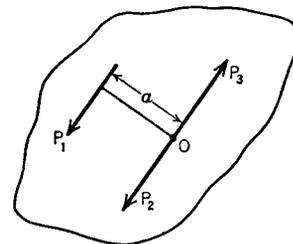

Fig. 8 Resolution of a force into a force plus couple.

Moment Resultant. The moment resultant of a set of nonconcurrent moments about a point O is the vector sum of the moments of the individual forces about O :

$$\mathbf{M} = \sum_{i=1}^n \mathbf{M}_i = \sum_{i=1}^n (\mathbf{r}_i \times \mathbf{F}_i)$$

2.5 Principles of Equilibrium

Forces in Equilibrium. A system of forces is in equilibrium if their combined action produces no change in motion of the body to which they are applied. There is no change in motion if the body remains at rest or moves in a straight line at constant speed. When a force system is in equilibrium, its resultant must be zero. This statement may be called the *general condition of equilibrium*. It implies both zero force and zero couple.

In all cases, the conditions of equilibrium can be written in vector form as

$$\sum \mathbf{F} = 0 \quad \sum \mathbf{M} = 0$$

and in scalar form in rectangular Cartesian coordinates as

$$\begin{aligned} \sum F_x &= 0 & \sum M_x &= 0 \\ \sum F_y &= 0 & \sum M_y &= 0 \\ \sum F_z &= 0 & \sum M_z &= 0 \end{aligned}$$

Note: If a problem is planar (e.g., in the xy plane), then the force equation in the z direction and the moment equations in the x and y directions are identically zero and may be ignored.

Body in Equilibrium. A rigid body is in equilibrium if it remains at rest or moves in a straight line at constant speed, that is, if its state of motion does not change. This condition obtains if all the external forces acting upon it (including those due to pull of gravity, friction, etc.) form a system in equilibrium.

Conditions of Equilibrium In a problem in statics a body is known to be in equilibrium; hence the system composed of all the external forces acting upon it must be in equilibrium. In such a case, tests are not needed to ascertain if equilibrium exists, but they are used to set up relations involving unknown forces, distances, or angles, and the unknown elements are then computed provided their number does not exceed the number of independent equations that may be set up by means of the equilibrium conditions. When the number of unknown elements exceeds the number of independent equations, the problem is said to be statically indeterminate.

Special Conditions. If three forces are in equilibrium, they must be coplanar and concurrent or parallel; if concurrent, each force is proportional to the sine of the angle between the other two; if parallel, each force is proportional to the distance between the other two. If a force system is in equilibrium, the resultant of any part must balance the resultant of the other part. It follows that if four coplanar nonconcurrent nonparallel forces are in equilibrium, the resultant of any two is concurrent with the other two.

Stability of Equilibrium. When a body (or collection of bodies) is in equilibrium and the state is such that when displaced slightly in any way the body returns of itself to its original position, the equilibrium is *stable*; when displaced slightly the body moves further from its original position, the equilibrium is *unstable*; and when displaced slightly it remains in that displaced position, the equilibrium is *neutral* or *indifferent*. The body or collection is also said to be stable, unstable, or neutral (or indifferent) under these respective conditions. When the body is stable or unstable, the system of forces is changed by the slight displacement and is no longer in equilibrium—hence the further displacement. Only when the stability is neutral is the equilibrium of the force system undisturbed by a slight displacement of the body.

2.6 Equilibrium Problems

General Principles

1. It frequently happens that the external force system acting on a body as a whole cannot be solved directly owing to the presence of more unknown elements (forces, distances, and angles) than there are conditions of equilibrium. In such cases, endeavor to separate the original body into simpler parts that will permit solutions, making use of the unknowns thus determined in solving the force systems acting on other sections until the complete solution, if obtainable, has been found.

2. To facilitate computations, it is desirable if resolution equations are used, to resolve perpendicular to one of the unknown forces; if a moment origin is used, to select it on the action line of an unknown force; if moment axes are used, to select them so as to intersect some of the unknown forces.

3. Assume senses for unknown forces. A plus answer then indicates the sense to have been correctly assumed; a minus answer, incorrect assumption.

4. When force polygons are used, letter action lines of wholly known forces first and those of the remainder last. Draw the force polygon to the end of the last known vector. Vectors required to close it (remembering that the senses must read confluent! from the starting point back to the same point) determine unknown magnitudes and senses and/or lines of action.

Typical Problems

I. System of Coplanar Concurrent Forces in Equilibrium. In this system all forces are known except two whose action lines only are known. The magnitudes and senses of these two forces are to be determined.*

Example 1. Two smooth cylinders rest upon a 30° plane and against a vertical wall as shown in Fig. 9. Determine all forces acting on each cylinder (a) The forces involved are 100 lb, 200 lb, P , Q , R , and S , the last four being normal to the surfaces of contact (smooth surfaces). (b) Consider the two cylinders as a single free body. The external force system is 100 lb, 200 lb, P , R , and S (Q_1 and Q_2 are internal). The system is nonconcurrent and so does not come under a typical problem I. Consider the large cylinder as a free body. The external force system is 100 lb, Q , R , and S . While this system is concurrent, it cannot be solved because there are more than two unknown quantities. Next consider the small cylinder as a free body. The force system is 200 lb, P , and Q , and this is a typical problem I.

Algebraic Solution. Choose X and Y directions parallel and perpendicular to the plane. $\sum F_x = 0 = Q_1(\sqrt{60}/8) - 200 \sin 30^\circ$. Hence $Q_1 = 800/\sqrt{60} = 103.3$ lb. $\sum F_y = 0 = P - 200 \cos 30^\circ - 103.3 \times 2/8$. Hence $P = 199$ lb. Consider the large cylinder as a free body. $Q_1 = Q_2 = 103.3$ lb. Use the same X and Y directions. $\sum F_x = 0 = S \cos 30^\circ - 103.3 \times (\sqrt{60}/8) - 100 \sin 30^\circ$. Hence, $S = 173.2$ lb. $\sum F_y = 0 = R - 100 \cos 30^\circ - 173.2 \sin 30^\circ + 103.3 \times 2/8$. Hence $R = 147.4$ lb.

II. System of Coplanar Parallel Forces in Equilibrium. In this system all forces are known except two whose action lines only are known. The magnitudes and senses of these two forces are to be determined.

Example 2. A beam is loaded as shown in Fig. 10 and supported at the points P and Q . Determine the

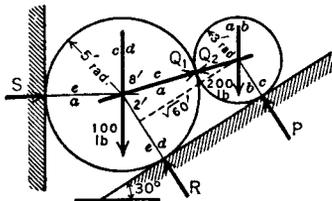

Fig. 9 Space diagram of cylinders.

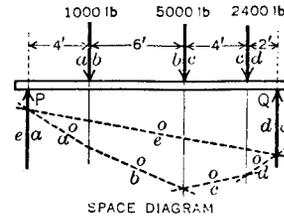

Fig. 10 Space diagram of beam.

reactions of the supports. Consider the beam as a free body. The external force system consists of the forces 1000 lb, 5000 lb, 2400 lb, P , and Q . This is a coplanar parallel system and is a typical problem II.

Algebraic Solution. Assume senses for the reactions,

$$\sum M_p = 0 = -4 \times 1000 - 10 \times 5000 - 14 \times 2400 + 16Q$$

Hence $Q = 5475$ lb; the correct sense was assumed,

$$\sum M_q = 0 = 2 \times 2400 + 6 \times 5000 + 12 \times 1000 - 16P$$

Hence $P = 2925$ lb; the correct sense was assumed. As a check, apply a third equilibrium condition,

$$\sum F = 0 = -2925 + 1000 + 5000 + 2400 - 5475$$

III. System of Coplanar Nonparallel Nonconcurrent Forces in Equilibrium. In this system all forces are known except two, of which the action line of one and a point in the action line of the other are known. The magnitude and sense of the one and the magnitude, sense, and angular direction of the other are to be determined.†

Example 3. A roof truss is loaded as in Fig. 11. The left end of the truss rests on a smooth horizontal support. The right end is secured to a wall by means of a pin. Determine the reactions. The external forces acting on the truss are the given loads, the left reaction P (vertical, on account of the smooth support), and the right reaction Q (inclined, through point M). The unknown quantities are the reactions P and Q . This is a typical problem III.

*This is a common problem in the determination of the stresses of a roof or bridge truss.

†This is a common problem in the determination of the reactions on a roof truss sustaining wind pressures, the truss being fixed at one end and resting on rollers at the other.

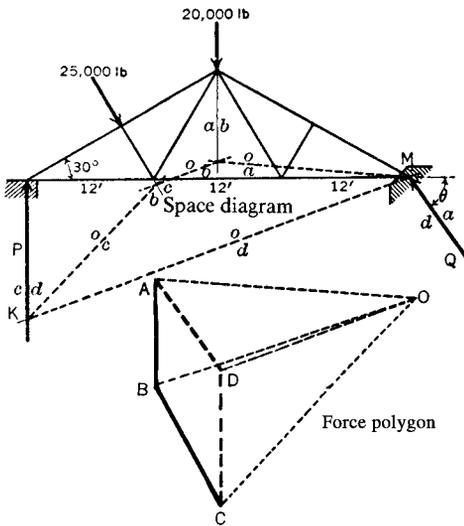

Fig. 11 Space diagram of roof truss.

Algebraic Solution. Assume P upward,

$$\sum M_M = 0 = 20,000 \times 18 + 25,000 \times 24 \cos 30^\circ - 36P$$

hence, $P = 24,430$ lb; the correct sense was assumed.

Assume Q upward to the left at angle θ with horizontal,

$$\sum F_x = 0 = 25,000 \sin 30^\circ - Q \cos \theta$$

$$\sum F_y = 0 = -25,000 \cos 30^\circ - 20,000 + 24,430 + Q \sin \theta$$

Solving simultaneously, $Q = 21,300$ lb and $\theta = 54^\circ$. Sense and direction were correctly assumed; hence Q acts upward to the left at 54° to the horizontal. As a check, apply condition $\sum M_P = 0$,

$$\sum M_P = 0 = -25,000 \times 12 \cos 30^\circ - 20,000 \times 18 + 21,300 \times 36 \sin 54^\circ$$

Graphic Solution. ab and bc are the action lines of the given loads, cd of the reaction P , and da of the reaction Q . Draw the vectors AB and BC and a line through C parallel to cd . Choose a pole and draw the rays. Construct the funicular polygon, drawing oa through M , and draw closing string od from K to M . Draw OD through O parallel to od to intersect CD at D . Draw DA . Vectors CD and DA represent the two

unknown forces $P = 24,430$ lb and $Q = 21,300$ lb. The action line of Q is da , making the angle with the horizontal 54° .

Special Case. A case coming under the preceding classification that requires a variation in treatment when employing the graphic method is one in which the action lines of all three forces are known but their magnitudes and senses are unknown. The procedure is in general similar to methods employed before except that, in the graphic solution, two of the unknown forces that are concurrent must be replaced by their unknown resultant acting through their point of concurrency along an unknown action line. After the magnitude and sense of this resultant have been determined (by the method employed in Example 3), it is resolved into its two components along the action lines of the two unknown forces that it had replaced. These components represent the magnitudes and senses of this pair of forces.

IV. System of Noncoplanar Nonparallel Nonconcurrent Forces in Equilibrium. In this system one force is completely known and action lines (or a point in the action line) of the others are known. All unknown force magnitudes, action lines, and senses are to be determined.

Example 4. The crane (Fig. 12) is supported by a socket at the foot of the post at D , is kept from overturning by the backstays AB and AC , and carries a load of 600 lb (E, A, F, G, D are in the vertical XY plane). Determine the axial components of the reaction of the post at D and the tensions in the backstays. The external forces acting on the post are the load, the reaction at D , and the tensions in the backstays at A . This is a typical problem IV. Moment equations are the most convenient to apply for this solution:

$$\sum M_{BC} = 0 = 600 \times 40 - 20D_y \quad D_y = 1200 \text{ lb}$$

$$\sum M_{ZA} = 0 = 600 \times 20 - 16D_x \quad D_x = 750 \text{ lb}$$

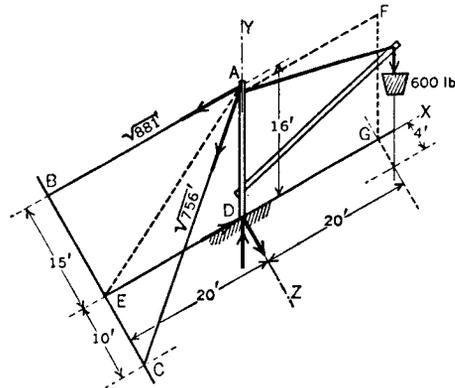

Fig. 12 Space diagram of truss.

$$\begin{aligned}\sum M_{X_A} = 0 &= 600 \times 4 - 16D_z & D_z &= 150 \text{ lb} \\ \sum M_{X_C} = 0 &= AB \times \frac{16}{\sqrt{881}} \times 25 & AB &= 622 \text{ lb} \\ &\quad - 1200 \times 10 + 600 \times 6 \\ \sum M_{X_B} = 0 &= AC \times \frac{16}{\sqrt{756}} \times 25 & AC &= 452 \text{ lb} \\ &\quad + 600 \times 19 - 1200 \times 15\end{aligned}$$

The senses of all forces are as shown in Fig. 12.

Truss Analysis A *truss* is a framework* for carrying loads, each *member* of which is subjected only to tension or compression loads. The members are usually pin jointed with loads applied only at the joints.

The *stress in a member* at any section is the force that either of its two parts exerts internally on the other part as a result of the external forces acting on the member. Longitudinal stresses, like external longitudinal forces, may be either tensile or compressive.

The *analysis of a truss* under a given loading condition refers to the determination of the stresses in its members due to the loads.

Analysis by Method of Sections. First, determine the reactions on the truss due to the loads; second, imagine the truss separated into two distinct parts (i.e., pass a section through the truss) so that the member under consideration is one of the members cut and so that the system of forces, including stresses, acting on either part of the truss is solvable for the desired stress; third, solve the system.

To *pass the section*, suppose the stress in *HI* (Fig. 13a) is required, the truss being supported at its ends and bearing five loads *L* and one *P*, and suppose the reactions determined. Trying section 1-1, the force system on the left part of the truss (Fig. 13b) is a nonconcurrent one of seven forces and includes four unknown stresses *S*₁, *S*₂, *S*₃, and *S*₄; it is not solvable

for the desired stress *S*₁. Trying section 2-2, the force system on the lower part (Fig. 13c) is a concurrent one and includes four unknown stresses *S*₁, *S*₂, *S*₅, and *S*₆; it is not solvable. Trying section 3-3, the force system on the left part (Fig. 13d) is nonconcurrent with three unknown stresses *S*₁, *S*₇, and *S*₈; it is solvable. In some instances different sections may be used, each leading to a solution.

*S*₁ having been determined, the force system of Fig. 13b becomes solvable, and then, with *S*₂ also determined, the force system of Fig. 13c may be solved.

Algebraic Solution. Following the general method of procedure outlined above, determine the various stresses by employing algebraic conditions of equilibrium in manners similar to those illustrated in Section 2.6.

In making the *imaginary separations of the truss*, care should be taken to cut not more than three members in which the stresses are unknown. It is advantageous to make the separation so that not more than two such members are cut. If this is done, a single force polygon will determine the two unknowns, whereas if three are cut, a force polygon and an equilibrium polygon, or the equivalent, are necessary for determining the three unknowns.

Analysis by Method of Joint Resolution.[†] Consider the pin at each joint as a body acted upon by forces in equilibrium.

Algebraic Solution. Determine the various stresses by employing algebraic conditions of equilibrium in manners similar to those illustrated in Section 2.6.

Graphic Solution. For each joint, draw the force polygon. In doing so, it will be advantageous to represent the forces in the order in which they occur about the joint. A force polygon so drawn will be called a polygon for the joint; for brevity, if the order taken

**Redundant frames* (i.e., ones having more members than necessary to preserve their shapes under the loading conditions) are not considered in this section, since the stresses in them cannot be determined by elementary static methods.

[†]This method is not usually so convenient for determining algebraically the stress in a single specific member.

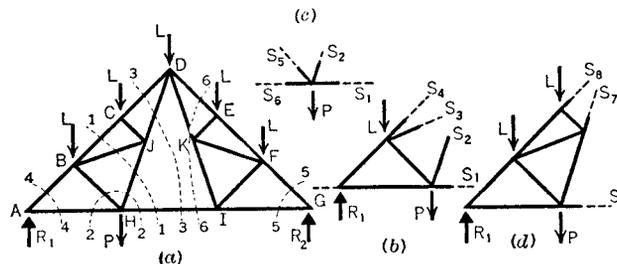

Fig. 13 Truss sections.

is clockwise, the polygon will be called a clockwise polygon, and if counterclockwise, it will be called a counterclockwise polygon. If the polygons for all the joints of a truss are drawn separately, the stress in each member will have been represented twice. It is possible to combine the polygons so that it will not be necessary to represent the stress in any member more than once, thus reducing the number of lines to be drawn. Such a combination of force polygons is called a *stress diagram*. Each triangular space in the truss diagram is marked by a small letter; also the space between consecutive action lines of the loads and reactions. Then the two letters on opposite sides of any line serve to designate that line, and the same large letters are used to designate the magnitude of the corresponding force.

To construct a stress diagram for a truss under given loads: (a) Determine the reactions. (b) Letter the truss diagram as directed. (c) Construct a force polygon for all the external forces applied to the truss (loads and reactions), representing them in the order in which their application points occur about the truss, clockwise or counterclockwise. (d) On the sides of that polygon construct the polygons for all the joints. They must be clockwise or counterclockwise according as the polygon for the loads and reactions was drawn clockwise or counterclockwise. (The first polygon drawn must be for a joint at which only two members are fastened; the joints at the supports are usually such. Next, that joint is considered, and its polygon is drawn, at which not more than two stresses are unknown.)

Example 5. Figure 14 represents a roof truss sustaining loads of 600, 1000, 1200, and 1800 lb; the right reaction is 2100 lb, and the left 2500 lb. *ABCDEF* is a polygon for the loads and reactions, these being represented in the order in which their points of application occur about the truss. The polygon for joint 1 is *FABGF*; the force *BG* acts toward the joint, hence *bg* is under compression, and *GF* acts away from the joint, hence *gf* is in tension. The polygon for joint 2 is *CDEHC*; the force *EH* acts away

from the joint, hence *eh* is in tension; and *HC* acts toward the joint, hence *hc* is in compression. The polygon for joint 3 is *HEFGH*; the force *GH* acts away from the joint and hence *gh* is in tension. If the work has been done correctly, *GH* is parallel to *gh*. (In Fig. 14*a* all the polygons are clockwise, and in Fig. 14*b* counterclockwise.)

2.7 Center of Gravity

Definitions The *centroid* of a system of parallel forces having fixed application points is the point through which their resultant will always pass regardless of how the forces may be turned, provided they remain parallel.

The *center of gravity* of a body* or system of bodies is the *centroid of the forces of gravitation*† acting upon all the particles thereof. Referring the application points of such a force system to a set of coordinate axes, the coordinates of the centroid, or center of gravity (CG), are

$$\bar{x} = \frac{\sum F_i \cdot x_i}{\sum F_i} = \frac{\int x dF}{F}$$

$$\bar{y} = \frac{\sum F_i \cdot y_i}{\sum F_i} = \frac{\int y dF}{F}$$

$$\bar{z} = \frac{\sum F_i \cdot z_i}{\sum F_i} = \frac{\int z dF}{F}$$

in which F_i represents the force on (or weight of) one particle and x_i, y_i, z_i are the coordinates of its application point. If a group of bodies is involved, the coordinates of the center of gravity of the group are

$$\bar{x} = \frac{\sum W_i \cdot \bar{x}_i}{\sum W_i} \quad \bar{y} = \frac{\sum W_i \cdot \bar{y}_i}{\sum W_i} \quad \bar{z} = \frac{\sum W_i \cdot \bar{z}_i}{\sum W_i}$$

in which W_i represents the weight of one body and $\bar{x}_i, \bar{y}_i, \bar{z}_i$ are the coordinates of its center of gravity.‡ A body (or system of bodies), if supported at its center of gravity, will remain at rest in any position.

The center of gravity of part of a body may be located by the rule that its moment, with respect to any plane, equals the moment of the whole minus, algebraically, the moment of the remainder.

The center of gravity of a line, surface, or volume is that point that would be the center of gravity if

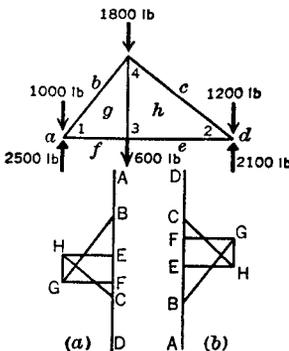

Fig. 14 Roof truss/polygon solution.

*Sometimes called *center of mass* or *center of inertia*.

†For practical purposes, the forces of gravitation may be considered as parallel.

‡As F (in the gravitational system of units) equals W , these symbols may be used interchangeably in the two sets of formulas. Also, any one of the expressions may be read as “the sum of the moments divided by the sum of the forces (or weights).”

the line were replaced by a homogeneous rod of infinitesimal diameter, the surface by a homogeneous plate of infinitesimal thickness, or the volume by a homogeneous body.

Symmetry. Two points are symmetrical with respect to a third point if the line joining the two is bisected by the third. Two points are symmetrical with respect to a line or a plane if the line joining them is perpendicular to the given line or plane and is bisected by it. A body, line, surface, or volume is symmetrical with respect to a point, a line, or a plane if all the points of the body, line, surface, or volume can be paired so that each pair is symmetrical with respect to the point, line, or plane. If a homogeneous body or a line, surface, or volume is symmetrical with respect to a point, line, or plane, its center of gravity is at the point, in the line, or in the plane.

The *static moment* of a body (having weight), a line (having length), a surface (having area), or a solid* (having volume) with respect to any plane is the product of the weight, length, area, or volume and the distance of the center of gravity of the body, line, surface, or solid from the plane. The static moment of a plane line or plane surface with respect to a straight line in the plane is the product of the length or area and the distance of the center of gravity of the line or surface from the reference line. A static moment is regarded as positive or negative according as the corresponding center of gravity is on the positive or negative side of the reference plane or line.

Determination of Center of Gravity Location

When practicable, determination of center of gravity location by algebraic or integration methods, based on dividing the sum of the moments by the sum of the forces, is generally the simplest process. For some bodies of nonhomogeneous nature or of very irregular shape, one of the following methods of procedure may be necessary or at least preferable:

Graphic Method. For application to plane figures[†] Referring to Fig. 15, take a point O and a line bb on opposite sides of the figure at any convenient distance m apart; project any width of the figure parallel to bb as aa on bb , connect the projections bb with O , and note the intersections cc ; determine other points cc and draw a smooth curve through them as shown; measure the area A' within the curve cc ; then $A'm$ is the static

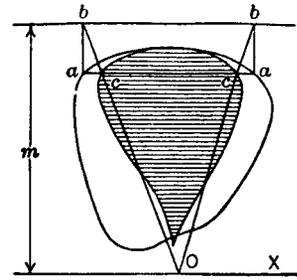

Fig. 15 Center-of-gravity determination.

moment of the given figure with respect to OX ; if A is the area of the given figure and y the distance of its center of gravity from OX , $y = A'm/A$. In a similar way the distance of the center of gravity from a line perpendicular to OX can be determined and its exact position thus definitely located.

Suspension Method. For application to plane figures[‡] Suspend the body (or a model representing it) from a point near its edge and mark on it the direction of a plumb line hung from that point. Repeat this operation using a second suspension point. The center of gravity is at (or behind) the intersection of the two markings.

Weighing Method. Generally applied where location of the center of gravity in one plane only is required. Determine weight \bar{W} of the body and then support it on a knife edge (Fig. 16) and on a point support resting upon a platform scale. Weigh reaction R of the point support and measure the horizontal distance a between the point and the knife edge. Then the horizontal distance from the knife edge to the center of gravity is $\bar{x} = Ra/W$.

Balancing Method. For general application. Balance the body (or a model representing it) on a straightedge, marking on the body the vertical plane containing the edge. Repeat for two more balancing positions of the body. The center of gravity is at the point common to the three planes thus determined.

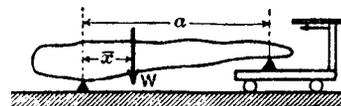

Fig. 16 Weighing/knife edge method.

*Herein the word "solid" denotes "that which has volume." Care should be taken to distinguish this from a "body," which has "mass" (as well as "volume"). Some writers use the word solid to denote at various times either volume or mass, which is sometimes confusing. In this section, the word volume is frequently used even in preference to solid to avoid the possibility of confusion with mass.

[†]Including areas or flat homogeneous bodies of uniform thickness.

[‡]Including areas or flat bodies of uniform homogeneous thickness.

2.8 Moment of Inertia

Plane Surfaces — Definitions The *moment of inertia* of a plane surface (or figure) with respect to (or about) a line (or axis) is the sum of the products obtained by multiplying the area of each element of the surface by the square of its distance from the line*. Letting I_x denote the moment of inertia about an X axis,

$$I_x = \int y^2 dA$$

in which A is the total area and y is the perpendicular distance of any element of area dA from the axis. The moment of inertia of a surface is obviously the sum of the moments of inertia of its parts. The moment of inertia of a plane surface is *rectangular* if the axis used is *in* the plane of the area; it is *polar* if the axis is *perpendicular* to the plane of the area.

The *radius of gyration* of a plane surface with respect to a line is the length whose square multiplied by the area of the surface equals the moment of inertia of the surface with respect to the line. Letting k denote the radius of gyration,

$$I = k^2 A \quad \text{or} \quad k = \sqrt{I/A}$$

in which I is the moment of inertia and A the area.

The *product of inertia* of a plane surface with respect to a pair of coordinate axes in the plane is the algebraic sum of the products obtained by multiplying the area of each element of the surface by its coordinates† Letting U_{xy} denote the product of inertia with respect to X and Y axes,

$$U_{xy} = \int xy dA$$

in which A is the total area and x and y are the coordinates of any element of area dA .

The *principal axes of inertia* of a plane surface at a particular point in the plane are the two axes about which the moments of inertia are greater and less than for any other axis through the point in the plane.‡ The corresponding moments of inertia are called the *principal moments of inertia* of the surface at the point.

*Moment of inertia is always positive and never zero. Product of inertia may be positive, zero, or negative, depending on the distribution of the area with respect to the axes. If a surface has an axis of symmetry, its product of inertia with respect to that axis and one perpendicular thereto is zero.

†In certain special cases, as for axes through the point in the center of a circular area, the moment of inertia is the same for any axis and therefore there is no principal axis through that point.

‡If U_{xy} and $I_y - I_x$ are both zero, there is no principal axis through the point.

The principal axes are always at right angles to each other. The product of inertia with respect to them is zero.

The *customary engineer's unit* for both moment and product of inertia of a surface is biquadratic inches (in.⁴).

Determination of Moment of Inertia of Plane Surfaces When practicable, determination of moment of inertia with respect to an axis by algebraic or integration methods is generally the simplest process. For some surfaces of very irregular shape, the following graphic method of procedure may be necessary or at least preferable.

Graphic Method. Let $aaaa$ (Fig. 17) be the outline and XX' the axis with respect to which the moment of inertia is desired; at any convenient distance m from XX' draw two parallels (but if XX' does not cut the figure only one parallel, the one on the opposite side of the figure from XX'); draw any line as aa parallel to XX' and project the points aa on the nearer parallel; join the projections bb to any point O in XX' , and note the intersections cc on aa ; project cc on the same parallel; join the projections dd with O , and note the intersections ee on aa . In a similar manner determine points like ee for other widths like aa , and connect all points e as shown. Then measure the area of the loops OPO and OQO ; denoting this combined area by A'' , $I = A''m^2$. (There will be only one loop if only one parallel bb is used.)

Transformation Formulas — Plane Surfaces

Parallel-Axes Theorems. Let I = moment of inertia (either rectangular or polar) of a plane figure with respect to any line or axis, \bar{I} = that with respect to a parallel axis passing through the center of gravity of the figure, d = distance between the axes, k , k = radii of gyration with respect to the same area, respectively, and A = area of the figure; then

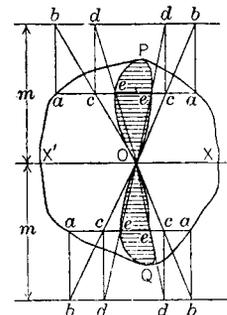

Fig. 17 Moments of inertia/graphic method.

$$I = \bar{I} + Ad^2 \quad \text{and} \quad k^2 = \bar{k}^2 + d^2$$

These show that with respect to all parallel axes the moment of inertia and the radius of gyration are least for the one passing through the center of gravity of the figure

Similarly, let U = product of inertia of a plane figure with respect to a pair of coordinate axes in the plane and \bar{U} = that with respect to a parallel pair whose origin is at the center of gravity; \bar{x}, \bar{y} the coordinates of the center of gravity referred to the first pair, and A the area of the figure then $U = \bar{U} + A\bar{x}\bar{y}$.

Relation of Rectangular and Polar Moments of Inertia. Let I_x, I_y, J_z = moments of inertia of a plane figure with respect to $x, y,$ and z axes, respectively, the axes being at right angles to each other and the x and y axes in the plane; and let k_x, k_y, k_z = corresponding radii of gyration; then $J_z = I_x + I_y, k_z^2 = k_x^2 + k_y^2$.

Rotated-Axes Theorem. Let XOY and UOV (Fig. 18) be two sets of rectangular coordinate axes with a common origin and in a given plane figure; I_x, I_y, I_u, I_v = moments of inertia of the figure with respect to $x, y, u,$ and v axes, respectively; U_{xy}, U_{uv} = its products of inertia with respect to the sets of axes, respectively; α = angle through which x axis must be rotated to bring it into u axis, regarded as positive or negative according as the turning is counterclockwise or clockwise. Then $I_u + I_v = I_x + I_y$ and

$$I_u = I_x \cos^2 \alpha + I_y \sin^2 \alpha - U_{xy} \sin 2\alpha$$

$$U_{uv} = \frac{1}{2}(I_x - I_y) \sin 2\alpha + U_{xy} \cos 2\alpha$$

If OU and OV are principal axes (see definition already given), $U_{uv} = 0$ and therefore $\tan 2\alpha = 2U_{xy}/(I_y - I_x)$. Hence, the principal axes of a figure at a point can be readily found if the moments of inertia and the product of inertia of the figure with respect to two rectangular axes through the point and in the plane are known. The principal moments of inertia are then I_u from the preceding formula and I_v from the same formula after replacing α by $\alpha + \pi/2$. As a check, $I_u + I_v = I_x + I_y$.

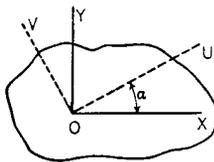

Fig. 18 Rotated-axes theorem.

Graphic Transformations — Plane Surfaces The *inertia circle* is a device for determining *graphically*, the moment of inertia of a plane figure with respect to any line of the plane through a given point and the principal axes and principal moments of inertia for the same point. To construct the circle, it is necessary to know the moments of inertia and the product of inertia with respect to two rectangular axes through the point in the plane figure. Suppose $I_x, I_y,$ and U_{xy} given for the shaded area in Fig. 19. To convenient scale, plot OX' and OY' to represent I_x and I_y and $Y'A$ to represent U_{xy} (downward if negative and upward if positive). Center C is midway between X' and Y' . With CA as radius, describe the inertia circle. To find I_u , draw chord AB parallel to axis OU ; draw perpendicular BU' . OU' (to scale) = I_u , and BU' (to scale) = U_{uv} . OM , parallel to $A2$, is axis of least I ; and a parallel to $A1$, through O , is axis of greatest I . $O2$ (to scale) is the value of least $I = I_2$; and $O1$, value of greatest $I = I_1$. Least radius of gyration for an axis through point $O = \sqrt{I_2/\text{area}}$.

Bodies — Definitions The moment of inertia of a body with respect to (or about) a line (or axis) is the sum of the products obtained by multiplying the mass of each elementary part by the square of its distance from the line.* Letting I_x denote the moment of inertia about an X axis,

$$I_x = \int y^2 dm$$

in which m is the total mass and y is the perpendicular distance of any element of mass dm from the

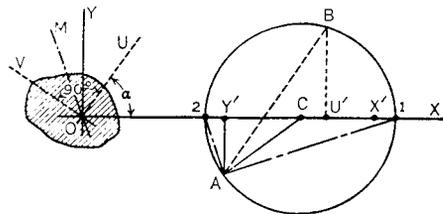

Fig. 19 Inertia circle.

*Moment of inertia is always positive and never zero. Product of inertia may be positive, zero, or negative, depending on the distribution of the mass with respect to the coordinate planes. If a body has a plane of symmetry, its product of inertia with respect to that plane and one perpendicular thereto is zero.

axis.* The moment of inertia of a body is obviously the sum of the moments of inertia of its parts.

The *center of gyration* of a body with respect to a line is a point at such a distance from the line that, if the entire mass of the body were concentrated there, its moment of inertia would be the same as that of the body.

The **radius of gyration of a body** with respect to a line is the distance from the center of gyration to the line. Letting k denote the radius of gyration,

$$I = k^2 m \quad \text{or} \quad k = \sqrt{\frac{I}{m}}$$

in which I is the moment of inertia and m the mass.

The **product of inertia of a body** with respect to a pair of coordinate planes is the algebraic sum of the products obtained by multiplying the mass of each element of the body by its coordinates with reference to those planes. Thus with respect to YOZ and ZOX (Fig. 20), ZOX and XOY , and XOY and YOZ planes, the products of inertia are, respectively,

$$U_{xy} = \int xy \, dm \quad U_{yz} = \int yz \, dm \quad U_{zx} = \int zx \, dm$$

Principal Axes of Inertia of a Body at a Particular Point.

The values of moments of inertia of a body for all axes through a given point are in general unequal; for one axis the moment of inertia is greater and for another it is less than for any other axis through the point. These two axes are at right angles, and they together with one at right angles to their plane and passing through the point are *principal axes of inertia* of the body at the point; the corresponding moments of inertia are the *principal moments of inertia* of the body at the point. If the point is the center of gravity of the body, the axes and moments are called *central principal axes* and *central principal moments of inertia*. For a set of principal axes, the

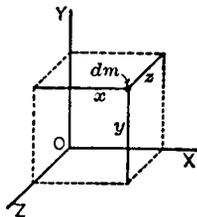

Fig. 20 Products of inertia.

three products of inertia, with respect to the *principal planes* determined by them, are zero.

The **customary engineer's unit** for both moment and product of inertia is slug-ft.²

Transformation Formulas – Bodies

Parallel-Axes Theorems. Let I = moment of inertia of a body with respect to any line or axis, \bar{I} = that with respect to a parallel axis passing through the center of gravity of the body, d = distance between the axes, k, \bar{k} = radii of gyration with respect to the same axes, respectively, and m = mass of the body; then

$$I = \bar{I} + md^2 \quad \text{and} \quad k^2 = \bar{k}^2 + d^2$$

Rotated-Axes Theorems. Let $I_x, I_y,$ and I_z denote the moments of inertia of a body with respect to rectangular axes $x, y,$ and $z,$ respectively; $U_{xy}, U_{yz},$ and U_{zx} its products of inertia with respect to yz and zx planes, zx and xy planes, and xy and yz planes, respectively; I the moment of inertia of the body with respect to a line through the origin of coordinates having direction angles $\alpha, \beta,$ and $\gamma;$ then

$$I = I_x \cos^2 \alpha + I_y \cos^2 \beta + I_z \cos^2 \gamma - 2U_{yz} \cos \beta \times \cos \gamma - 2U_{zx} \cos \gamma \cos \alpha - 2U_{xy} \cos \alpha \cos \beta$$

If $U_{xy} = U_{yz} = 0,$ the y axis is a principal axis at the origin. If $U_{yz} = U_{zx} = 0,$ the z axis is a principal axis at the origin. If $U_{zx} = U_{xy} = 0,$ the x axis is a principal axis at the origin.

If a homogeneous body has a plane of symmetry, any perpendicular to the plane is a principal axis of the body at the point where the line pierces the plane. If it has two planes of symmetry at right angles to each other, their intersection is a principal axis at any point of the intersection, the other two being in the planes of symmetry. If it has three planes of symmetry, their lines of intersection are the central principal axes of the body.

Properties of Various Lines, Surfaces, Volumes, and Bodies

Symbols. I_i = rectangular moment of inertia; k_i = corresponding radius of gyration; J_o = polar moment of inertia about axis through O perpendicular to plane; k_o = corresponding radius of gyration; m = mass = $W/g,$ where W = weight and g = acceleration due to gravity. Moments of inertia of bodies are given in terms of mass. For their values in terms of weight, replace m by W in the formulas.

*Strictly speaking, this is the moment of inertia of the mass of a body. If m be replaced by w = weight, the result is the moment of inertia of the weight of a body.

Decimal Equivalents (for reference in using Table 1):

$\pi = 3.1416$	$\sqrt{2} = 1.414$	$\frac{1}{\sqrt{2}} = 0.707$
$\frac{\pi}{2} = 1.5708$	$\sqrt{3} = 1.732$	$\frac{1}{\sqrt{3}} = 0.577$
$\frac{\pi}{4} = 0.7854$	$\sqrt{5} = 2.236$	$\frac{1}{\sqrt{5}} = 0.447$
$\frac{\pi}{8} = 0.3927$	$\sqrt{6} = 2.449$	$\frac{1}{\sqrt{6}} = 0.408$
$\frac{\pi}{32} = 0.0982$	$\sqrt{8} = 2.828$	$\frac{1}{\sqrt{8}} = 0.354$
$\frac{\pi}{64} = 0.0491$	$\sqrt{10} = 3.162$	$\frac{1}{\sqrt{10}} = 0.316$
$\frac{\pi}{128} = 0.0245$	$\sqrt{12} = 3.464$	$\frac{1}{\sqrt{12}} = 0.289$
$\frac{1}{\pi} = 0.318$	$\sqrt{18} = 4.242$	$\frac{1}{\sqrt{18}} = 0.238$

3 KINEMATICS

3.1 Motions of a Particle

Definitions *Motion* of a particle is the continual change of its position with respect to some base point or coordinate set. Particle motion is characterized by a time-dependent position vector $\mathbf{r}(t)$ that describes the location of the particle with respect to the base point or coordinates.

Rectilinear motion is motion along a straight line.

Curvilinear motion is motion along a curved path that may be planar or in three dimensions.

Displacement of a particle is its change of position and is a vector quantity. The displacement vector associated with the times t_1 and t_2 , $\Delta\mathbf{r}$, is given by

$$\Delta\mathbf{r} = \mathbf{r}(t_2) - \mathbf{r}(t_1)$$

Velocity of a particle is the time rate of change of its displacement and is a vector quantity. If the time interval $t_2 - t_1$ is denoted as Δt , then

$$\mathbf{v} = \lim_{\Delta t \rightarrow 0} \frac{\Delta\mathbf{r}}{\Delta t} = \frac{d\mathbf{r}}{dt}$$

Acceleration of a particle is the time rate of change of its velocity vector and is itself a vector quantity:

$$\mathbf{a} = \lim_{\Delta t \rightarrow 0} \frac{\Delta\mathbf{v}}{\Delta t} = \frac{d\mathbf{v}}{dt}$$

3.2 Rectilinear Motion

Velocity. Let s = distance measured along the path of a particle, s_1 = distance from origin at time t_1 , s_2 = distance at a later time t_2 , $\Delta s = s_2 - s_1$ = displacement* in time interval $\Delta t = t_2 - t_1$. Then *average velocity* = $\Delta s / \Delta t$. If the position changes at a uniform rate (which implies no change in sense), actual velocity at any time is $\Delta s / \Delta t$. For every case, *instantaneous velocity* is

$$v = \frac{ds}{dt} = \lim_{\Delta t \rightarrow 0} \frac{\Delta s}{\Delta t}$$

The *unit of velocity* is any distance unit divided by any time unit. Units commonly used are feet per second, meters per second, miles per hour, and so on.

Acceleration. Let v_1 = velocity of particle at time t_1 , v_2 = velocity at a later time t_2 , $\Delta v = v_2 - v_1$ = change in velocity in time interval $\Delta t = t_2 - t_1$. Then *average acceleration* = $\Delta v / \Delta t$. If the velocity changes at a uniform rate, the actual acceleration at any time is $\Delta v / \Delta t$. For every case, *instantaneous acceleration* is

$$a = \frac{dv}{dt} = \frac{d^2s}{dt^2} = \lim_{\Delta t \rightarrow 0} \frac{\Delta v}{\Delta t}$$

The *unit of acceleration* is the distance unit divided by the square of any time unit. Units commonly used are feet per second per second (feet per second squared), meters per second squared, and so on.)

Formulas for Determination of a , v , s , t . If s is given algebraically in terms of t , then v and a may be determined in terms of t by differentiation as indicated previously. If a is given algebraically in terms of t , then v and s may be determined in terms of t by integration. Other relations not involving t may be determined by similar methods. The common formulas are

$$v = \frac{ds}{dt} \quad a = \frac{dv}{dt} = \frac{d^2s}{dt^2} \quad \frac{a}{v} = \frac{dv}{ds}$$

$$s_2 - s_1 = \int_{t_1}^{t_2} v dt \quad v_2 - v_1 = \int_{t_1}^{t_2} a dt$$

$$t_2 - t_1 = \int_{s_1}^{s_2} \frac{ds}{v} = \int_{v_1}^{v_2} \frac{dv}{a} \quad v_2^2 - v_1^2 = 2 \int_{s_1}^{s_2} a ds$$

*The difference in distances along the path equals the displacement *only* when the path is a straight line. (See definition of displacement.)

Table 1 Centroids of Lines and Plane Areas

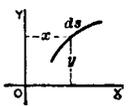

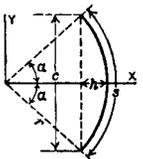

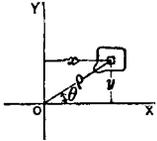

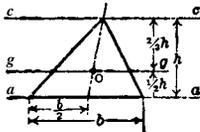

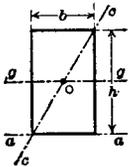

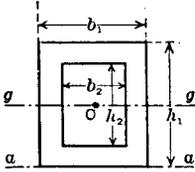

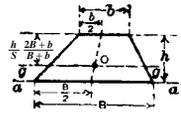

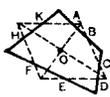

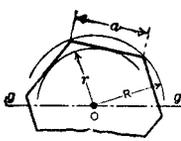

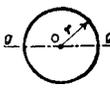

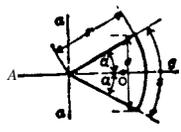

Lines	
Figure	Centroid Location
<p>1. Any plane curve</p> 	<p>CG is at point having coordinates \bar{x}, \bar{y}, where</p> $\bar{x} = \frac{\int x ds}{\text{length}} \text{ where } ds = \sqrt{1 + \left(\frac{dy}{dx}\right)^2} dx$ $\bar{y} = \frac{\int y ds}{\text{length}} \text{ where } ds = \sqrt{1 + \left(\frac{dx}{dy}\right)^2} dy$
<p>2. Circular arc</p> 	<p>CG is on axis of symmetry at $\bar{x} = r \sin \alpha / \alpha = rc/s$. If α is small, distance from CG to chord = approx. $2h/3$. (Error is small even for $\alpha = 45^\circ$.)</p> <p>For semicircle $\bar{x} = 2r/\pi$ For quadrant: $\bar{x} = 2r\sqrt{2}/\pi$ and distance from radius drawn to either end of arc = $2r/\pi$</p>
<p>3. Any Plane surface</p> 	<p>CG is at point having coordinates \bar{x}, \bar{y}, where</p> $\bar{x} = \frac{\iint x dx dy}{\text{area}} = \frac{\iint \rho^2 \cos \theta d\rho d\theta}{\text{area}}$ $\bar{y} = \frac{\iint y dx dy}{\text{area}} = \frac{\iint \rho^2 \sin \theta d\rho d\theta}{\text{area}}$ $I_x = \iint y^2 dx dy; \quad I_y = \iint x^2 dx dy; \quad J_0 = \iint \rho^3 d\rho d\theta = I_x + I_y$ $k_x = \sqrt{\frac{I_x}{\text{area}}}; \quad k_y = \sqrt{\frac{I_y}{\text{area}}}; \quad k_0 = \sqrt{\frac{J_0}{\text{area}}} = \sqrt{\frac{I_x + I_y}{\text{area}}}$
<p>4. Triangle</p> 	<p>CG is at $O =$ intersection of medians. Perpendicular distance from $a - a = \frac{1}{3}h$</p> $I_g = \frac{bh^3}{36}; \quad I_a = \frac{bh^3}{12}; \quad I_c = \frac{bh^3}{4}$ $k_g = \frac{h}{3\sqrt{2}}; \quad k_a = \frac{h}{\sqrt{6}}; \quad k_c = \frac{h}{\sqrt{2}}$
<p>5. Solid rectangle (or square)</p> 	<p>CG is at $O =$ intersection of diagonals. For rectangle:</p> $I_g = \frac{bh^3}{12}; \quad I_a = \frac{bh^3}{3}; \quad I_c = \frac{b^3h^3}{6(b^2 + h^2)}; \quad J_0 = \frac{bh(b^2 + h^2)}{12}$ $k_g = \frac{h}{2\sqrt{3}}; \quad k_a = \frac{h}{\sqrt{3}}; \quad k_c = \frac{bh}{\sqrt{6(b^2 + h^2)}}; \quad k_0 = \sqrt{\frac{b^2 + h^2}{12}}$ <p>For square (letting $b = h = s$):</p> $I_g = \frac{s^4}{12}; \quad I_a = \frac{s^4}{3}; \quad I_c = \frac{s^4}{12}; \quad J_0 = \frac{s^4}{6}$ $k_g = \frac{s}{2\sqrt{3}}; \quad k_a = \frac{s}{\sqrt{3}}; \quad k_c = \frac{s}{2\sqrt{3}}; \quad k_0 = \frac{s}{\sqrt{6}}$

Table 1 (Continued)

Figure	Lines	Centroid Location
6. Hollow rectangle (or square)		CG is at O = intersection of diagonals. For hollow rectangle:
		$I_g = \frac{(b_1 h_1^3 - b_2 h_2^3)}{12}; \quad I_a = \frac{b_1 h_1^3}{3} - \frac{b_2 h_2(3h_1^2 + h_2^2)}{12}$ $k_g = \sqrt{\frac{b_1 h_1^3 - b_2 h_2^3}{12(b_1 h_1 - b_2 h_2)}}; \quad J_0 = \frac{b_1 h_1(b_1^2 + h_1^2) - b_2 h_2(b_2^2 + h_2^2)}{12}$
		<p>For hollow square (letting $b_1 = h_1 = s_1$ and $b_2 = h_2 = s_2$):</p> $I_g = \frac{1}{12}(s_1^4 - s_2^4); \quad I_a = \frac{1}{3}s_1^4 - \frac{1}{12}s_2^2(3s_1^2 + s_2^2)$ $k_g = \sqrt{\frac{1}{12}(s_1^2 + s_2^2)}; \quad J_0 = \frac{1}{6}(s_1^4 - s_2^4)$ <p>(Note: For a diagonal $c - c$, $I_c = I_g$ and $k_c = k_g$)</p>
7. Trapezoid		CG is at O , located as shown.
		$I_g = \frac{h^3(B^2 + 4Bb + b^2)}{36(B + b)}; \quad I_a = \frac{h^3(B + 3b)}{12}$ $k_g = \frac{h\sqrt{2(B^2 + 4Bb + b^2)}}{6(B + b)}; \quad k_a = \frac{h}{\sqrt{6}}\sqrt{\frac{B + 3b}{B + b}}$
8. Quadrilateral		CG is at O , located as follows: Divide the sides into thirds and construct the parallelogram with sides passing through the third points as shown. The intersection of the diagonals of this parallelogram is the desired centroid.
		
9. Regular polygon		CG is at O = geometric center. Let $g - g$ be any axis through O and in plane of polygon. Then
		$I_g = \frac{1}{24} \text{area} \cdot (6R^2 - a^2) = \frac{1}{48} \text{area} \cdot (12r^2 + a^2)$ $J_0 = \frac{1}{12} \text{area} \cdot (6R^2 - a^2) = \frac{1}{24} \text{area} \cdot (12r^2 + a^2)$ $k_g = \sqrt{\frac{1}{24}(6R^2 - a^2)} = \sqrt{\frac{1}{48}(12r^2 + a^2)}$ $k_0 = \sqrt{\frac{1}{12}(6R^2 - a^2)} = \sqrt{\frac{1}{24}(12r^2 + a^2)}$
10. Circle		CG is at O = geometric center.
		$I_g = \frac{1}{4}\pi r^4 = \frac{1}{64}\pi d^4; \quad J_0 = \frac{1}{2}\pi r^4 = \frac{1}{32}\pi d^4$ $k_g = \frac{1}{2}r = \frac{1}{4}d; \quad k_0 = \frac{r}{\sqrt{2}} = \frac{d}{\sqrt{8}}$
11. Circular sector		CG is on axis of symmetry at O . Distance from $a - a = 2r \sin \alpha / (3\alpha) = 2rc / (3s)$.
		$A = \text{area} = r^2 \alpha$ $I_g = \frac{Ar^2}{4} \left(1 - \frac{\sin \alpha \cos \alpha}{\alpha} \right); \quad I_a = \frac{Ar^2}{4} \left(1 + \frac{\sin \alpha \cos \alpha}{\alpha} \right)$ $k_g = \frac{r}{2} \sqrt{1 - \frac{\sin \alpha \cos \alpha}{\alpha}}; \quad k_a = \frac{r}{2} \sqrt{1 + \frac{\sin \alpha \cos \alpha}{\alpha}}$

12. Semicircle CG is on axis of symmetry at O . Distance from $a - a = 4r/(3\pi) = 0.424r$.

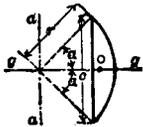

$$I_g = \frac{d^4(9\pi^2 - 64)}{1152\pi} = \frac{r^4(9\pi^2 - 64)}{72\pi} = 0.1098r^4$$

$$I_a = I_b = \frac{\pi d^4}{128} = \frac{\pi r^4}{4}; J_o = r^4 \left(\frac{\pi}{4} - \frac{8}{9\pi} \right) = 0.5025r^4$$

$$k_g = \frac{d\sqrt{9\pi^2 - 64}}{12\pi} = \frac{r\sqrt{9\pi^2 - 64}}{6\pi} = 0.264r; k_a = k_b = \frac{d}{4} = \frac{r}{2}$$

$$k_o = r\sqrt{\frac{1}{2} - \frac{16}{9\pi^2}} = 0.566r$$

13. Circular segment CG is on axis of symmetry at O . Distance from

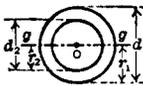

$$a - a = \frac{2r^3 \sin^3 \alpha}{3A} = \frac{c^3}{12A} \text{ where } A = \text{area} = \frac{r^2(2\alpha - \sin 2\alpha)}{2}$$

$$I_g = \frac{Ar^2}{4} \left(1 - \frac{2 \sin^3 \alpha \cos \alpha}{3(\alpha - \sin \alpha \cos \alpha)} \right); I_a = \frac{Ar^2}{4} \left(1 + \frac{2 \sin^3 \alpha \cos \alpha}{\alpha - \sin \alpha \cos \alpha} \right)$$

$$k_g = \frac{r}{2} \sqrt{1 - \frac{2 \sin^3 \alpha \cos \alpha}{3(\alpha - \sin \alpha \cos \alpha)}}; k_a = \frac{r}{2} \sqrt{1 + \frac{2 \sin^3 \alpha \cos \alpha}{\alpha - \sin \alpha \cos \alpha}}$$

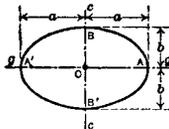

14. Annulus CG is at O = geometric center.

$$I_g = \frac{1}{64} \pi (d_1^4 - d_2^4) = \frac{1}{4} \pi (r_1^4 - r_2^4); J_o = \frac{1}{32} \pi (d_1^4 - d_2^4) = \frac{1}{2} \pi (r_1^4 - r_2^4)$$

$$k_g = \sqrt{\frac{1}{4} (d_1^2 + d_2^2)} = \sqrt{\frac{1}{2} (r_1^2 + r_2^2)}; k_o = \sqrt{\frac{1}{8} (d_1^2 + d_2^2)} = \sqrt{\frac{1}{2} (r_1^2 + r_2^2)}$$

15. Ellipse CG is at O = geometric center. For semiellipse ABB' , CG is on OA at distance to right of $c - c = 4a/(3\pi)$. For quarter-ellipse ABO , CG is at distance to right of $c - c = 4a/(3\pi)$ and at distance above $g - g = 4b/(3\pi)$.

$$I_g = \frac{1}{4} \pi ab^3 = \frac{1}{4} Ab^2; I_c = \frac{1}{4} \pi a^3 b = \frac{1}{4} Aa^2; J_o = \frac{1}{4} A(a^2 + b^2)$$

$$k_g = \frac{1}{2} b; k_c = \frac{1}{2} a; k_o = \sqrt{\frac{1}{2} (a^2 + b^2)}$$

16. Parabolic segment CG is on axis of symmetry at O . Distance from $c - c = 3a/5$.

$$I_g = \frac{4ab^3}{15}; I_c = \frac{4a^3b}{7}$$

$$k_g = \frac{b}{\sqrt{5}} = 0.447b; k_c = a\sqrt{\frac{3}{7}} = 0.654a$$

Homogeneous Bodies (Including Nonplanar Surfaces)^a

17. Any surface or body of revolution Let axis of revolution be X axis. Then generating curve is $y = f(x)$. CG is at point having coordinates $\bar{x}, \bar{y}, \bar{z}$.

For surface:

$$\bar{x} = \frac{\int 2\pi xy \, ds}{\int 2\pi y \, ds} = \frac{\int xy\sqrt{1+(dy/dx)^2} \, dx}{\int y\sqrt{1+(dy/dx)^2} \, dx}; \bar{y} = 0; \bar{z} = 0$$

For body (letting δ = density = m/volume):

$$\bar{x} = \frac{\int \pi xy^2 \, dx}{\int \pi y^2 \, dx}; \bar{y} = 0; \bar{z} = 0$$

$$I_x = \frac{1}{2} \pi \delta \int y^4 \, dx; I_y = I_z = \pi \delta \int \left(\frac{1}{4} y^4 + x^2 y^2 \right) dx$$

$$k_x = \sqrt{\frac{I_x}{m}}; k_y = k_z = \sqrt{\frac{I_y}{m}} = \sqrt{\frac{I_z}{m}}$$

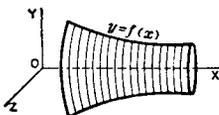

Table 1 (Continued)

Homogeneous Bodies (Continued)	
Figure	Centroid Location; Moments of Inertia; Radii of Gyration
For thin shell having mass: CG. coordinates are same as for surface. $I_x = 2\pi\delta \int y^3 ds = 2\pi\delta \int y^3 \sqrt{1 + \left(\frac{dy}{dx}\right)^2} dx; \quad k_x = \sqrt{\frac{I_x}{m}}$	
18. Thin straight rod	CG is at O = geometric center. For body: $I_g = \frac{1}{12} ml^2; \quad I_b = \frac{1}{3} ml^2; \quad I_c = \frac{1}{12} ml^2 \sin^2 \alpha; \quad I_d = \frac{1}{3} ml^2 \sin^2 \alpha$ $k_g = \frac{l}{\sqrt{12}}; \quad k_b = \frac{l}{\sqrt{3}}; \quad k_c = \frac{l \sin \alpha}{\sqrt{12}}; \quad k_d = \frac{l \sin \alpha}{\sqrt{3}}$
19. Thin rod bent into circular arc	CG is on axis of symmetry at $\bar{x} = \frac{r \sin \alpha}{\alpha}$. For body: $I_x = \frac{mr^2}{2} \left(1 - \frac{\sin \alpha \cos \alpha}{\alpha}\right); \quad I_y = \frac{mr^2}{2} \left(1 + \frac{\sin \alpha \cos \alpha}{\alpha}\right); \quad I_z = mr^2$ $k_x = r \sqrt{\frac{1}{2} - \frac{\sin \alpha \cos \alpha}{2\alpha}}; \quad k_y = r \sqrt{\frac{1}{2} + \frac{\sin \alpha \cos \alpha}{2\alpha}}; \quad k_z = r$
20. Rectangular parallelepiped (or cube)	CG is at O = geometric center. For parallelepiped: $I_g = \frac{1}{12} m(b^2 + c^2); \quad I_d = \frac{1}{12} m(a^2 + b^2); \quad I_e = \frac{1}{12} m(4a^2 + b^2)$ $k_g = \sqrt{\frac{1}{12}(b^2 + c^2)}; \quad k_d = \sqrt{\frac{1}{12}(a^2 + b^2)}; \quad k_e = \sqrt{\frac{1}{12}(4a^2 + b^2)}$ For cube (letting $a = b = c = s$): $I_g = I_d = \frac{ms^2}{6}; \quad I_e = \frac{5ms^2}{12}$ $k_g = k_d = \frac{s}{\sqrt{6}}; \quad k_e = s \sqrt{\frac{5}{12}}$
21. Right rectangular pyramid	CG is on axis of symmetry at O. Distance from base = $h/4$. Drawing $g-g$ axis through O parallel to side a : $I_g = \frac{m}{20} \left(b^2 + \frac{3h^2}{4}\right); \quad I_c = \frac{m}{20} (a^2 + b^2)$ $k_g = \sqrt{\frac{4b^2 + 3h^2}{80}}; \quad k_c = \sqrt{\frac{a^2 + b^2}{20}}$
22. Pyramid (or frustum of pyramid)	For surface of any pyramid: CG of surface (base excluded) is on line joining apex with centroid of perimeter of base at a distance two-thirds its length from the apex. For body of any pyramid: CG of body is on line joining apex with centroid of base at a distance three-fourths its length from the apex. For surface of frustum of pyramid having rectangular bases: Letting R and r be the lengths of sides of the larger and smaller bases respectively, and h the altitude: CG of surface (bases excluded) is at distance from larger base = $h(R + 2r)/[3(R + r)]$. For body of frustum of any pyramid: Letting A and a be the areas of the larger and smaller bases, respectively, and h the altitude: CG of body is at distance from larger base = $h(A + 2\sqrt{Aa} + 3a)/[4(A + \sqrt{Aa} + a)]$.

^a "Body" is to be understood unless "Surface" is indicated.

For uniform acceleration, $a = \text{constant}$; $v = at + v_0$; $s = \frac{1}{2}at^2 + v_0t + s_0$; $v^2 = 2a(s - s_0) + v_0^2$; v_0 being initial velocity and s_0 initial distance.

If algebraic relations between a , v , s , and t are not given but a number of pairs of corresponding values of two of the variables are known, curves may be plotted for the approximate determination of other corresponding pairs of values and of other unknowns within the range of the data. Such curves are discussed below under "Motion Graphs."

Examples of Rectilinear Motion

Falling Body.* If a body falls from rest in a vacuum, $v_0 = 0, s_0 = 0$, and $a = g = 32.2 \text{ ft/sec}^2$ (approx). Hence $v = gt$; $s = \frac{1}{2}gt^2$. If a body is projected upward at an initial velocity v_0 , $a = -g$ and the formulas become $v = -gt + v_0 = \sqrt{-2gs + v_0^2}$, $s = -\frac{1}{2}gt^2 + v_0t$. Total ascent (to highest position) is $v_0^2/2g$ and time required v_0/g .

Crank and Connecting Rod Mechanism. The problem is to find expressions for the velocity and acceleration of any point in the crosshead, as A in Fig. 21. Such a point describes rectilinear motion. Let $c = r/l, n = \text{revolutions per second}$ (assumed constant), $\omega = \text{radians of angle described by crank per second}$, and $s = \text{distance of A from its extreme left position}$, all distances expressed in feet. Then.

$$s = (l + r) - l(1 - c^2 \sin^2 \theta)^{1/2} - r \cos \theta$$

$$v = r\omega \left(\sin \theta + \frac{c \sin 2\theta}{2(1 - c^2 \sin^2 \theta)^{1/2}} \right)$$

$$a = r\omega^2 \left(\cos \theta + \frac{c \cos 2\theta + c^3 \sin^4 \theta}{(1 - c^2 \sin^2 \theta)^{3/2}} \right)$$

*Rotation is disregarded and the body is considered as a particle.

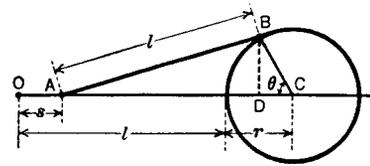

Fig. 21 Motion graph.

These formulas are exact; close approximations are

$$s = r(1 - \cos \theta) + \frac{1}{4}cr(1 - \cos 2\theta)$$

$$v = r\omega(\sin \theta + \frac{1}{2}c \sin 2\theta)$$

$$a = r\omega^2(\cos \theta + c \cos 2\theta)$$

Motion Graphs Space-time, velocity-time, acceleration-time, velocity-space, and acceleration-space curves for a particle are graphs showing the relations between magnitudes of s and t , v and t , a and t , v and s , and a and s , respectively. Figures 22-26 illustrate such graphs but do not correspond to the same motion.

Space-Time Diagram. In Fig. 22, the slope of the curve at any point represents the magnitude of the velocity. If AB and BC are measured by the s and t scales of the drawing, respectively, the slope equals the velocity magnitude; thus if $AB = 0.2 \text{ in.}$ and $BC = 0.4 \text{ in.}$, $v = 0.4/4 = 0.1 \text{ ft/sec}$.

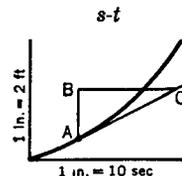

Fig. 22 Motion graph.

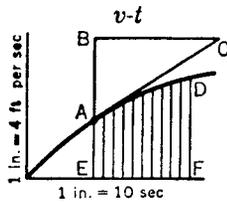

Fig. 23 Velocity versus time.

Velocity–Time Diagram. In Fig. 23, the slope of the curve at any point represents the magnitude of the acceleration.* If AB and BC are measured by the v and t scales, respectively, the slope equals the acceleration magnitude; thus if $AB = 0.3$ in. and $BC = 0.5$ in., $a = 1.2/5 = 0.24$ ft/sec². The area included between any two ordinates (as AE and DF), the curve, and the t axis represents the displacement† of the moving point in the time EF . If the area is below the time axis, it is considered minus. If the area is computed by multiplying its average ordinate measured by the velocity scale (this being the average velocity) by EF measured by the time scale, the product equals the displacement; thus if the average ordinate is 0.35 in. and EF is 0.4 in., the displacement is $1.4 \times 4 = 5.6$ ft.

Acceleration–Time Diagram. In Fig. 24, the slope represents the rate at which the acceleration is changing. The area (plus above and minus below time axis) included between any two ordinates (as AE and DF), the curve, and the t axis represents the velocity change in the time EF .‡ Thus if the average ordinate is 0.3 in. and EF is 0.2 in., the velocity change is $6 \times 2 = 12$ ft/sec.

Velocity–Space Diagram. In Fig. 25, the subnormal represents the acceleration.§ If the length of the subnormal is multiplied by the square of the velocity scale number and the product is divided by the space scale number, the result will equal the acceleration; thus suppose that the subnormal $BC = \frac{1}{3}$ in., then $a = (\frac{1}{3} \times 25)/10 = 0.83$ ft/sec².

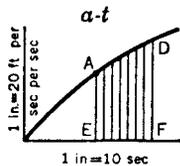

Fig. 24 Acceleration versus time.

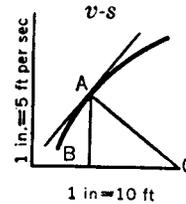

Fig. 25 Velocity versus distance.

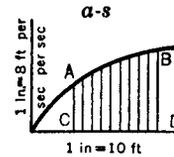

Fig. 26 Acceleration versus distance.

Acceleration–Space Diagram. In Fig. 26, the area (plus above and minus below the space axis) included between two ordinates (as AC and BD), the curve, and the s axis represents the change in the velocity square. If the area is computed by multiplying the mean ordinate measured by the acceleration scale by CD measured by the space scale, the product times 2 equals the change in the velocity square; thus if the average ordinate is 0.3 in. and $CD = 0.4$ in., the change is $2.4 \times 4 \times 2 = 19.2$ ft²/sec².

Simple Harmonic Motion

Simple Harmonic Motion and Its Motion Graphs.

These have wide application in physics and engineering. If a point P moves in a circular path of radius r at uniform speed, its projection on any diameter has *simple harmonic motion*. The radius r is called the *amplitude*. The *period* is the time required for the projection to go from one end of the diameter to the other and back. The *frequency* is the number of periods per unit time, which makes it the reciprocal of the period. Angle XOP (Fig. 27) (considered as less than 2π radians) is the *phase angle*. The displacement at any time is the distance of the point having simple harmonic motion from the center of its path or range.

When $t = 0$, let P be at P_0 . *varepsilon* is called the *lead angle* (*lag*, if negative). For simple harmonic motion (SHM) of V in the vertical diameter, $y = r \sin(\theta + \varepsilon) = r \sin(\omega t + \varepsilon)$, in which $\omega = d\theta/dt$ in radians per unit time (i.e., 2π times the frequency):

$$v_y = r\omega \cos(\omega t + \varepsilon) = \omega x$$

$$a_y = -r\omega^2 \sin(\omega t + \varepsilon) = -\omega^2 y$$

*For curvilinear motion, this is tangential acceleration only.

†For curvilinear motion, this is distance along the path (not displacement).

‡For rectilinear motion only.

§For curvilinear motion, this is tangential acceleration only.

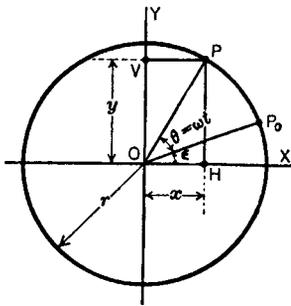

Fig. 27 Simple harmonic motion.

For SHM of H in horizontal diameter,

$$x = r \cos(\theta + \epsilon) = r \cos(\omega t + \epsilon)$$

$$v_x = -r\omega \sin(\omega t + \epsilon) = -\omega y$$

$$a_x = -r\omega^2 \cos(\omega t + \epsilon) = -\omega^2 x$$

If the time is reckoned from the instant when V is in its midposition and moving upward, $\epsilon = 0$. The three curves (Fig. 28) OA , $O'B$, and OC are the space–time, velocity–time, and acceleration–time curves, respectively, for one complete period of a simple harmonic motion; $\epsilon = 0$; Ot represents the period; the values of y , v , and a marked are for position Q , shown. In Fig. 28a the curve is the velocity–space curve and the inclined line the acceleration–space curve. They show how v and a vary with the displacement of the moving point; thus for the position Q (Fig. 28b), v and a have values as marked.

From the preceding equations and curves, it will be noted that simple harmonic motion may be define also as any rectilinear motion in which the acceleration is always directed toward a fixed point in the path and is proportional to the distance between that point and the moving point.*

*A common example of simple harmonic motion is the motion of a weight suspended from an elastic spring.

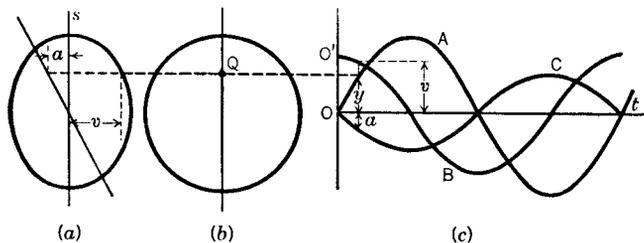

Fig. 28 (a) Space–time curve; (b) velocity–time curve; (c) acceleration–time curve.

3.3 Curvilinear Motion

Velocity. If s is distance measured along the curved path of a particle, then the magnitude of velocity (speed) at any instant is ds/dt ; the linear direction of the velocity is tangent to the path at the instantaneous position of the particle; and the sense of the velocity corresponds to the direction of motion of the particle at the instant.

The velocity vector changes in magnitude and direction. In Fig. 29, let A, B, C represent positions of particle P in its curved path; s distance along the path; and v_1, v_2, v_3 velocity vectors at A, B, C . Plot velocity vectors $O'A', O'B', O'C'$, and so on, from any origin O' to represent the velocities at A, B, C , and so on. The curve $A'B'C'$, drawn through the ends of the vectors, is called a *hodograph* for the motion. For every position of P in its path, there is a corresponding position P' in the hodograph; and P' describes distances s' on the hodograph while P describes distance s on the path. Vector $O'P'$ represents the velocity of P . In time Δt , P moves from A to C , its velocity changes from $O'A'$ to $O'C'$, and the velocity change is $A'C'$.

Acceleration. Referring to the hodograph (Fig. 29), average acceleration for interval Δt , during which particle P moves from A to C , is vector $A'C'/\Delta t$, and it has the direction of the chord $A'C'$. The instantaneous acceleration of P at $A = a$ = limit of the average acceleration as Δt approaches zero,

$$a = \lim_{\Delta t \rightarrow 0} \left(\frac{\text{vector } A'C'}{\Delta t} \right)$$

$$= \lim_{\Delta t \rightarrow 0} = \frac{\text{arc } A'B'C'}{\Delta t} = \frac{ds'}{dt} = \text{speed of } P'$$

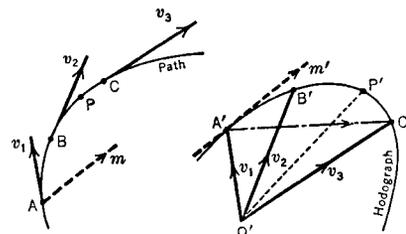

Fig. 29 Curvilinear motion.

on the hodograph. The direction of a is along the tangent $A'm'$, and as P' is moving clockwise, the sense is as indicated by arrow at m' . Hence acceleration at A is Am , parallel to $A'M'$ and $= ds'/dt'$. Its tangential component is ds'/dt' and its normal component is v^2/ρ , ρ being the radius of curvature at A . The unit of acceleration is any velocity unit divided by any time unit.

Components of Velocity and Acceleration

Components of Velocity and Acceleration of a Particle for Any Curved Path (not necessarily planar). The position of the particle P being define by its coordinates, x, y, z , the axial components of velocity are $v_x = dx/dt$, $v_y = dy/dt$, and $v_z = dz/dt$. Resultant velocity $v = \sqrt{v_x^2 + v_y^2 + v_z^2}$, and its direction cosines are $\cos \theta_x = v_x/v$, $\cos \theta_y = v_y/v$, and $\cos \theta_z = v_z/v$. The axial components of acceleration are

$$a_x = \frac{dv_x}{dt} = \frac{d^2x}{dt^2} \quad a_y = \frac{dv_y}{dt} = \frac{d^2y}{dt^2}$$

$$a_z = \frac{dv_z}{dt} = \frac{d^2z}{dt^2}$$

The resultant acceleration $a = \sqrt{a_x^2 + a_y^2 + a_z^2}$ and its direction cosines are

$$\cos \phi_x = \frac{a_x}{a} \quad \cos \phi_y = \frac{a_y}{a} \quad \cos \phi_z = \frac{a_z}{a}$$

The tangential and normal components of acceleration are $a_t = dv/dt = d^2s/dt^2$ and $a_n = v^2/\rho$, ρ being the radius of curvature. The resultant acceleration is

$$a = \sqrt{a_t^2 + a_n^2} = \sqrt{a_x^2 + a_y^2 + a_z^2}$$

If the path is a plane curve, $v_z = 0$ and $a_z = 0$.

The preceding discussion shows that velocities and accelerations (like forces) may be composed or resolved according to the parallelogram and parallelepiped laws.

Motion of a Projectile

Projectile* Describing Plane Curvilinear Motion.

In the following formulas air resistance is neglected; v_0 = velocity of projection; θ = angle of projection

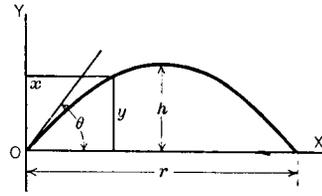

Fig. 30 Projectile motion.

(Fig. 30); x, y = coordinates of the projectile at any time t after projection; v = velocity; v_x and v_y are x and y components, respectively, of v ; r = range on the horizontal plane through O ; θ_1 = value of θ for maximum r ; h = greatest height attained; and T = time of flight. The path of the projectile, or the trajectory, is a parabola as represented, and a set of parametric equations for it are

$$x = v_0 \cos \theta \cdot t \quad y = v_0 \sin \theta \cdot t - \frac{1}{2}gt^2$$

from which

$$y = x \tan \theta - \frac{gx^2}{2v_0^2 \cos^2 \theta}$$

Also,

$$v_x = v_0 \cos \theta \quad r = \frac{\sin 2\theta \cdot v_0^2}{g}$$

$$v_y = v_0 \sin \theta - gt \quad \theta_1 = 45^\circ$$

$$v = \sqrt{v_0^2 - 2gy} \quad T = \frac{2v_0 \sin \theta}{g}$$

$$h = \frac{\sin^2 \theta \cdot v_0^2}{2g}$$

If the direction of projection is horizontal, $\theta = 0$; the equation of the path is $y = -gx^2/2v_0^2$; and $x = v_0t$ and $y = -\frac{1}{2}gt^2$.

The fact that the horizontal component of velocity is constant indicates that the hodograph of the motion of a projectile is a straight vertical line.

Motion Graphs Motion graphs similar to those previously discussed for rectilinear motion may be constructed for curvilinear motion of a particle. Great care must be exercised, however, in interpreting the significance of slopes, areas, and subnormals when acceleration or distance is involved. In this connection, reference should be made to the footnotes referred to in the previous discussion.

In general, accelerations obtained are tangential components only, while "displacements" must be replaced by "distances along the curve." Thus, in the velocity-time graph (Fig. 23), the slope of the curve represents the magnitude of the *tangential component*

*Rotation is disregarded and the body is considered as a particle.

of the acceleration,* while the area under the curve represents the *distance along* the curve.

3.4 Motions of a Body

Translation of a *rigid body* is a motion such that each straight line in it remains fixed in direction. The paths of all particles of the body are exactly alike, straight or curved (not necessarily plane curves); the displacements of all particles during a given time are the same; the velocities of all particles at any instant are the same; and their accelerations at any instant are the same. For these reasons, it is customary to use the expressions “velocity of the body” and “acceleration of the body.” The motion is described by the same formulas as those previously derived for rectilinear and curvilinear motions of a particle.

Rotation of a rigid body is a motion such that one line of the body, or of its extension, remains fixed. The fixed line is the *axis*. The plane through the mass center perpendicular to the axis is the *plane of rotation*.

Plane motion of a rigid body is a motion such that each particle of the body moves in a plane at a constant distance from a fixed plane through the mass center (called the *plane of motion*), while each line of the body parallel to the plane of motion turns through the same angle in the same time interval.

Three-dimensional motion of a rigid body is a term covering all types of motion in three-dimensional space, including pure translation along a skewed curve as a special case. Even in the most general case, any three-dimensional motion of a rigid body may be regarded as consisting of two components: one a translation equal to that of the mass center and the other a rotation about some axis through the mass center.

Angular displacement of a rigid body is the change of angular position of any line in the plane of motion. The angular displacement of a rigid body *cannot* be expressed as a vector quantity.

Angular velocity of a rigid body is its time rate of angular displacement (i.e., rate of change of angular position). The angular velocity of a rigid body can be expressed as a vector quantity.

Angular acceleration of a rigid body is its time rate of change of angular velocity. The angular acceleration of a rigid body can be expressed as a vector quantity.

3.5 Rotation

Angular Velocity. The paths of all particles are circles with centers on the axis. Since all lines of the body parallel to the plane of rotation sweep out equal angles in equal times, it is customary to describe rotation by the behavior of one radial line. In Fig. 31,

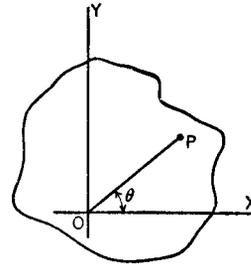

Fig. 31 Angular displacement.

let θ be the angle from the x axis to the radial line OP . $\Delta\theta = \theta_2 - \theta_1$ is the angular displacement of the body in the time $\Delta t = t_2 - t_1$ and is expressed in any angular unit,

$$\text{Average angular velocity} = \frac{\theta_2 - \theta_1}{t_2 - t_1} = \frac{\Delta\theta}{\Delta t}$$

If the angle changes at a uniform rate, actual velocity at any time equals $\Delta\theta/\Delta t$. For every case, the instantaneous angular velocity is

$$\omega = \lim_{\Delta t \rightarrow 0} \left(\frac{\Delta\theta}{\Delta t} \right) = \frac{d\theta}{dt}$$

The sign depends on the numerator of the fraction, or the way in which θ is changing. The *unit of angular velocity* is any angular displacement unit divided by any time unit, such as radians per second, revolutions per minute, and so on.

Angular velocity is generally expressed as a vector quantity. The direction of the vector is along the instantaneous axis of rotation, and the magnitude of the vector is equal to the instantaneous angular velocity. The sense along the axis is such that the right-hand rule applies (if the right hand grasps the axis of rotation with the fingers curled in the direction of rotation, the right thumb points in the direction of the angular velocity vector).

Angular Acceleration

$$\text{Average angular acceleration} = \frac{\omega_2 - \omega_1}{t_2 - t_1} = \frac{\Delta\omega}{\Delta t}$$

If the angular velocity changes at a uniform rate, actual angular acceleration at any time equals $\Delta\omega/\Delta t$. For every case, the instantaneous angular acceleration is

$$\alpha = \lim_{\Delta t \rightarrow 0} \left(\frac{\Delta\omega}{\Delta t} \right) = \frac{d\omega}{dt} = \frac{d^2\theta}{dt^2}$$

*However, if a velocity–time graph were made for motion along the hodograph of the original motion, the slope of the curve would represent the magnitude of the *total* acceleration of the original particle along the original path.

The sign of α depends on the numerator of the fraction or on the way in which ω is changing. The *unit of angular acceleration* is any angular velocity unit divided by any time unit, as radians per second per second (i.e., radians per second squared).

Formulas for Determination of $\alpha, \omega, \theta, t$. The formulas are exactly analogous to those previously derived for rectilinear motion, $a, v,$ and s being replaced by $\alpha, \omega,$ and $\theta,$ respectively. The formulas are

$$\omega = \frac{d\theta}{dt} \quad \alpha = \frac{d\omega}{dt} = \frac{d^2\theta}{dt^2} \quad \frac{\alpha}{\omega} = \frac{d\omega}{d\theta}$$

$$\theta_2 - \theta_1 = \int_{t_1}^{t_2} \omega dt \quad \omega_2 - \omega_1 = \int_{t_1}^{t_2} \alpha dt$$

$$t_2 - t_1 = \int_{\theta_1}^{\theta_2} \frac{d\theta}{\omega} = \int_{\omega_1}^{\omega_2} \frac{d\omega}{\alpha}$$

$$\omega_2^2 - \omega_1^2 = 2 \int_{\theta_1}^{\theta_2} \alpha d\theta$$

Angular acceleration is generally expressed as a vector quantity. The magnitude of the vector is equal to the instantaneous angular acceleration. The direction of the angular acceleration vector is perpendicular to the plane formed by successive values of the angular velocity vector. The sense along the axis is such that the right-hand rule applies (if the right hand grasps the axis of rotation with the fingers curled in the direction of increasing angular velocity, the right thumb points in the direction of the angular acceleration vector).

In the case of planar motion, there is no plane formed by successive values of the angular velocity vector. In this case, the angular velocity vector and the angular acceleration vector both lie perpendicular to the plane of motion.

Relations between Rectilinear and Angular Velocities and Accelerations. Let ω and $\alpha,$ respectively, be instantaneous angular velocity and acceleration of a rotating body and v and a the corresponding instantaneous rectilinear velocity and acceleration of a point P of the body located at distance r from the axis of rotation. Then

$$v = r\omega \quad a_t = r\alpha \quad a_n = r\omega^2 \quad a = r\sqrt{\alpha^2 + \omega^4}$$

The sense of v must agree with the sense of $\omega,$ and the sense of a_t with the sense of $\alpha.$ The sense of a_n is always toward the axis.

Motion Graphs Motion graphs analogous to those previously discussed for rectilinear motion may be constructed to show the relations between angular displacement, velocity and acceleration, and time. $\theta, \omega,$ and α correspond to $s, v,$ and $a,$ respectively.

3.6 Plane Motion

Any displacement resulting from plane motion may be accomplished by a translation of the body that will bring any one line of it, which is perpendicular to the plane of motion, into final position, followed by a rotation of the body about that line into final position. The necessary amount of translation depends on the line of the body selected as axis of the rotation; the amount of the rotation does not. The *state of motion* of a body at any instant may be regarded as consisting of two components, a translational motion and a rotational motion. Thus a plane motion may be traced by giving the history of the movement of one point of the body (called a base point) in its own curved path and a description of the rotation of the body about the selected base point.* The point selected as base should be one for which the motion is readily specified. For a wheel rolling along a straight path, the center would be selected as a base point.

Velocity of any point P of the body at any instant with respect to a fixed point O is the vector sum of the velocity of base point A with respect to O and of the velocity of P with respect to A due to rotation about $A.$ Thus (Fig. 32) O is the fixed point, A the moving base point, and P any other point of the body at distance r from $A;$ v_1 is the velocity of A with respect to $O,$ and $v_2 = r\omega$ is the velocity of P with respect to $A.$ The resultant velocity of P with respect to O is $v,$ or $v_{ptoO} = v_{pToA} + v_{AtoO}.$ In vector form this relation can be written as the vector cross product:

$$\mathbf{V}_P = \mathbf{V}_A + \boldsymbol{\omega} \times \mathbf{r}_P$$

Acceleration of any point P with respect to a fixed point O at any instant has two components; one is that of the base point A with respect to O and the other that of P with respect to base $A.$ Acceleration of P with respect to A is rotational and is conveniently replaced by its tangential and normal components, $a_t = r\alpha$ and $a_n = r\omega^2.$ Then resultant acceleration of

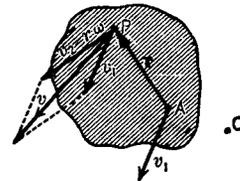

Fig. 32 Velocity of a point on a rigid body.

*To simplify matters, "points" are referred to throughout this and the following discussion but "lines" through the points perpendicular to the plane of motion should be understood. Thus, in Fig. 32 and 33, the parallel lines through $P, A,$ and O perpendicular to the plane of motion move relative to each other.

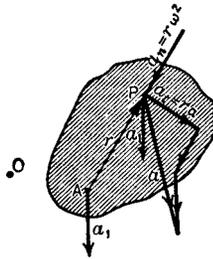

Fig. 33 Acceleration of a point on a rigid body.

P , with respect to O is the vector sum of $r\alpha$, $r\omega^2$, and acceleration of A with respect to O . Thus (Fig. 33) a_1 is acceleration of A to O and acceleration P to A is resultant of a_t and a_n . Acceleration of P to O is a , the vector sum of a_1 , a_t , and a_n . In vector form this relation can be written as three vector cross products:

$$\mathbf{a}_P = \mathbf{a}_A + \boldsymbol{\alpha} \times \mathbf{r} + \boldsymbol{\omega} \times (\boldsymbol{\omega} \times \mathbf{r})$$

Instantaneous Axis. For a body having plane motion, there is always one point in it (or in its extension) at each instant for which the velocity with respect to A (Fig. 32) is equal and opposite to velocity of A with respect to O ; that is, its velocity is zero at the instant. This point Q is called the *instantaneous (or instant) center* of rotation, and a line through Q perpendicular to the plane of motion is called the *instantaneous axis*. Since Q is at rest for the instant, the resultant velocities of all points at the instant are purely rotational about the instant axis. The instant center is the intersection of two lines drawn from any two points, C and D , in the plane of the motion perpendicular to their velocities. If the velocity of the point C is known, ω for the body is determined by dividing v_C by the distance of C from Q , or by r_C . The velocity of any other point E is $\omega \times \mathbf{r}_E$, perpendicular to the radius \mathbf{r}_E .

The position of Q in the body (or in its extension) is continually changing; its locus is a line (usually curved) fixed in the body and moving with it, called the *body centrode*. The locus of the positions of Q in the fixed plane of motion is a line (usually curved) called the *space centrode*. The plane motion may be considered as produced by the rolling, without slipping, of the body centrode upon the space centrode.

Example 36. Rolling Wheel Describing Plane Motion. A wheel of 6 ft radius rolls along a straight horizontal path, and at a certain instant the point P , 2 ft from the center of the wheel, is in the position shown in Fig. 34a. At this instant $\omega = 16.75$ rad/sec and $\alpha = 5.6$ rad/sec². Determine the velocity and acceleration of point P with respect to fixed point O at the specific instant.

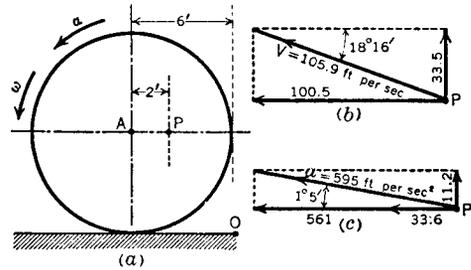

Fig. 34 Instantaneous axis of rotation.

Solution. Select center A as base point. From relations between v and a of any point of a rotating body and ω and α of the body, $v_{A \text{ to } O} = r\omega = 6 \times 16.75 = 100.5$ ft/sec, horizontally toward left, and $v_{P \text{ to } A} = r\omega = 2 \times 16.75 = 33.5$ ft/sec, vertically upward. Therefore, $v_{P \text{ to } O} = 105.9$ ft/sec, upward to left, at $18^\circ 16'$ to horizontal (Fig. 34b).

Then $a_{A \text{ to } O} = r\alpha = 6 \times 5.6 = 33.6$ ft/sec², horizontally toward left; $a_{tP \text{ to } A} = r\alpha = 2 \times 5.6 = 11.2$ ft/sec², vertically upward; and $a_{nP \text{ to } A} = r\omega^2 = 2 \times (16.75)^2 = 561$ ft/sec², horizontally toward left. Therefore, $a_{P \text{ to } O} = 595$ ft/sec², upward to left, at $1^\circ 5'$ to horizontal (Fig. 34c).

4 KINETICS

4.1 Basic Quantities

System of Units* The *unit of force* is the pound force in the English system and is the newton in the SI system: The pound force is defined as the force required to give one slug of mass an acceleration of one foot per second per second. The newton is defined as the force required to give one kilogram of mass an acceleration of one meter per second per second.

The *unit of acceleration* in the English system is the foot per second per second. In the SI system, the unit is the meter per second per second.

The *unit of mass* in the English system is the slug, which is the mass of 32.1739 standard pounds. The standard pound is a platinum standard kept at the National Bureau of Standards in Washington, D.C. Its mass is 0.45359243 kg. The SI unit of mass is the standard kilogram, a platinum standard kept at the International Bureau of Weights and Measures near Paris, France.

The *relation* between force, mass, and acceleration of a constant mass particle, using either of the preceding systems of units, is expressed by the relation

$$\mathbf{F} = m\mathbf{a} \quad \left(\text{or } \mathbf{F} = \frac{W}{g}\mathbf{a} \right)$$

*The units herein defined are those of the English gravitational system. For a complete discussion of English and metric gravitational and absolute units, see Section 2.2.

where F is the force in pounds or newtons, m is the mass in slugs or kilograms, and a is acceleration in feet per second per second or meters per second per second.*

4.2 Derived Quantities and Relations

Work, Power, and Energy

Work. The *work of a force*, if constant, is the product of the force and the effective displacement of its application point. *Effective displacement* of the application point is the component of the displacement parallel to the force. The body exerting the force is also said to do work. In Fig. 35, the work of force F as the application point describes path $AB = F \times AC$. Since $F \cdot (AB \cos \alpha) = (F \cos \alpha) \cdot AB$, the work is also equal to displacement of the application point times the component of force parallel to the displacement. *Work of a variable force* in moving a body through distance $\Delta S = (s_2 - s_1)$ is $W = \int_{s_1}^{s_2} F \cos \alpha \, ds = \int_{s_1}^{s_2} F_t \, ds$, in which F is the variable force, ds is the elementary length of path, α is the angle between the force and element ds , and F_t is the tangential component of force. The *sign of work* is positive if force and effective displacement have the same sense; it is negative if they differ in sense. Work done by a body against a force is equal and opposite to work done by the force on the body.

In vector form, work is calculated by integrating the dot product $\mathbf{F} \cdot d\mathbf{r}$ along the path of the application point. In equation form,

$$W = \int_{s_1}^{s_2} \mathbf{F} \cdot d\mathbf{r}$$

where \mathbf{F} is the vector representation of the force and $d\mathbf{r}$ is the differential displacement along the path of the application point. Work is a scalar quantity.

The *unit of work* is any force unit times any distance unit (such as the foot-pound or newton-meter) or any power unit times any time unit (such as the watt-hour).

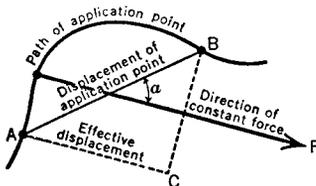

Fig. 35 Effective displacement of a force.

*With any system of units, $F = Kma$, where K is a constant. In this system $K = 1$.

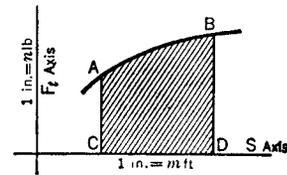

Fig. 36 Work of a force.

In a *work diagram* (Fig. 36), plot values of F_t as ordinates, corresponding values of s as abscissas; draw curve AB through ends of ordinates. Area $ABDC$ times mn equals work, in foot-pounds, done by F_t over distance $s_2 - s_1$.

The *work of gravity* on a body in any motion equals the product of weight and the change in height of the mass center. The *work of a central force* F (one always directed toward a fixed point), in any displacement of its application point, is $\int_{r_1}^{r_2} F \, dr$, in which r_2 and r_1 are the distances of the application point from the center at the beginning and end of the displacement.

The *work of a torque* T on a rotating body for an angular displacement $\theta = (\theta_2 - \theta_1)$ radians is $W = \int_{\theta_1}^{\theta_2} T \, d\theta$. If T is constant, $W = T(\theta_2 - \theta_1)$.

The *mechanical efficiency* of a machine is the ratio of useful output to total input of work. Let W_u = useful work performed, W_f = uselessly work required to overcome friction or air or any other type of resistance, W_a = work applied to the machine. Then $W_a = W_u + W_f$, and mechanical efficiency = W_u / W_a .

Power. The *power of a force* is its time rate of doing work. The body exerting the force is also said to have power. Let P = power and W = work. Then instantaneous power $P = dW/dt = F_t(ds/dt) = F_t v$, where v is the instantaneous velocity of an application point of force F .

The *unit of power* is any work unit divided by any time unit (as foot-pound per second). One horsepower = 550 ft-lb/sec = 33,000 ft-lb/min = 0.7457 W.

The *power of a torque* at any instant is $P = dW/dt = T(d\theta/dt) = T\omega$, where ω is the instantaneous angular velocity of the body.

Energy. The *energy*[†] of a body (or system of bodies) is the amount of work it can do, by virtue of its motion or position, against forces applied to it while changing to a standard state.

The *potential energy* (PE) of a body is that possessed by virtue of its configuration. Thus, a body of weight W located at a height above the earth's surface such that its mass center can descend h feet has a potential energy $PE = Wh$.

[†]Mechanical energy (which includes potential and kinetic energy) is referred to in this definition. There are other forms of energy such as thermal, chemical, and electrical.

The *kinetic energy* (KE) of a body is that possessed by virtue of its velocity, and the standard state is zero velocity, KE of a *body in translation* is $\frac{1}{2}mv^2$. KE of a *rotating body* is $\frac{1}{2}I\omega^2 = \frac{1}{2}mk^2\omega^2$, I , k , and ω being the moment of inertia, radius of gyration, and angular velocity, respectively, about the axis of rotation. KE of a body having plane motion is $\frac{1}{2}I\omega^2 = \frac{1}{2}mk^2\omega^2 = \frac{1}{2}m\bar{v}^2 + \frac{1}{2}I\omega^2$, in which I and k are referred to instantaneous axis, \bar{v} = velocity of mass center, and I = moment of inertia about axis through mass center perpendicular to plane of motion. The *unit of energy* is the same as the unit of work. For KE in foot-pounds, use m in slugs, v in feet per second, ω in radians per second, and k in feet.

Principle of Conservation of Energy. If a body or system of bodies is isolated so that it neither receives nor gives out energy, its total store of energy, all forms included, remains constant; there may be a transfer of energy from one part of the system to another, but the total gain or loss in one part is exactly equivalent to the loss or gain in the remainder. This is the principle of conservation of energy.

Principle of Work and Kinetic Energy. The total work of the applied forces acting on any body or on any system of connected bodies equals the change in the kinetic energy of the body or bodies. (This assumes no work is converted into nonmechanical types of energy.) Work done = ΔKE . ΔKE in translation is $\frac{1}{2}m(v_2^2 - v_1^2)$, v_1 and v_2 being initial and final velocities. ΔKE in rotation is $\frac{1}{2}I(\omega_2^2 - \omega_1^2) = \frac{1}{2}mk^2(\omega_2^2 - \omega_1^2)$, ω_1 and ω_2 being initial and final angular velocities. In plane motion, change in KE is

$$\begin{aligned}\Delta KE &= \frac{1}{2}I(\omega_2^2 - \omega_1^2) = \frac{1}{2}mk^2(\omega_2^2 - \omega_1^2) \\ &= \frac{1}{2}m(\bar{v}_2^2 - \bar{v}_1^2) + \frac{1}{2}I(\omega_2^2 - \omega_1^2) \\ &= \frac{1}{2}m(\bar{v}_2^2 - \bar{v}_1^2) + \frac{1}{2}m\bar{k}^2(\omega_2^2 - \omega_1^2)\end{aligned}$$

in which I and k are referred to instantaneous axis and \bar{I} and \bar{k} to a parallel axis through the mass center and \bar{v} is velocity of mass center.

Example 7. Water falling from a height of 120 ft at the rate of 1000 ft³/min drives a turbine directly connected to an electric generator at 120 rpm. If the total resisting torque due to friction is 250 lb-ft and the water leaves the turbine blades with a velocity of 15 ft/sec, find the power developed by the generator.

Solution. This is a problem in the conversion of potential energy to work that in turn is converted to useful kinetic energy, wasted kinetic energy, and wasted thermal energy, the total energy of the system

of course remaining constant. Assume that 1 ft³ of water weighs 62.5 lb and $g = 32$ ft/sec². In 1 min,

$$\begin{aligned}\Delta PE &= Wh \\ &= 1000 \times 62.5 \times 120 \\ &= 7,500,000 \text{ ft-lb}\end{aligned}$$

$$\begin{aligned}\text{Wasted } \Delta KE &= \frac{1}{2}mv^2 \\ &= \frac{1000 \times 62.5 \times 15^2}{2 \times 32} \\ &= 219,700 \text{ ft-lb}\end{aligned}$$

$$\begin{aligned}\text{Wasted friction (thermal) } \Delta TE &= T\theta \\ &= 250 \times 2\pi \times 120 \\ &= 188,500 \text{ ft-lb}\end{aligned}$$

Therefore

$$\begin{aligned}\text{Useful } \Delta KE &= \Delta PE - \text{wasted } \Delta KE - \text{wasted } \Delta TE \\ &= 7,500,000 - 219,700 - 188,500 \\ &= 7,091,800 \text{ ft-lb} \\ P &= \frac{7,091,800}{33,000} = 215 \text{ hp or } 215 \times 0.7457 \\ &= 160 \text{ kW}\end{aligned}$$

Impulse, Momentum, and Impact of a Force

Impulse. *Linear impulse* of a force is the integral of the force over the time of application of the force. The integral can be separated into components along convenient coordinate directions. Linear impulse is a vector quantity. Thus the linear impulse of a force \mathbf{F} , can be calculated as

$$\int_{t_1}^{t_2} \mathbf{F} dt = \int_{t_1}^{t_2} F_x dt \mathbf{i} + \int_{t_1}^{t_2} F_y dt \mathbf{j} + \int_{t_1}^{t_2} F_z dt \mathbf{k}$$

The direction cosines of the resultant vector are determined in the usual manner. The *unit of impulse* is any unit force times any unit time, as pound (force) seconds.

Angular impulse of a force about a point is the time integral of the moment of that force about the point. If \mathbf{r} is the vector from the point O to any point on the line of application of the force, \mathbf{F} , then the angular impulse of \mathbf{F} about O is given by

$$\int_{t_1}^{t_2} (\mathbf{r} \times \mathbf{F}) dt$$

The angular impulse of a force about a line is the time integral of the moment of the force about the line. If the line connects points O and A , and if \mathbf{r} is the vector from O to any point on the line of action of \mathbf{F} , then the moment of the force \mathbf{F} about OA is given by $\mathbf{M}_{OA} = \mathbf{r} \times (\mathbf{F} - \mathbf{F} \cdot \mathbf{U}_{OA})$, and the angular impulse of \mathbf{F} about OA is

$$\int_{t_1}^{t_2} \mathbf{r} \times (\mathbf{F} - \mathbf{F} \cdot \mathbf{U}_{OA}) dt$$

where \mathbf{U}_{OA} is a unit vector along the OA line selected to be positive when directed from O to A . The *unit of angular impulse* is unit torque times unit time, as pound (force) feet seconds.

Momentum. *Linear momentum* of a particle is the product of its mass and velocity. It is a vector quantity and has the sense and direction of the velocity. The *unit of momentum* is the same as the unit of impulse. Linear momentum of a body is the resultant, or vector sum, of the momentums of its particles. In any motion the linear momentum of a body is mv , m being the mass of the body and \bar{v} the velocity of its mass center.

Angular momentum of a particle about a point is the moment of its linear momentum about that point. If the linear momentum of the particle is $\mathbf{P} = m\mathbf{v}$, O is the reference point, and \mathbf{r} is the vector from O to the particle, then the angular momentum of the particle about O is

$$\mathbf{h}_O = \mathbf{r} \times \mathbf{P} = \mathbf{r} \times m\mathbf{U}$$

Angular momentum is a vector quantity. The *unit of angular momentum* is mass times velocity times distance.

Angular momentum of a particle about an axis is the moment of the particle's linear momentum component which is not parallel to the axis about any point on the axis. If OA is the axis, then the angular momentum of the particle about the axis is

$$\mathbf{h}_{OA} = \mathbf{r} \times (\mathbf{P} - \mathbf{P} \cdot \mathbf{U}_{OA})$$

where \mathbf{U}_{OA} is a unit vector along the line OA .

In Fig. 37, let $mv =$ momentum of particle P . Resolve the momentum into components parallel and perpendicular to the axis. DE is the perpendicular distance from the axis to line AP . The angular momentum of $P = mv \cos \alpha \times DE$. The angular momentum of a body about an axis is the algebraic sum of the angular momentums of its particles. The angular momentum of a rotating body about the axis of rotation is $I\omega = mk^2 \omega$, I and k being the moment of inertia and radius of gyration, respectively, about the axis of rotation and ω the angular velocity. The unit of angular momentum is the same as the unit of angular impulse.

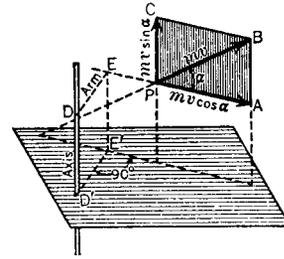

Fig. 37 Angular momentum of a particle.

Principle of Conservation of Linear and Angular Momentum.

When no external forces are acting upon a body or system of bodies, the component linear momentum along any line and the angular momentum about any line remain constant; this is the principle of conservation of linear and angular momentum.

Principle of Impulse and Momentum.

For linear momentum, the impulse of the resultant force acting for an infinitesimal time upon a body is equal to the change in linear momentum of its mass center during that time parallel to the direction of the force. Referred to coordinate axes, the change in the component of linear momentum parallel to any axis x for any length of time $t_2 - t_1$ equals the algebraic sum of the components of the impulses of the applied forces parallel to the axis in the same time, or, more briefly $\Delta(m\bar{v}_x) = \sum \int_{t_1}^{t_2} F_x dt$. Similarly, the change in the angular momentum about any axis y in the time $t_2 - t_1$ equals the algebraic sum of the angular impulses of the applied forces about the axis in the same time, or, more briefly $\Delta(I_y \omega) = \sum \int_{t_1}^{t_2} T_y dt$.

Example 8. A jet of water strikes a concave vessel with a velocity of 80 ft/sec and leaves it with a velocity that has the same magnitude but makes an angle of 120° with the original direction. If the diameter of the jet is 1 in., find the force necessary to hold the vessel in position.

Solution. The sustaining force \mathbf{F} must bisect the acute angle between the lines representing the original and final velocities. Let the line of action of \mathbf{F} (Fig. 38) be taken as the X axis. There is no change in the Y component of momentum. The impulse of the force in the X direction in t seconds is $F \times t$ pound-seconds. The weight of water deflected in t seconds is $W = 80\pi \times 62.5t/576$ lb. The component of the original momentum in the X direction is $-80 W \cos 30^\circ/g$ pound-seconds. The component of the final momentum in the X direction is $80 W \cos 30^\circ/g$ pound-seconds. The change in momentum in the X direction is $160 W \cos 30^\circ/g = 5 W \cos 30^\circ$ pound-seconds. The fundamental relation gives $F \times t = 5 \times 80\pi \times 62.5 \times \cos 30^\circ \times t/576$, whence $F = 118$ lb. Observe that the sustaining force F does no mechanical work and that the water suffers no loss of kinetic energy.

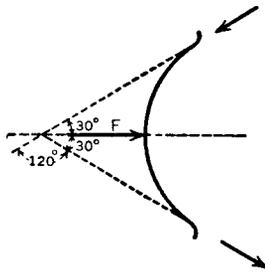

Fig. 38 Deflected water jet.

Impact. *Impact* occurs when two bodies collide. It is *direct* when the motion is perpendicular to the striking surfaces; otherwise it is *oblique*. It is *central* if the forces that the bodies exert on each other are directed along the line joining the mass centers; otherwise it is *eccentric*. In any collision, the forces that the two bodies exert on each other are equal and opposite at each instant; hence the total impulses of these forces during the collision are equal and opposite, and according to the principle of impulse and momentum the changes in the momentum of the bodies produced by the collision must be equal and opposite; or, otherwise stated, the total momentum of the two bodies is unchanged by the collision. Or, for *direct central impact*,

$$m_1 v_1 + m_2 v_2 = m_1 V_1 + m_2 V_2$$

wherein m_1, m_2 are the masses of the bodies, v_1, v_2 their velocities before, and V_1, V_2 their velocities after the collision; but in numerical substitution, velocities in one direction are given the same sign and those in the other direction the opposite sign.

Experiments on direct central impact of spherical bodies have shown that the relative velocities of spheres after impact are always less than before the impact and that these relative velocities are opposite in direction. The ratio of the relative velocities after impact to that before impact is called *coefficient of restitution*; it seems to depend only on the material of the impinging spheres. For glass the coefficient is $\frac{15}{16}$, for steel and cork $\frac{5}{9}$, ivory $\frac{8}{9}$, wood about $\frac{1}{2}$, clay and putty 0. If $e =$ coefficient then

$$V_1 - V_2 = -e(v_1 - v_2)$$

This equation and the preceding one solved simultaneously show that

$$V_1 = v_1 - \frac{(1 + e)m_2}{m_1 + m_2}(v_1 - v_2)$$

$$V_2 = v_2 - \frac{(1 + e)m_1}{m_1 + m_2}(v_2 - v_1)$$

During impact there is, in general, loss of kinetic energy*; the loss is $\frac{1}{2}(v_1 - v_2)^2(1 - e^2)m_1 m_2 / (m_1 + m_2)$. Bodies for which $e = 0$ are said to be *inelastic*, and those for which e is nearly 1 are said to be nearly perfectly *elastic*. When a sphere is dropped on a horizontal surface of a large body from a height h , if $H =$ height of rebound, then $H = e^2 h$. This equation furnishes a means of computing e .

Example 9. Ballistic Pendulum. This is a device for determining the velocity of a bullet. The bullet is imbedded in soft material, such as clay, for which $e = 0$. Referring to Fig. 39, let $m_1 =$ mass of bullet, $m_2 =$ mass of pendulum, $k =$ radius of gyration about axis of suspension O , $v_1 =$ velocity of bullet (to be determined), $v_2 = r\omega =$ velocity of bullet after impact, and $\omega =$ angular velocity of pendulum after impact and assume the pendulum is stationary before impact. Then the angular momentum of the system before impact is $m_1 v_1 r$, and the angular momentum of the system just after impact is $m_1 r^2 \omega + m_2 k^2 \omega$. Since the total momentum of the system remains constant, $m_1 v_1 r = m_1 r^2 \omega + m_2 k^2 \omega$. If the mass center of the pendulum rises to height h , $k^2 \omega^2 = 2gh$. Combining the last two equations to eliminate ω and solving for v_1 , $v_1 = (m_1 r^2 + m_2 k^2) \sqrt{2gh} / m_1 r k$. The quantities on the right-hand side of this equation are easily determined experimentally.

4.3 Kinematic and Kinetic Formulas

Symbols. $s =$ distance along path of motion; $x, y, z =$ coordinates of any point; $\bar{x}, \bar{y}, \bar{z} =$ coordinates of mass center; $t =$ time; $a =$ resultant linear acceleration of any point; $\bar{a} =$ resultant linear acceleration of mass center; $a_{x,y,z} =$ components of resultant acceleration along x, y, z axes; $a_t =$ resultant tangential acceleration of any point; $a_n =$ resultant normal acceleration of any point; $v, \bar{v}, v_{x,y,z} =$ linear velocities having corresponding significances $\theta =$ angular displacement; $\alpha =$ angular acceleration;

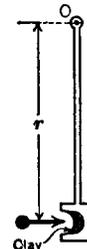

Fig. 39 Ballistic pendulum.

*As energy can be neither created nor destroyed, the total energy remains constant. The "lost" kinetic energy is simply converted into other forms, as, e.g., into work done in distorting the bodies' thermal (heat) energy.

ω = angular velocity; n = revolutions per unit time; r = radius (of curvature); g = acceleration of gravity = 32.2 ft/sec² (approx.); m = weight/ g = mass; F = resultant force; $F_{x,y,z}$ = components of resultant force along x, y, z axes; F_t = resultant tangential force; F_n = resultant normal force; W = work; Eff = efficiency; P = power; KE = kinetic energy; Imp = linear impulse; Mom = linear momentum; T = resultant torque about axis of rotation; $T_{x,y,z}$ = torques about x, y, z axes; Ang Imp = angular impulse; Ang Mom = angular momentum; I = moment of inertia (for mass) about axis of rotation; $I_{x,y,z}$ = moments of inertia about x, y, z axes; \bar{I} = moment of inertia about axis through mass center; $k, k_{x,y,z}, \bar{k}$ = corresponding radii of gyration; d = distance between axes; U = product of inertia; U_{xy} = product of inertia with respect to YOZ and ZOX planes; (U_{yz}, U_{zx} have corresponding significances) Δ indicates "change in."

Gravitation and Inertia Functions. Mass center has coordinates:

$$\begin{aligned}\bar{x} &= \frac{\int x dm}{m} & \bar{y} &= \frac{\int y dm}{m} & \bar{z} &= \frac{\int z dm}{m} \\ \bar{I} &= \int r^2 dm & I &= \bar{I} + md^2 & k^2 &= \bar{k}^2 + d^2 \\ \bar{k} &= \sqrt{\frac{\bar{I}}{m}} & k &= \sqrt{\frac{I}{m}} \\ U_{xy} &= \int xy dm & U_{yz} &= \int yz dm & U_{zx} &= \int zx dm\end{aligned}$$

Translation* — (Rectilinear Motion)

$$\begin{aligned}v &= \frac{ds}{dt} & a &= \frac{dv}{dt} = \frac{d^2s}{dt^2} & \frac{a}{v} &= \frac{dv}{ds} \\ \Delta s &= \int_{t_1}^{t_2} v dt & \Delta v &= \int_{t_1}^{t_2} a dt \\ \Delta t &= \int_{s_1}^{s_2} \frac{ds}{v} = \int_{v_1}^{v_2} \frac{dv}{a} & \Delta v^2 &= 2 \int_{s_1}^{s_2} a ds \\ F &= m\bar{a} & \Delta W &= \int_{s_1}^{s_2} F ds \\ KE &= \frac{1}{2}m\bar{v}^2 & \Delta W &= \Delta KE \\ P &= \frac{dW}{dt} = Fv & \Delta \text{Imp} &= \int_{t_1}^{t_2} F dt \\ \text{Mom} &= m\bar{v} & \Delta \text{Imp} &= \Delta \text{Mom}\end{aligned}$$

*For a rigid body in translation, accelerations and velocities of all particles are equal. However, \bar{a} and \bar{v} are indicated in certain of the kinetic translation formulas to make them applicable also to nonrigid bodies.

Translation — (curvilinear Motion)

$$\begin{aligned}v &= \frac{ds}{dt} & v_x &= \frac{dx}{dt} & v_y &= \frac{dy}{dt} & v_z &= \frac{dz}{dt} \\ v &= \sqrt{v_x^2 + v_y^2 + v_z^2}\end{aligned}$$

Directional cosines of v are $\cos \theta_x = v_x/v$, $\cos \theta_y = v_y/v$, and $\cos \theta_z = v_z/v$:

$$\begin{aligned}a_x &= \frac{dv_x}{dt} = \frac{d^2x}{dt^2} & a_y &= \frac{dv_y}{dt} = \frac{d^2y}{dt^2} \\ a_z &= \frac{dv_z}{dt} = \frac{d^2z}{dt^2} & a &= \sqrt{a_x^2 + a_y^2 + a_z^2}\end{aligned}$$

Directional cosines of a are $\cos \phi_x = a_x/a$, $\cos \phi_y = a_y/a$, and $\cos \phi_z = a_z/a$:

$$a_t = \frac{dv}{dt} = \frac{d^2s}{dt^2} \quad a_n = \frac{v^2}{r} \quad a = \sqrt{a_t^2 + a_n^2}$$

$$\frac{a_t}{v} = \frac{dv}{ds}$$

$$\Delta s = \int_{t_1}^{t_2} v dt \quad \Delta v = \int_{t_1}^{t_2} a_t dt$$

$$\Delta t = \int_{s_1}^{s_2} \frac{ds}{v} = \int_{v_1}^{v_2} \frac{dv}{a_t} \quad \Delta v^2 = 2 \int_{s_1}^{s_2} a_t ds$$

$$\mathbf{F} = m\bar{\mathbf{a}} \quad F_x = m\bar{a}_x \quad F_y = m\bar{a}_y$$

$$F_z = m\bar{a}_z \quad F_t = m\bar{a}_t \quad F_n = m\bar{a}_n$$

$$F = \sqrt{F_x^2 + F_y^2 + F_z^2} \quad \text{or} \quad F = \sqrt{F_t^2 + F_n^2}$$

$$\Delta W = \int_{s_1}^{s_2} F_t ds \quad KE = \frac{1}{2}m\bar{v}^2 \quad \Delta W = \Delta KE$$

$$P = \frac{dW}{dt} = F_t v$$

$$\Delta \text{Imp}_x = \int_{t_1}^{t_2} F_x dt \quad \Delta \text{Imp}_y = \int_{t_1}^{t_2} F_y dt$$

$$\Delta \text{Imp}_z = \int_{t_1}^{t_2} F_z dt \quad \text{Imp} = \sqrt{\text{Imp}_x^2 + \text{Imp}_y^2 + \text{Imp}_z^2}$$

$$\text{Mom}_x = m\bar{v}_x \quad \text{Mom}_y = m\bar{v}_y \quad \text{Mom}_z = m\bar{v}_z$$

$$\text{Mom} = \sqrt{\text{Mom}_x^2 + \text{Mom}_y^2 + \text{Mom}_z^2}$$

$$\Delta \text{Imp}_x = \Delta \text{Mom}_x \quad \Delta \text{Imp}_y = \Delta \text{Mom}_y$$

$$\Delta \text{Imp}_z = \Delta \text{Mom}_z \quad \Delta \text{Imp} = \Delta \text{Mom}$$

Directional cosines of $\Delta \text{Imp} = \Delta \text{Mom}$ are $\cos \psi_x = \Delta \text{Imp}_x / \Delta \text{Imp}$, $\cos \psi_y = \Delta \text{Imp}_y / \Delta \text{Imp}$, and $\cos \psi_z = \Delta \text{Imp}_z / \Delta \text{Imp}$.

For kinetic formulas applying to a translated body for rotation about an axis not fixed in the body or its extension, use formulas applying to “rotation of a particle” about its axis, considering the entire mass of the body as concentrated at the mass center.

Rotation*

$$\omega = \frac{d\theta}{dt} \quad \alpha = \frac{d\omega}{dt} = \frac{d^2\theta}{dt^2} \quad \frac{\alpha}{\omega} = \frac{d\omega}{d\theta}$$

$$\Delta\theta = \int_{t_1}^{t_2} \omega dt \quad \Delta\omega = \int_{t_1}^{t_2} \alpha dt$$

$$\Delta t = \int_{\theta_1}^{\theta_2} \frac{d\theta}{\omega} = \int_{\omega_1}^{\omega_2} \frac{d\omega}{\alpha} \quad \Delta\omega^2 = 2 \int_{\theta_1}^{\theta_2} \alpha d\theta$$

For a “particle” (\bar{I} infinitesimal compared with I for finite body):

$$s = r\theta \quad v = r\omega \quad a_t = r\alpha \quad a_n = r\omega^2$$

$$a = r\sqrt{\alpha^2 + \omega^4}$$

$$T = F_t r = mr^2\alpha \quad F_t = mr\alpha \quad F_n = mr\omega^2$$

$$F = mr\sqrt{\alpha^2 + \omega^4}$$

$$\Delta W = \int_{\theta_1}^{\theta_2} T d\theta \quad KE = \frac{1}{2}mr^2 \omega^2 \quad \Delta W = \Delta KE$$

$$P = \frac{dW}{dt} = T\omega$$

$$\Delta \text{AngImp} = \int_{t_1}^{t_2} \mathbf{T} dt \quad \text{Ang Mom} = mr^2 \omega$$

$$\Delta \text{AngImp} = \Delta \text{AngMom}$$

For a body:

$$T = I\alpha = mk^2\alpha \quad \Delta W = \int_{\theta_1}^{\theta_2} T d\theta \quad \Delta W = \Delta KE$$

$$P = \frac{dW}{dt} = T\omega \quad KE = \frac{1}{2}I\omega^2 = \frac{1}{2}mk^2 \omega^2$$

$$\Delta \text{AngImp} = \int_{t_1}^{t_2} \mathbf{T} dt \quad \text{AngMom} = I\omega = mk^2\omega$$

$$\Delta \text{AngImp} = \Delta \text{AngMom}$$

Constrained Rotation† Assume the plane of rotation is fixed above and parallel to the horizontal XZ plane; the vertical Y axis of rotation is not passing through the mass center (except as a special case). All previous rotation formulas apply if T is replaced by T_y . Additional formulas are:

For a particle (\bar{I} infinitesimal compared with I for a finite body):

$$F_x = m\bar{z}\alpha - m\bar{x}\omega^2 \quad F_y = 0$$

$$F_z = -m\bar{x}\alpha - m\bar{z}\omega^2 \quad F = \sqrt{F_x^2 + F_y^2 + F_z^2}$$

$$T_x = F_z\bar{y} = -m\bar{x}\bar{y}\alpha - m\bar{y}\bar{z}\omega^2$$

$$T_y = F_x\bar{z} = m\bar{z}^2\alpha - m\bar{x}\bar{z}\omega^2 = mr^2\alpha$$

$$= -F_z\bar{x} = m\bar{x}^2\alpha + m\bar{x}\bar{z}\omega^2 = mr^2\alpha$$

$$T_z = -F_x\bar{y} = -m\bar{y}\bar{z}\alpha + m\bar{x}\bar{y}\omega^2$$

(θ, ω, α , positive for counterclockwise rotation facing origin from plus point on axis)

For a body:

$$T_x = -U_{xy}\alpha - U_{yz}\omega^2 \quad T_y = I_y\alpha$$

$$T_z = -U_{yz}\alpha + U_{xy}\omega^2 \quad (\text{sign convention as before})$$

The **center of percussion and center of oscillation** of a pendulum are located at a distance from the center of suspension, given as k^2/\bar{z} , where \bar{z} is distance from the center of suspension to the mass center.

Plane and Three-Dimensional Motions For translation of mass center, consider the entire mass as concentrated at the mass center. Refer motion to a set of fixed axes located outside the body. To determine acceleration of the mass center, apply formulas for translation.

For rotation about mass center, consider the mass center as fixed and the resultant of forces as a couple. Refer motion to a set of central principal axes. To determine the components of angular acceleration about these axes, use the formulas

$$T_x = I_x\alpha_x + (I_z - I_y)\omega_y\omega_z$$

$$T_y = I_y\alpha_y + (I_x - I_z)\omega_z\omega_x$$

$$T_z = I_z\alpha_z + (I_y - I_x)\omega_x\omega_y$$

For complete resultant motion, combine the motion of translation of mass center with the motion of rotation about mass center.

*Formulas are for rigid bodies.

†In obtaining total forces and torques, the effect of the weight of a body (this effect depending on position of plane of rotation) must not be neglected.

Work and kinetic energy changes also are equal to the respective sums of the corresponding changes under the preceding component motions.

4.4 Translation

Kinetic formulas for motion of translation follow directly from the kinematic formulas applying to such motion and the previous discussion on kinetic quantities and their relations. The formulas are summarized in Section 4.3 under the heading "Translation." For the solution of a specific problem, careful choice of formulas will often facilitate the computations. As there is no rotation, the resultant force acts through the mass center and there is no couple.

Example 10. Motion of Parallel Rod of a Locomotive. The problem is to find the forces acting upon the parallel rod when it is in any position with respect to the wheels. Assume the velocity of the locomotive constant at 60 mph on a level track, driver diameter 5.5 ft, crank length 1 ft, and weight of rod 275 lb. The forces acting on the rod are its weight and the pressures of the crank pins at its ends; the latter are represented (Fig. 40) by their horizontal and vertical components. Since the resultant of all these forces acts through the mass center, $V_1 = V_2$; also $2V_1 - 275 = (W/g)a_y = 8.55a_y$ and $H_1 - H_2 = (W/g)a_x = 8.55a_x$. To determine a_x and a_y , The velocity of the center of either crank pin relative to the locomotive is $(88 \times 1)/2.75 = 32$ ft/sec (60 mph = 88 ft/sec), and the relative motion of the pin being circular at constant velocity, the relative acceleration is toward the center of the crank pin circle at all times and equals $32^2/1 = 1024$ ft/sec². This is also the absolute acceleration of the crank pin, since the locomotive is assumed to have no acceleration. But the rod has the same acceleration as the crank pin; hence $a_x = 1024 \sin \theta$ and $a_y = 1024 \cos \theta$. Thus $V = \frac{1}{2}(8755 \cos \theta + 275)$ and $H_1 - H_2 = 8755 \sin \theta$. In the lowest position of the rod, $\theta = 0$, $a_x = 0$, $a_y = 1024$, $H_1 = H_2$, and $V = \frac{1}{2}(8755 + 275) = 4515$. In a midposition, when $\theta = 90^\circ$, $a_x = 1024$, $a_y = 0$, $H_1 - H_2 = 8755$, and $V = \frac{1}{2}(275) = 137.5$. In the highest position, $\theta = 180^\circ$, $a_x = 0$, $a_y = -1024$, $H_1 = H_2$, and $V = \frac{1}{2}(275 - 8755) = -4240$, the negative sign meaning that V acts downward on the rod.

4.5 Rotation

Kinetic formulas for motion of rotation follow directly from the kinematic formulas applying to such motion

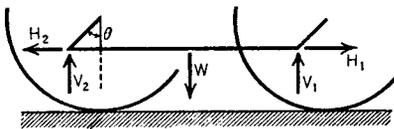

Fig. 40 Translational motion/locomotive parallel rod.

and the previous discussion on kinetic quantities and their relations. The formulas are summarized in Section 4.3 under the heading "Rotation." For the solution of a specific problem, careful choice of formulas will often facilitate the computations. As there is no translation, the resultant force is zero but there is a couple.

Example 11. A punch is required to exert a force of 100,000 lb through a distance of $\frac{1}{4}$ in., and the work is to be supplied by a flywheel of radius of gyration 1.5 ft making 120 rpm. Find the weight of the wheel if the speed is not to be reduced below 100 rpm.

Solution. $\omega_1 = 120$ rpm = 4π rad/sec, $\omega_2 = 100$ rpm = $(10/3)\pi$ rad/sec. Work done by punch = 100,000/48 ft-lb = reduction in KE of flywheel.

Change in KE = $\frac{1}{2}mk^2 \Delta\omega^2 = W \times 2.25(\omega_1^2 - \omega_2^2)/64 = W \times 2.25(\omega_1 - \omega_2)(\omega_1 + \omega_2)/64$. Hence $(W \times 2.25)/64(2\pi/3)(22\pi/3) = 100,000/48$; hence $W = 1230$ lb = minimum weight of flywheel

Constrained Rotation *Constrained rotation* refers to rotation of a body about a fixed axis that does not pass through its mass center. Such an axis, since it constrains the motion,* must be held by forces (exerted by bearings) to keep it from shifting position. These bearing reactions depend on the weight of the body, the manner in which the mass of body is distributed about the axis, the applied forces, the angular velocity ω , and the angular acceleration α . Generally, the resultant of the applied forces for such a body is not a single force, but a single force at a selected origin and a couple. Selecting the origin on the axis of rotation, the axial components of the single force and axial components of the couple are given by the following six equations.†

$$\Sigma F_x = m\bar{z}\alpha - m\bar{x}\omega^2$$

$$\Sigma T_x = -\alpha \int xy \, dm - \omega^2 \int yz \, dm$$

$$= -U_{xy}\alpha - U_{yz}\omega^2$$

$$\Sigma F_y = 0 \quad \Sigma T_y = I_y\alpha$$

$$\Sigma F_z = -m\bar{x}\alpha - m\bar{z}\omega^2$$

$$\Sigma T_z = -\alpha \int yz \, dm + \omega^2 \int xy \, dm$$

$$= -U_{yz}\alpha + U_{xy}\omega^2$$

In these equations, the axis of rotation is fundamentally the y axis; \bar{x} , \bar{y} , \bar{z} are the instantaneous coordinates of the mass center; ΣF_x , ΣF_y , ΣF_z are the sums of

*In certain cases, the "physical path" itself constrains the rotation, as the action of the track on a train rounding a curve.
†In obtaining total forces and torques, the effect of the weight of the body must not be neglected.

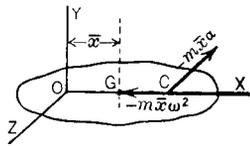

Fig. 41 Constrained rotation.

components of all applied forces in the axial directions; $\Sigma T_x, \Sigma T_y, \Sigma T_z$ are the sums of moments of all applied forces about the axes; and the convention of signs for moments of forces and senses of $\theta, \omega,$ and α are that counterclockwise rotation, facing the origin from any point on an axis, is positive.

The equations are simultaneous at each instant. They are used more often to determine the forces exerted by the bearings on the axle than to determine the resultant.

Special Cases (Fig. 41). Choose the x axis through an instantaneous location of the mass center and let XZ be a plane of symmetry of a homogeneous body. The resultant is a single force in the plane of symmetry having the Z component $-m\bar{x}\alpha$ and the X component $-m\bar{x}\omega^2$ acting at point $C, \overline{OC} = k_y^2/\bar{x}, k_y$ being the radius of gyration about the y axis. If $\bar{x} = 0$, the resultant becomes a couple in the XZ plane of moment $\Sigma T_y = I_y\alpha$. If $\alpha = 0$ and $\bar{x} \neq 0$, the resultant is $-m\bar{x}\omega^2$ in the sense CO . If $\alpha = 0$ and $\bar{x} = 0$, the resultant vanishes.

Centrifugal Force. Let any particle of mass m move in a circular path of radius r about a fixed y axis. The resultant of all forces acting on the particle has a normal component mrv^2 and a tangential component mra . The component mra increases or decreases the speed of the particle; the component mrv^2 continually changes the direction of the linear velocity. The resultant of such forces for all the particles of the body is equivalent to the resultant specified by the preceding general equations. If ω is constant and $\alpha = 0$, the resultant force acting on the particle to make it rotate in its circular path is mrv^2 toward the axis and is called *centripetal force*. *Centrifugal force* for the particle is equal and opposite to centripetal force and is exerted by the particle upon its neighboring particles or upon the axis of rotation. The *centrifugal resultant* for a body is the resultant of the centrifugal forces of all its particles. Generally, this resultant is not a single force; it may be computed from the general equations by making $\alpha = 0$ and reversing senses of resultant force and couple.

Center of Percussion. A prismatic bar (Fig. 42) is suspended on a horizontal y axis at O and G is the mass center. If a force P , parallel to the x axis, is applied to the body, the axle reaction OD will generally be inclined to the z axis at some angle $\pm\beta$, the angle depending on the distance h of P from

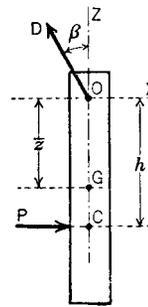

Fig. 42 Center of percussion.

the axis of rotation. If $h = k_y^2/\bar{z}$, in which k_y is the radius of gyration about the y axis, P will cause no x component of axle reaction; that is, β will be zero, and the point C , where the action line of P intersects OG , is the *center of percussion*. In impact testing machines, heavy pendulums are used to deliver blows, and proper design requires the striking point to coincide with the center of percussion in order to avoid shock to the axle and detrimental vibration of the pendulum itself.

Examples of Constrained Rotation

Simple Pendulum. This consists of a small heavy bob on a light string (Fig. 43).^{*} The forces acting on it are the weight W and tension T . The resultant force along the tangent is $-W \sin \theta$; the resultant force along the normal is $T - W \cos \theta$. The force equations are $Wa_t/g = -W \sin \theta, Wa_n/g = T - W \cos \theta$. Since $a_n = l\omega^2$, tension $T = W(\cos \theta + l\omega^2/g)$.

To determine the motion, $a_t/g = l\alpha/g = -\sin \theta$. The solution of this equation leads to elliptic functions. An approximate solution for small oscillations can be obtained by putting $\sin \theta = \theta$. (The difference between θ and $\sin \theta$ is less than 1% if θ is less than 14° .) The differential equation becomes $\omega d\omega/d\theta = -g\theta/l$. If the pendulum is at the end of its swing

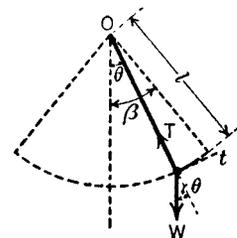

Fig. 43 Simple pendulum.

^{*}The radius of gyration of the bob about its axis through its mass center parallel to the axis of rotation is considered negligible compared with the radius of its path.

when $t = 0$, then $\theta = \beta, \omega = 0$. Integrating, $\omega^2 = g(\beta^2 - \theta^2)/l$ and $\omega = d\theta/dt = \pm\sqrt{(g/l)(\beta^2 - \theta^2)}$. Integrating, $\theta = \beta \cos \sqrt{(g/l)t}$. Period of oscillation = $2\pi \sqrt{l/g}$.

Conical Pendulum.* This consists of a small heavy bob suspended from a fixed point by a light string go that it can be made to rotate about the vertical axis through the fixed point (Fig. 44). If the bob rotates with constant angular velocity ω , the quantities ϕ, r, h are constants. Since there is no vertical acceleration, $T \cos \phi = W$. The force acting inward on the bob is $T \sin \phi$. Hence the force equation gives $T \sin \phi = W a_n/g = W v^2/gr$ and $\tan \phi = v^2/gr = r\omega^2/g$. Also $h = g/\omega^2, T = Wl\omega^2/g$, period of one revolution = $2\pi/\omega = 2\pi \sqrt{h/g}$.

Compound (or Physical) Pendulum. This is any rigid body suspended from a horizontal axis about which it may rotate under the action of its own weight. The forces acting on the body are its weight, acting downward at G (Fig. 45), and the reaction of the axis at O . Let \bar{r} = distance OG ; k = radius of gyration about O . The torque equation gives $Wk^2\alpha/g = -W\bar{r} \sin \theta$, whence $\alpha = -\bar{r}g \sin \theta/k^2$. This is the equation of a simple pendulum (discussed previously) of length $l = k^2/\bar{r}$ called the length of the equivalent simple pendulum. The motion of a compound pendulum is the same as the motion of the equivalent simple pendulum. The point on the compound pendulum located at the distance k^2/\bar{r} from the axis of rotation is called the *center of oscillation*. It coincides with the center of percussion (discussed previously).

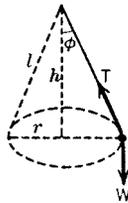

Fig. 44 Conical pendulum.

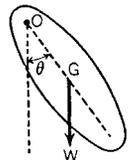

Fig. 45 Compound pendulum.

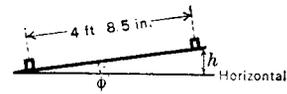

Fig. 46 Banking of track on a curve.

Superelevation of Outer Rail of a Railroad Track.

This is determined as follows (Fig. 46): Let r = radius of curvature in feet and v = speed in feet per second of car. Then horizontal centrifugal force is Wv^2/gr and vertical force is W acting through mass center.† For the resultant to be perpendicular to the track and thus impose no side load on the rails, $\tan \Phi = v^2/gr$. For small angles, the sine instead of the tangent may be used and, if h = superelevation of the outer rail in inches, $h = 56.5v^2/gr$.

Skidding and Tipping.

Suppose a car (Fig. 47) is taking a curve of radius r feet at a speed of v feet per second, G is mass center, N_1 is the vertical and F_1 the horizontal pressure on the outer wheel, and f is the coefficient of friction. The problem becomes one of statics by introducing $Wv^2/gr = F_1 + F_2 = F = fW$. If $f < v^2/gr$, the car will skid. Suppose $f \geq v^2/gr$; then $N_1 = W(\frac{1}{2} + v^2/dgr)$, $N_2 = W(\frac{1}{2} - v^2/dgr)$. The critical speed is $v_1 = \sqrt{dgr/2h}$ when the total weight is borne on the outer wheel. If this critical speed is exceeded, the car will tip over.

Note on Use of Rotation Formulas.

In practice, nearly all problems of the nature illustrated by the car problems are solved by the use of formulas applying to rotation of a *particle* about an axis. It should be realized, however, that the assumption thus made that the mass is concentrated at the mass center is not strictly correct except in the event that the body has a true motion of translation (as exemplified by the motion of the parallel rod of a locomotive). Seldom is this the case in practice as usually every line of the body lying in the plane of motion makes one complete revolution for each revolution of the body about the center of rotation of its path. Therefore the formulas

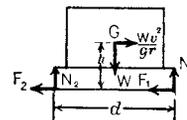

Fig. 47 Skidding and tipping on a curve.

*The principle of the conical pendulum is employed in the Watt governor for steam engines.

†Here and in the next problem, the radius of gyration of the car about its axis through its mass center parallel to the axis of rotation is considered negligible compared with the radius of its path.

applying to rotation of a body are the only ones giving absolutely correct results.

For example, in the problem above on the motion of a simple pendulum, considering the path as that of the mass center, the actual torque $T = Wk^2\alpha/g$, where k is radius of gyration of the bob about the horizontal axis of rotation through O . Let \bar{k} = radius of gyration of bob about horizontal axis through mass center parallel to axis through O . Then $k^2 = l^2 + \bar{k}^2$ and actual torque $T = W(l^2 + k^2)\alpha/g$. But the approximate assumption made in the problem that $F_1 = Wl\alpha/g$ gives $T = Wl^2\alpha/g$, which is too small by the amount $W\bar{k}^2\alpha/g$. However, when \bar{k} is very small compared with l , the results obtained are sufficiently near accurate.

4.6 Plane Motion

Kinetic formulas for plane motion are a combination of those for motions of translation and rotation. The procedure for solution of a problem was summarized under the heading "Plane and Three-Dimensional Motions." The general formula given there for determination of angular accelerations reduces to $T_x = I_x\alpha = mk_x^2\alpha$ the x axis being perpendicular to the plane of motion and passing through the mass center. The theory forming the basis for the assumptions regarding mass concentration and arrangement of forces is explained under the general case of "Three-Dimensional Motion."

Example 12. Wheel on Inclined Plane. In Fig. 48, $\tan \beta = \frac{3}{4}$, the wheel weighs 100 lb, diameter = 4 ft, radius of gyration = 1.6 ft. (a) Find the acceleration of the center if the wheel rolls without slipping. (b) Find the least coefficient of friction to prevent slipping. (c) If the coefficient of friction is 0.1, find the acceleration of the center and the number of turns made while the center moves 20 ft.

Solution. (a) The forces acting to move the wheel are $W \sin \beta = 60$ lb and friction F . The equation of motion of the center is $100a/32 = 60 - F$. The force acting to turn the wheel is F . The torque equation is $100 \times 1.6 \times 1.6\alpha/32 = 2F$. Since the wheel does not slip, $a = 2\alpha$. Elimination of F and α gives $a = 11.7$ ft/sec².

(b) Friction = minimum coefficient of friction \times normal pressure, or $F = fW \cos \beta = \text{minimum } f \times$

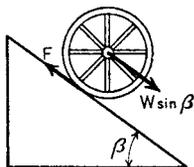

Fig. 48 Wheel on an inclined plane.

80. From the equation above, $F = 23.4$ lb; thus minimum $f = 0.29$.

(c) The relation between a and α is not known when the wheel slips. $F = 80 \times 0.1 = 8$ lb. The equation of motion of the center is $100a/32 = 60 - 8 = 52$, whence $a = 16.6$ ft/sec². Distance moved by center, $x = 8.3t^2$. Time to move 20 ft is given by $t^2 = 20/8.3$. Torque equation is $100 \times 1.6 \times 1.6\alpha/32 = 2 \times 8$, hence $\alpha = 2$ rad/sec². The angle turned through, $\theta = t^2 = 20/8.3 = 2.41$ rad = 0.38 rev.

4.7 Three-Dimensional Motion

Kinetic formulas for three-dimensional motion are a combination of those for motions of translation and rotation. The procedure for the solution of a problem was summarized under the heading "Plane and Three-Dimensional Motions."

Any motion of a body may be regarded as consisting of two components: one a translation equal to that of the mass center and the other a rotation about some axis through the mass center. These motions may be said to be produced independently by the forces acting on the body: thus (a) the acceleration of the mass center is the same as if the whole mass were concentrated there and acted upon by forces equal in magnitude to and in the same in direction as the actual external forces and (b) the angular acceleration is the same as if the mass center were fixed and the actual external forces applied. The reasonableness of this will be seen from the following: Imagine each force acting on the body replaced by a force acting at the mass center G and a couple; the resultant of all the forces acting at G is a single force R , and the resultant of all the couples is a single couple C ; R cannot turn the body but gives it a motion of translation only, and C cannot move G but merely turns the body about some line through G . In general, C does not cause turning about a line perpendicular to the plane of C , only so if the plane of C is perpendicular to one of the principal central axes of the body. To determine the acceleration of the mass center, take fixed x , y , and z axes outside the body and resolve all external forces F_1, F_2 , and so on, into x , y , and z components; then

$$\Sigma F_x = m\bar{a}_x \quad \Sigma F_y = m\bar{a}_y \quad \Sigma F_z = m\bar{a}_z$$

m denoting the mass of the body. To determine the angular acceleration of the body, take moments of all the forces F_1, F_2 , and so on, about the three central principal axes; calling the sums of the moments about these axes $\Sigma T_1, \Sigma T_2$, and ΣT_3 , the components of the angular acceleration α_1, α_2 , and α_3 , and the components of the angular velocity ω_1, ω_2 , and ω_3 ,

$$\Sigma T_1 = I_1\alpha_1 + (I_3 - I_2) \omega_2 \omega_3$$

$$\Sigma T_2 = I_2\alpha_2 + (I_1 - I_3) \omega_3 \omega_1$$

$$\Sigma T_3 = I_3\alpha_3 + (I_2 - I_1) \omega_1 \omega_2$$

wherein I_1 , I_2 , and I_3 denote the three central principal moments of inertia of the body. In any motion of a body, the kinetic energy may be computed in two parts: (a) the kinetic energy of the whole body moving with a velocity equal to that of the mass center and (b) the sum of the kinetic energies of the constituent particles of the body due to their velocities relative to an axis through the mass center.

4.8 Moving Axes

A *frame of reference* is a set of coordinate axes or coordinate curves with respect to which linear and angular positions, velocities, and accelerations are measured. For brevity, the word *frame* will denote a frame of reference, and a measurement with respect to a frame will be said to be made *in* that frame. A frame may move relative to another frame. In so doing, it has the same freedom of motion as a rigid body.

Forces can be specific and measured in a manner independent of the observer's frame of reference, as, for example, by spring extensions. It follows that Newton's third law, which is concerned with forces only, holds in all frames: in the mechanical interaction of two bodies, their mutual forces are equal but opposite and in the same line of action.

An *inertial frame* is a frame in which the first law of Newton holds, that is, that a particle free from forces is unaccelerated. This defines an inertial frame, while experiment shows that inertial frames exist. The second law of Newton, that net force equals mass times acceleration, is experimentally true in all inertial frames and only in inertial frames. There is no particular inertial frame that may be called absolute; but rather there are infinitely many possible inertial frames, and all of them are equivalent. Suppose that a frame R_1 is inertial. Other inertial frames may have any position of their origin in R_1 and their axes may have any orientation in R_1 . Another frame R_2 is inertial if and only if its origin has no acceleration in R_1 and in addition its orientation in R_1 is fixed. In other words, R_2 is inertial if and only if its motion in R_1 is at most a pure translation without acceleration. These conditions are necessary and sufficient in order that all accelerations should appear the same in R_2 as in R_1 ; they are therefore the conditions that, if R_1 is inertial, R_2 is also. Acceleration in an inertial frame will be called *true acceleration*.

Noninertial frames are of practical interest, for all terrestrial experiments are performed in such frames. Any frame fixed in the earth is noninertial because the earth is both spinning and accelerating relative to an inertial frame. Nevertheless, the observation of phenomena caused by the noninertial character of an earth-fixed frame is a matter of some delicacy, so that to a certain approximation such a frame may be considered inertial. An earth-fixed frame will be referred to simply as *the earth*.

The effects of the noninertial character of a frame are apparent accelerations or forces not accounted for by actual forces. Let a_x , a_y , and a_z be the components

of the apparent acceleration of a point mass m observed in a noninertial frame S . Let the true acceleration components in the same directions be a'_x , a'_y , and a'_z . Define components of *acceleration difference*, the difference between apparent and true accelerations:

$$g_x \equiv a_x - a'_x \quad g_y \equiv a_y - a'_y \quad g_z \equiv a_z - a'_z$$

The acceleration difference involves the motion of S relative to an inertial frame R , but it also involves the position x , y , z and the velocity v_x , v_y , v_z of m in S . Now, if the mass is free from actual forces, it is observed in S to have the acceleration g_x , g_y , g_z ; or, if the actual forces on it are specified it is observed to have this acceleration in addition to that predicted from Newton's second law by the observer in S . If, on the other hand, the observer in S specifies the motion of the particle relative to his frame, he finds it necessary to exert upon m , in addition to the force that he computes from Newton's second law, the force

$$f_x = -mg_x \quad f_y = -mg_y \quad f_z = -mg_z$$

The particle m thus exerts a reaction force having no apparent physical cause:

$$r_x = mg_x \quad r_y = mg_y \quad r_z = mg_z$$

The following paragraphs classify the possible acceleration differences.

Translational acceleration of frame S with components a_{0x} , a_{0y} , a_{0z} relative to an inertial frame R produces an acceleration difference

$$g_x = -a_{0x} \quad g_y = -a_{0y} \quad g_z = -a_{0z}$$

Thus, in a train that has acceleration a_{0x} along a straight track in the forward direction, a body free to move would have an apparent backward acceleration $g_x = -a_{0x}$. A mass m constrained to remain at rest in the train would exert a backward reaction $-ma_{0x}$.

Centripetal acceleration causes an acceleration difference when the system S rotates relative to R . If the rotation of S is about its z axis with an angular speed ω , then a point mass m at x , y , z has an acceleration difference $\omega^2\sqrt{x^2 + y^2}$ directed perpendicularly away from the z axis. The components of acceleration difference are

$$g_x = \omega^2 x \quad g_y = \omega^2 y \quad g_z = 0$$

If m is fixed in S , its reaction force is $r_x = m\omega^2 x$, $r_y = m\omega^2 y$. This is called centrifugal force. The rider on a merry-go-round exerts this force on his mount.

Angular acceleration of S in R produces an acceleration difference. Consider first the case when the axis of rotation remains in a fixed direction, and let this coincide with the z axis. Let $\alpha = d\omega/dt$ be the

rate of change of the magnitude of the angular velocity ω . The resulting acceleration difference for a mass point m at x, y, z is given by $\alpha\sqrt{x^2 + y^2}$ in a direction tangent to the circle of radius $\sqrt{x^2 + y^2}$ about the z axis. The components of the acceleration difference are

$$g_x = \alpha y \quad g_y = -\alpha x \quad g_z = 0$$

If a speck of dust is to cling to a phonograph record as the turntable starts or stops, the frictional force on it must be $-m\alpha y\mathbf{i} + m\alpha x\mathbf{j}$.

Precessional acceleration occurs when the frame S is rotating in R in such a way that its angular velocity vector changes direction. This change of direction may be described at a given instant as the rotation of the angular velocity vector about some axis perpendicular to itself with an angular velocity of precession Ω . Let the axes of S and R coincide at a particular instant, let the angular velocity ω of S be directed along positive z , and let the precession be along positive y . The right-handed-screw convention may be used to refer both angular velocities to their axis directions. The components of the acceleration difference for a mass point at x, y, z are then

$$g_x = 0 \quad g_y = \Omega\omega z \quad g_z = -\Omega\omega y$$

Its magnitude is $\Omega\omega\sqrt{y^2 + z^2}$, and its direction is tangent to a circle about the x axis. The force required to be exerted on mass m is then

$$f_x = -m\Omega\omega z \quad f_y = m\Omega\omega y$$

If a collection of particles fixed in S forms a flywheel there must be exerted on the flywheel a torque about the positive x axis in order to supply these forces and produce the precession. This is the well-known gyroscopic torque.

Coriolis acceleration is the only difference acceleration that depends on the velocity v_x, v_y, v_z of a point m in a rotating frame S . It occurs when m has a component of velocity in S that is perpendicular to the axis of rotation. Coriolis acceleration is always perpendicular to the velocity of m in S and is independent of the location of m . Let the rotation of S be about the z axis in the positive sense. The components of the Coriolis acceleration are then

$$g_x = 2\omega v_y \quad g_y = -2\omega v_x \quad g_z = 0$$

Coriolis acceleration appears in a body falling freely on the earth, causing it to deviate eastward from the plumb line. If the velocity of fall is v and the latitude of the place is λ , the acceleration difference is $2\omega v \cos \lambda$. As another illustration, let a train run north on a horizontal track with velocity v at the same (north) latitude λ . The train then exerts a Coriolis reaction force eastward, on the track, of magnitude $r = 2\omega v \sin \lambda$.

The general case may involve all the above types of acceleration simultaneously. These accelerations simply add vectorially.

4.9 Gyroscopic Motion

A *gyroscope* is essentially a symmetrical rotor that spins rapidly about its axis. The moment of inertia about the axis is made as large as possible within the limitations of weight and size of the instrument. Gyroscopic phenomena are only those that relate changes of direction of the spin axis to applied torque.

Precession is a term for rotation of the axis direction.

The *angular momentum* of the gyroscope about the spin axis is its basic characteristic quantity. If the moment of inertia about the axis is I_1 and the component of the angular velocity parallel to the axis is ω , the component of angular momentum parallel to the axis is

$$\rho = I_1 \omega \quad (1)$$

When precession occurs, the total angular momentum vector is not parallel to the axis; also the value of ω may possibly be affected. In practice, however, the spin is very large compared with precession velocities. It is then a good approximation to consider that the total angular momentum vector is always parallel to the spin axis and has a constant magnitude ρ . This vector will be called ρ .

It is necessary to adopt a convention for the sense of ρ . The right-handed-screw convention will be adopted for both angular momentum and torque. Thus ρ has the direction in which a right-handed screw spinning with the rotor would advance. Likewise torque is in the direction of advance of a right-handed screw to which it is applied.

The theory of the gyroscope rests upon the theorem of mechanics that the rate of change of the angular momentum vector equals the applied torque vector. Thus, if \mathbf{L} is the vector torque applied to a gyroscope,

$$\mathbf{L} = \frac{d\rho}{dt} \quad (2)$$

Since ρ is assumed to have a constant magnitude in a gyroscope problem, $d\rho/dt$ must always be perpendicular to ρ . Thus the gyroscopic torques that can be applied to a gyroscope, and hence its reaction torques, are always perpendicular to the axis. If the vector ρ is drawn from a fixed origin, its tip moves always in the direction of the torque vector. Thus, suppose a gyroscope to have its ρ vector pointed toward an observer and to be mounted so as to be free to precess about its center of mass. See Fig. 49. If the observer exerts a downward force on the end of the axis projecting toward him, the torque direction is horizontally to the right. Hence, this end of the axis precesses horizontally to the right. If the gyroscope is constrained so that horizontal precession is prevented, no downward

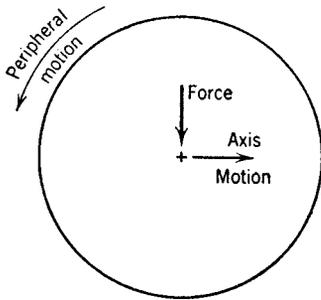

Fig. 49 Force/motion relations for gyroscope.

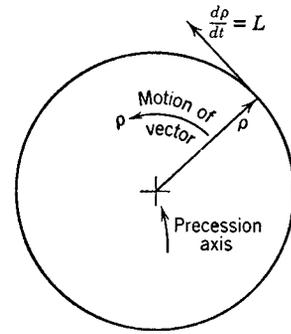

Fig. 51 Necessary condition for steady precession.

force (except that required for ordinary angular acceleration) can be exerted on the end of the axis: the axis yields freely. The constraints are then providing torque to produce this downward precession of the end of the axis.

In *steady precession* about a fixed axis, the tip of the ρ vector drawn from a fixed origin describes a circle about this axis, and the ρ vector sweeps out a half cone about the axis. See Fig. 50. In the simple case where the cone degenerates into a plane, that is, when the ρ vector is perpendicular to the precession axis, the magnitude of the torque is given by

$$L = \rho \Omega = I_1 \omega \Omega \quad (3)$$

where Ω is the angular velocity of precession. See Fig. 51. To maintain the precession, the torque axis must rotate with the ρ vector. In the general case of a cone of half angle θ , the torque is given, to the approximation that has been made, by

$$L = (\rho \sin \theta) \Omega \quad (4)$$

It should be noticed that the axis of precession is always perpendicular to the torque vector.

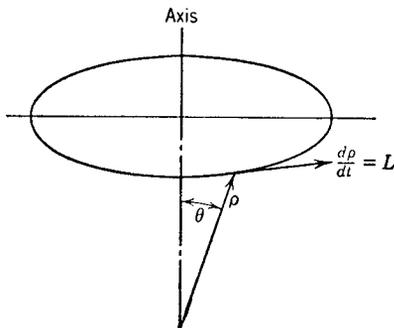

Fig. 50 Steady precession.

Example 13. A gyroscope has a rotor that weighs 8 lb, has a radius of gyration of 3 in., and spins at 3000 rpm. A torque of 2 lb-ft is applied, and precession occurs about an axis perpendicular to the spin. Find the velocity of precession.

$$I_1 = mk^2 = \frac{8}{32} \text{ slugs} \times \left(\frac{1}{4} \text{ ft}\right)^2 = \frac{1}{64} \text{ slug-ft}^2$$

$$\omega = 3000 \text{ rpm} = 100\pi \text{ rad/sec}$$

Therefore

$$\rho = \frac{100\pi}{64} \text{ slug-ft}^2 / \text{sec} = \frac{100\pi}{64} \text{ lb-ft/sec}$$

$$L = 2 \text{ lb-ft}$$

Therefore

$$\Omega = \frac{2 \text{ lb-ft}}{100\pi/64 \text{ lb-ft/sec}} = 0.408 \text{ rad/sec}$$

The “resistance” of a gyroscope to change of its axis direction involves two different types of motion: rotation about the precession axis and rotation about the torque axis. Suppose a torque \mathbf{L} is to be applied to a gyroscope that is free to precess. Let \mathbf{L} be exerted always about the axis of the angle θ between the spin and precession axes. See Fig. 52. A transient rotation about the torque axis occurs when the torque is first applied. After the transient motion dies out, there is a final steady deflection produced by the torque. The gyroscope behaves as if there were a strong spring opposing rotation about the torque axis. The transient motion may be analyzed by means of the general equations for rotation of a body about its mass center. The result is simple if the increment $\alpha \equiv \theta - \theta_0$ is sufficiently small, θ_0 being the value of θ for no applied torque and no precession. The equation is

$$L = I_2 \frac{d^2 \alpha}{dt^2} + \left(\frac{I_1^2 \omega^2}{I_2} \right) \alpha \quad (5)$$

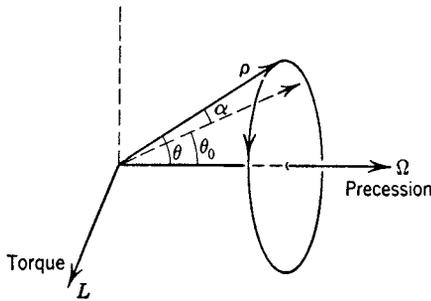

Fig. 52 Gyroscopic resistance.

Here L is torque related by the right-handed-screw rule to positive sense of α and I_2 is the moment of inertia of the rotor about a transverse axis. Solutions of (7) lead to simple harmonic motion when L is constant. When the friction that has been omitted from this equation has damped out the oscillations, the resulting deflection is

$$\alpha_{\text{final}} = \frac{I_2 L}{I_1^2 \omega^2} \tag{6}$$

Thus the gyroscope acts like a spring whose torsional stiffness is $I_1^2 \omega^2 / I_2 = \rho^2 / I_2$. The stiffness may be very large in practice.

Example 14. For the gyroscope of Example 13, find the torsional stiffness, assuming $I_2 = 0.80 I_1$:

$$\rho = \frac{100\pi}{64} \text{ lb-ft/sec} = 4.90 \text{ lb-ft/sec}$$

$$\rho^2 = 24 \text{ lb}^2 - \text{ft}^2 / \text{sec}^2$$

$$I_2 = \frac{0.80}{64} \text{ slug-ft}^2 = \frac{1}{80} \text{ slug-ft}^2 = \frac{1}{80} \text{ lb-ft/sec}^2$$

Therefore

$$\frac{\rho^2}{I_2} = \frac{24}{1/80} \text{ lb-ft/rad} = 1920 \text{ lb-ft/rad}$$

Here the angle unit of the radian has had to be supplied.

The total deflection of the gyroscope about the precession axis depends on the angular impulse received about the torque axis. If the angle α of Fig. 52 is small, then in the steady state the precession velocity is

$$\Omega = \frac{\rho}{I_2 \sin \theta_0} \alpha \tag{7}$$

If the torque acts for a time Δt and if $d\alpha/dt$ is the same at the beginning and end of Δt , the resulting deflection about the precession axis is

$$\Delta\psi = \frac{1}{\rho \sin \theta_0} \int_0^{\Delta t} L dt$$

$\Delta\psi$ may be made small for a given angular impulse by making ρ large. Thus the gyroscope yields but little in any direction to an applied impulse, provided it is free to precess. In time, however, a steady torque produces an indefinite large deflection about the precession axis.

Applications of the gyroscope are numerous and important. A few follow:

1. *Maintenance of a fixed orientation in space for a brief time.* The gyroscope's axis has this property when it is mounted in very friction-free gimbals and when it is balanced to remove gravitational torque. Such a free gyroscope is used to control a torpedo or a rocket.
2. *Indication of vertical in an airplane.* This cannot be done by a free gyroscope for any length of time because of rotation of the earth and motion over the earth's surface. Also the irreducible minimum of friction in the mounting would produce precession after long operation. Small correcting torques are applied to the gyroscope to cause it to precess very slowly toward the apparent vertical. In this way the time average of the apparent vertical is indicated; and if accelerations are random and relatively short-lived, this average will approximate the true vertical.
3. *Ship stabilization.* A huge gyroscope is mounted so that it can precess about a horizontal axis transverse to the ship. The precession is limited to a small range of angle so that the spin axis remains near the ship's vertical. The torque resulting from this precession is then about a fore-and-aft axis, so that it can combat rolling of the ship. The precession is not free but is motor driven and is controlled by a small gyroscope so as to be most effective.
4. *Bicycle operation* depends on gyroscopic action. Turning is a precession about a vertical axis and requires the torque produced by unbalancing the weight toward the inside of the turn. On the other hand, torque applied to the handlebars about a roughly vertical axis produces precession about a horizontal axis, which is tipping of the bicycle. This assists the rider to control her balance.
5. *Indication of the meridian.* The gyrocompass makes use of the rotation of the earth together with the gravitational field in such a way that the gyroscope axis seeks north.
6. *Indication of rate of turn of an airplane.* The gyroscope is mounted with its axis horizontal and is forced to turn with the airplane. This precession produces a reaction torque that works against a spring and actuates an indicator.

4.10 Generalized Coordinates

The configuration of a mechanical system is that characteristic that is determined by the position and orientation of all its parts. If the system is composed

of particles so small relative to the whole that their rotations are irrelevant to the mechanical problem, the configuration of the system may be specified by the Cartesian coordinates of all its particles in some inertial frame of reference. In problems of ordinary mechanics, the atoms of matter of which the system is composed may be treated as particles. The concept of configuration does not involve velocities or accelerations. A mechanical system is solved when its configuration is known as a function of time. From the time dependence of the configuration all the kinematic properties, such as velocity and acceleration, may be deduced. Generalized coordinates and Lagrange's equations provide a systematic procedure for solving mechanical systems.

A displacement of a mechanical system is a change of its configuration

Constraints are conditions imposed upon a system to limit its possible displacements. For example, a particle may be constrained to remain on a given surface or on a given line. The atoms composing a rigid body may for many purposes be considered to be constrained to remain at fixed distances from one another. A flywheel may be constrained to rotate in fixed bearings. Sometimes constraints change with time, as when a bead is constrained to slide on a moving wire. Such constraints will be called time dependent. Their motion will be supposed to be given; otherwise, the constraining body must be considered a part of the mechanical system to be solved.

Generalized coordinates are quantities describing the configuration of a system. They describe the configuration completely if the constraints are not time dependent; otherwise, the time is needed explicitly, together with the generalized coordinates, to specify the configuration. It is required for what follows that the set of generalized coordinates of a system be so chosen as to contain the least number of quantities necessary to describe the configuration. Thus, for example, the position of three noncollinear points of a rigid body is not a satisfactory set of generalized coordinates for the body, for it requires nine coordinates to locate these points, whereas only six coordinates are required for a rigid body. A true set of generalized coordinates is the location of one point of the body together with a set of three angles, the Euler angles, describing the orientation of the body. A set of generalized coordinates for a mechanical system will be denoted by $q_1, q_2, \dots, q_j, \dots, q_n$.

The number of degrees of freedom of a system is equal to the number n of generalized coordinates required to specify its configuration provided all n of the increments δq_j are independent. The criterion of independence of the increments δq_j is that any one of them can be specified arbitrarily while all the others are zero. When this is the case, the system is called *holonomic*. This discussion will be limited to holonomic systems. Nonholonomic systems are characterized by the existence of nonintegrable relations between infinitesimal increments δq_j so that they are not independent.

Generalized forces are quantities Q_j such that the work done by the actual forces of the system during an infinitesimal displacement δq_j of only one generalized coordinate is

$$\delta W_j = Q_j \delta q_j \quad (8)$$

The Q_j are ordinarily functions of the generalized coordinates, but they may also involve the time derivatives of the coordinates.

It is important to notice that any actual forces that do not work during possible displacements of the system may be omitted completely from consideration. This kind of force is often present owing to constraints. For example, a weightless, rigid rod connecting two masses may exert forces along its length, but these forces do no work since the length of the rod is constant. Forces that constrain a body to remain in contact with a surface are workless.

A generalized force does not have the dimensions of force unless its corresponding generalized coordinate has the dimensions of length. For example, the generalized force is a torque when its corresponding coordinate is an angle.

The generalized forces of a system can ordinarily be obtained directly by computing the work done by the applied forces for infinitesimal changes of the generalized coordinates. There is a formula for Q_j in terms of the Cartesian components of force, $X_i, Y_i,$ and $Z_i,$ acting on the particles of the system whose coordinates are $x_i, y_i,$ and z_i :

$$Q_j = \sum_{i=1}^N \left(X_i \frac{\partial x_i}{\partial q_j} + Y_i \frac{\partial y_i}{\partial q_j} + Z_i \frac{\partial z_i}{\partial q_j} \right) \quad (9)$$

This is summed over all N particles of the system.

In the case of moving constraints, the motion of the constraint is not considered in computing the generalized forces. The displacements δq_j of Eq. 8 are assumed to take place in zero time, that is, before the constraint has time to change.

The kinetic energy of a mechanical system may be expressed in terms of the generalized coordinates and their time derivatives. The time appears explicitly only if the constraints are time dependent. The usual notation for the time derivatives of the generalized coordinates is

$$\dot{q}_j \equiv \frac{dq_j}{dt} \quad (10)$$

The kinetic energy function is then written in general as

$$T(q_1, q_2, \dots, q_n; \dot{q}_1, \dot{q}_2, \dots, \dot{q}_n; t) \quad (11)$$

If the constraints are not time dependent, this function becomes a homogeneous quadratic form in the \dot{q}_j :

$$T = \sum_{j=1}^n \sum_{k=1}^n A_{jk}(q_1, q_2, \dots, q_n) \dot{q}_j \dot{q}_k \quad (12)$$

Equation (12) is quite easy to prove, starting with the kinetic energy equation in terms of the ultimate particles of the system,

$$T = \frac{1}{2} \sum_{l=1}^N m_l (\dot{x}_l^2 + \dot{y}_l^2 + \dot{z}_l^2) \quad (13)$$

and using the functional dependence of the Cartesian coordinates upon the generalized coordinates in the case of fixed constraints:

$$x_l = x_l(q_1, \dots, q_n) \quad (14)$$

In an actual problem, the kinetic energy function (11) or (12) is found not by working from Eq. (13) but rather by inspection of the system and addition of the kinetic energies of its large-scale members.

Lagrange Equations *Lagrange equations* of motion are second-order differential equations in the generalized coordinates, time being the independent variable. They have the same form for any holonomic system, and there are n such equations of this form for a given system:

$$\frac{d}{dt} \frac{\partial T}{\partial \dot{q}_j} - \frac{\partial T}{\partial q_j} = Q_j \quad j = 1, 2, \dots, n \quad (15)$$

The solution of any holonomic problem is thus systematized. The process involves assigning generalized coordinates; finding the Q_j functions and the T function; use of Eq. (15) to obtain n differential equations; simultaneous solution and integration of the differential equations; and consideration of boundary conditions.

In the use of Eq. (15), the meaning of the partial derivatives must be clearly understood. In the process of finding $\partial T / \partial q_j$, all other q 's besides q_j are considered constants; all the \dot{q} 's are considered constant, including \dot{q}_j ; and, if time appears explicitly, it too is considered constant. Similarly, to find $\partial T / \partial \dot{q}_j$, q_j is considered the only variable. It is understood, of course, that T has been expressed in the form of Eq. (15) to start with.

Two examples of the use of Lagrange's equations will illustrate most of the ideas involved. Consider first the Atwood machine shown in Fig. 53. This consists of a frictionless pulley of groove radius R and moment of inertia I over which is passed a light, inextensible cord tied to two masses m_1 and m_2 . The problem is simplest when the masses are constrained by frictionless guides to move only vertically. There is then only one degree of freedom. Let the generalized coordinate q be the

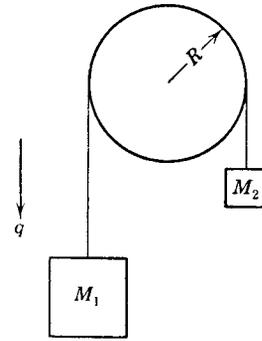

Fig. 53 Generalized coordinates/pulley system.

downward vertical coordinate to m_1 . The work done by gravity for a displacement δq is then

$$\delta W = (m_1 g - m_2 g) \delta q$$

whence the generalized force is

$$Q = (m_1 - m_2) g$$

The kinetic energy is the sum of the kinetic energies of the pulley and the weights:

$$T = \frac{1}{2} m_1 \dot{q}^2 + \frac{1}{2} m_2 \dot{q}^2 + \frac{1}{2} I \left(\frac{\dot{q}}{R} \right)^2$$

The Lagrange equation is thus

$$\frac{d}{dt} \left[\left(m_1 + m_2 + \frac{I}{R^2} \right) \dot{q} \right] = (m_1 - m_2) g$$

Therefore

$$\frac{d^2 q}{dt^2} = \frac{(m_1 - m_2) g}{m_1 + m_2 + I/R^2}$$

As a second example, consider the problem of a point mass m constrained to move in a plane under a central force $F = kr$ toward the origin, where r is the distance from the origin to m and k is constant. Let us choose polar coordinates r, θ as the generalized coordinates, as in Fig. 54,

$$q_1 = r \quad q_2 = \theta$$

For displacement δq_1 , the force F does work

$$W = -F \delta r = -kr \delta r = -kq_1 \delta q_1$$

Thus the generalized force Q_1 is $-kq_1$. No work is done during a rotation $\delta \theta$, so $Q_2 = 0$. The kinetic energy $\frac{1}{2} m v^2$ is readily expressed in polar coordinates:

$$T = \frac{1}{2} m (\dot{r}^2 + r^2 \dot{\theta}^2) = \frac{1}{2} m (\dot{q}_1^2 + q_1^2 \dot{q}_2^2)$$

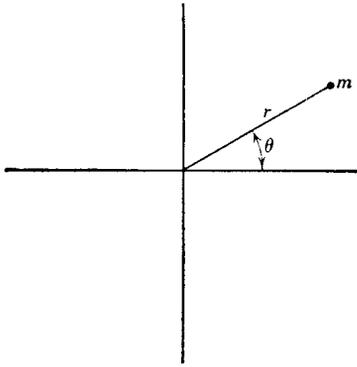

Fig. 54 Generalized coordinates/central force motion.

The two Lagrange equations of the motion are therefore

$$\frac{d}{dt}(m\dot{q}_1) - m q_1 \dot{q}_2^2 = -k q_1$$

and

$$\frac{d}{dt}(m q_1^2 \dot{q}_2) = 0$$

Potential energy may be used in the case of conservative systems. In such systems, there is a potential energy function V such that, during any displacement of the system, the work done by the force is

$$\delta W = -\delta V \quad (16)$$

Since potential energy is energy of position or configuration it must be expressible as a function $V(q_1, q_2, \dots, q_n)$ of the generalized coordinates. Then we may write for an infinitesimal displacement

$$\delta V = -\delta W = \left(\frac{\partial V}{\partial q_1} \delta q_1 + \frac{\partial V}{\partial q_2} \delta q_2 + \dots + \frac{\partial V}{\partial q_n} \delta q_n \right)$$

It follows immediately from definition (8) that the generalized forces are

$$Q_1 = -\frac{\partial V}{\partial q_1} \dots$$

or in general

$$Q_j = -\frac{\partial V}{\partial q_j} \quad (17)$$

If the Lagrangian function

$$\begin{aligned} L(q_1 \dots q_n; \dot{q}_1 \dots \dot{q}_n; t) \\ \equiv T(q_1 \dots q_n; \dot{q}_1 \dots \dot{q}_n; t) - V(q_1 \dots q_n) \end{aligned} \quad (18)$$

is formed, it may be seen immediately that for a conservative system the Lagrange equation 15 may be written in the compact form

$$\frac{d}{dt} \frac{\partial L}{\partial \dot{q}_j} - \frac{\partial L}{\partial q_j} = 0 \quad j = 1, 2, \dots, n \quad (19)$$

5 FRICTION

5.1 Static and Kinetic Friction

A *smooth surface* is one that offers no resistance to the sliding of a body upon it. A *rough surface* does offer resistance to such motion. The *total reaction* R (Fig. 55) of the surface of one body upon another body is its resultant force. *Friction* F is that component of the total reaction R that is tangent to the surface. *Normal reaction* N is that component that is normal to the surface.

Static frictional force F is that friction that opposes motion when there is no slipping. Its value varies as the need for it to prevent motion is developed. *Limiting frictional force* F' is the value of static frictional force when slipping impends. *Coefficient of static friction* (f) is the ratio F'/N . *Angle of static friction* (ϕ) is defined by $\tan \phi = F'/N = f$. *Angle of repose* is that angle that the surface of one body makes with the horizontal when slipping of another body upon it impends. It applies to the particular rubbing surfaces in contact. It equals the angle of static friction.

Kinetic frictional force F_k opposes motion when one body is slipping on the surface of the other. Its value is usually less than that of the limiting friction. *Coefficient of kinetic friction* (f_k) is the ratio F_k/N . *Angle of kinetic friction* (ϕ_k) is defined by $\tan \phi_k = F_k/N = f_k$.

Laws of Friction for Dry Surfaces

1. Friction between two given bodies is directly proportional to the pressure; the coefficient of friction is constant for all pressures.
2. The coefficient and amount of friction for given pressures are independent of the area of contact.
3. The coefficient of friction is independent of the relative velocity, although static friction is greater than kinetic friction.

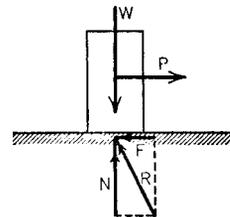

Fig. 55 Force diagram/friction.

The preceding laws are only approximately true. The coefficient of friction is slightly greater for small pressures upon large areas than for great pressures upon small areas. The coefficient of friction decreases as the speed increases.*

Coefficients of Static and Kinetic Friction These are affected by the preceding laws of friction and also

*Recent experiments have proved also that time of contact of the surfaces affects the coefficient of static friction.

by the characters of the surfaces, the kinds of material, and the nature of any lubricant used. Rough averages for a number of materials and conditions are given in Table 2.

5.2 Axle Friction and Lubricated Surfaces

Axle Friction, Nonlubricated Axle friction is the friction that opposes the turning of an axle in its bearing. For a dry bearing, the axle (Fig. 56) will obviously move to the right. It will climb until a point is reached, at some angle ϕ , where the friction

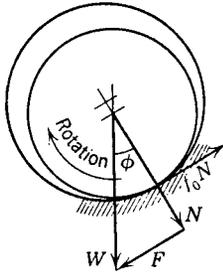

Fig. 56 Force diagram/axle friction.

force $f_0 N$ on the shaft or journal is balanced by the tangential component F of the vertical load W , that is, $f_0 N = F$. Normal force N is equal to $W \cos \phi$, and f_0 is the coefficient of friction for the surfaces in question. Friction force F is equal to $W \sin \phi$, so that the usual relationship $f_0 = \tan \phi$ for friction prevails. It is customary, however, to define the coefficient of friction f for a journal bearing as the ratio of load W to the tangential friction force F , or $f = F/W = \sin \phi$. The relationship between f_0 and f is then represented by $f = f_1 \cos \phi$.

Friction of Lubricated Surfaces The friction of lubricated surfaces is characterized by two types of sliding motion:

1. Hydrodynamic or thick-film lubrication
2. Boundary or thin-film lubrication

Hydrodynamic lubrication occurs with a plentiful supply of oil when the thickness of the film is large as compared with the height of the irregularities of the surfaces. Metallic contact or wear does not occur, and the frictional resistance is independent of the kinds of materials composing the bodies.

Although somewhat involved mathematically, the laws for this type of friction are well understood. Figure 57 shows a weightless plate of area A being pushed along at velocity U by force F as it rests on an oil film of thickness h . Newton observed that force F was directly proportional to area A and velocity U and inversely proportional to the film thickness h . This can be written in the form of an equation, $F = \mu U A / h$, where the constant of proportionality μ is called the coefficient of viscosity of the lubricant. It has dimensions of lb-sec/in² or dyne sec/cm².

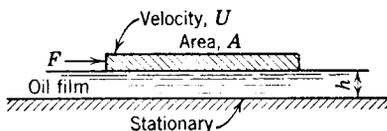

Fig. 57 Lubricated surface friction.

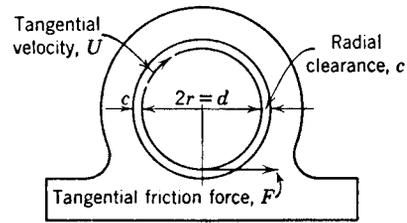

Fig. 58 Journal friction.

Example 15. Find the force necessary to maintain a velocity of 20 ft/sec for a 3 in. \times 3 in. plate if the film has a thickness of 0.003 in. A heavy oil of viscosity 0.000005 lb-sec/in.² is used.

Solution. Substitution in Newton's equation gives $F = 0.000005 \times 240 \times 9 / 0.003 = 3.6$ lb.

Journal Friction, Lubricated Newton's equation can be adapted to the journal bearing of Fig. 58 of radius r and axial length l by substituting $A = 2\pi r l$ and $U = 2\pi r n_s$, where n_s is in revolutions per second. Film thickness h is replaced by radial clearance c . The result,

$$F = 4\pi^2 \mu r^2 h_s \frac{l}{c}$$

is known as *Petroff's equation*. It is valid only for very lightly loaded bearings where the shaft is centrally located in the clearance space. The friction is practically unchanged when the bearing is loaded, and an equation for the coefficient of friction, $f = F/W$, is obtained by dividing both sides of Petroff's equation by the load W . The result, $f = 2\pi^2 \mu h_s r / pc$, is obtained by the substitution $p = W/2rl$, where p is the load per square inch of projected area of the bearing.

Example 16. Find the coefficient of friction for a 2-in.-diameter by 3-in.-long journal bearing carrying a load of 600 lb at a speed of 1200 rpm. Radial clearance is 0.002 in. Viscosity of the lubricant is 0.000003 lb-sec/in.²

Solution. Substitution gives

$$f = \frac{2\pi^2 0.000003 \times 20 \times 1}{100 \times 0.002} = 0.0059$$

This example shows that the coefficient of friction under conditions of flooded lubrication is very much smaller than the value of the coefficient when the surfaces are dry. It should be noted that the coefficient of friction for lubricated surfaces varies directly with the velocity and inversely with the pressure. This is in contrast with the coefficient of friction for dry surfaces, which is independent of both velocity and pressure.

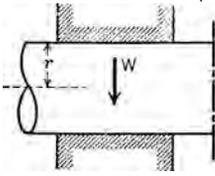

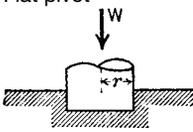

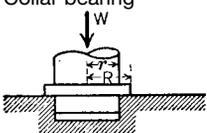

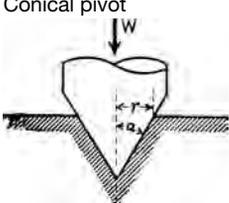

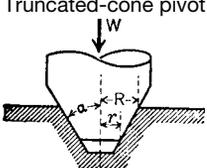

The plate of Fig. 57 could carry a downward load provided that the forward edge would be tipped at a small upward angle. The oil would be drawn into the wedge-shaped opening, and a hydrostatic pressure would be developed in the film sufficient to support the load. When a lubricated journal bearing carries a load, the shaft center will shift sidewise in the direction opposite to that for a dry bearing. The oil film will converge in such a manner as to produce the pressure necessary to carry the load. The mathematical treatment of these phenomena may be found in almost any treatise on lubrication.

Boundary Friction Boundary friction occurs between surfaces that are slightly oily or greasy but

where the oil supply is insufficient to maintain a hydrodynamic film. Although the bodies approach each other closely, the load is carried by the absorbed layers of lubricant attached to the surfaces. The chemical and physical properties of the lubricant and of the materials composing the bodies are now of importance. At the present time, available knowledge for this type of friction is highly specific and cannot be formulated into general laws. It would appear, however, that the friction is relatively independent of the area in contact and the velocity of sliding. The value for the coefficient of friction is usually intermediate between that for dry friction and that for hydrodynamic friction.

In boundary lubrication one type of oil may have less friction than another of the same viscosity. This

Table 3 Pivot Friction^a

Type of Pivot	Torque T (lb-in.)	Power P Lost by Friction (ft-lb/sec)
Shafts and Journals (180° bearing)		
	$T = fWr$	$P = \frac{2\pi n}{12} fWr$
Flat pivot		
	$T = \frac{2}{3} fWr$	$P = \frac{4\pi n}{3 \times 12} fWr$
Collar bearing		
	$T = \frac{2}{3} fW \frac{R^3 - r^3}{R^2 - r^2}$	$P = \frac{4\pi n}{3 \times 12} fW \frac{R^3 - r^3}{R^2 - r^2}$
Conical pivot		
	$T = \frac{2}{3} fW \frac{r}{\sin \alpha}$	$P = \frac{4\pi n fWr}{3 \times 12 \sin \alpha}$
Truncated-cone pivot		
	$T = \frac{2}{3} fW \frac{R^3 - r^3}{(R^2 - r^2) \sin \alpha}$	$P = \frac{4\pi n fW (R^3 - r^3)}{3 \times 12 (R^2 - r^2) \sin \alpha}$

^a f = coefficient of friction, W = load in pounds, T = torque of friction about the axis of the shaft.

r = radius in inches, n = revolutions per second.

property has been given the name of *oiliness*. Certain animal and vegetable oils and compounds are superior to mineral oils with respect to oiliness. They are therefore used as additives to mineral oils to decrease the friction.

If the load on a bearing is increased until the absorbed boundary layers of lubricant can no longer be maintained, metal-to-metal contact will occur at the high points of the sliding surfaces and wear will take place. The exact physical and metallurgical process of wear is not clearly understood. The harder metal may gouge off particles of the softer metal. Experimental evidence exists that the surfaces weld together at the points of metallic contact because of the extremely high localized pressures. The welds are broken as soon as made and may account for the major portion of the resistance to the motion. The amount of welding decreases with decrease of solid solubility between the metals of the two bodies. There is thus justification for the long-established rule that the two members of a bearing should be made of dissimilar metals to decrease friction and the possibility of galling and failure. The *running-in* of a bearing is a form of wear process in which an improvement is effected in the surface conditions.

In addition to a scanty oil supply, a bearing operating with boundary friction will be adversely affected by a decrease in the viscosity of the lubricant, a decrease in the speed, or an increase in the pressure. An unfavorable combination of these qualities may cause the coefficient of friction to increase until the bearing overheats and failure becomes imminent.

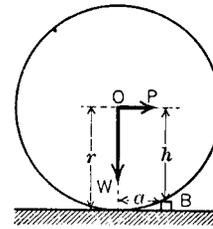

Fig. 59 Rolling friction.

5.3 Rolling Friction

Rolling friction is that friction developed when one body rolls over the surface of another and depends on the hardness of the surfaces in contact and the radius of the rolling surface. The theory is based on the idea that surfaces are slightly deformed at the place of contact and that the effect of rolling friction is the same as if the surfaces were not deformed and the rolling body passed constantly over a small obstruction. Let P (Fig. 59) be the horizontal force required to overcome the small obstruction B . Then $hP = aW$, and, since h is nearly equal to r , $P = aW/r$ (approximately). The *coefficient of rolling friction* is a and, as an analogy with definition of static and kinetic friction coefficients might be defined as the ratio T_r/W , where $T_r = Pr$ is the torque resisting rolling motion and W is the normal force (in this case, the weight of the body). The coefficient is a linear distance and is usually given in inches. The values of the coefficient of rolling

friction given by various investigators are not in close agreement and should be used with caution.

The following are some reported values of coefficients of rolling friction:

<i>Lignum vitae</i> roller on oak track	0.019 in.
Elm roller on oak track	0.032 in.
Cast-iron wheel (20 in. diameter) on cast-iron rail	0.018–0.019 in.
Railroad wheels (39.4 in. diameter)	0.020–0.022 in.
Iron or steel wheels on wood track	0.06–0.010 in.

5.4 Pivot Friction

Pivot friction is that friction that opposes the turning of the end of a vertical, or inclined, shaft in its bearing. Some examples of pivot friction, with friction torque and power formulas applying, are shown in Table 3.

5.5 Belt Friction

Belt, or coil, friction is that friction that opposes the slipping of a belt, rope, brake band, or similar article coiled about a pulley, sheave, post, capstan, or similar device. When power is being transmitted, say by a belt driving a pulley, the tension T_1 on the driving side of the belt is greater than the tension T_2 on the driven side. Neglecting the effect of centrifugal force, which is small at low speeds, the tensions are related by the formula $T_1/T_2 = e^{f\alpha}$, where $e = 2.718+$ (i.e., base of natural logarithms), f = coefficient of friction between belt and pulley, and α = angle of contact between belt and pulley (Fig. 60). Values of T_1/T_2 for various values of f and α are shown in Table 4.

Power transmitted is given by $P = (T_1 - T_2)v$, where P is power in foot-pounds per second and v

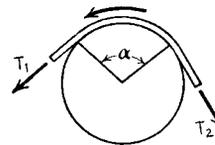

Fig. 60 Belt friction.

is velocity in feet per second. Coefficient of friction for belts and pulley material are shown in Table 5.

ACKNOWLEDGMENTS

This chapter was originally a revision of material in previous handbooks published by John Wiley & Sons, most of which was written by C. H. Burnside and E. R. Maurer for *Merriam's Civil Engineers' Handbook* and *Peele's Mining Engineers' Handbook*. Later revisions by Janvier M. Rice appeared in the *Handbook of Engineering Fundamentals*, third edition, a part of the Wiley Handbook Series. The present chapter was revised by Fowler, with the primary revisions being focused on the introduction of vector mechanics.

1 INTRODUCTION

1.1 Metals and Alloys

Metals are a unique class of elements which provide special properties not available in naturally occurring materials such as wood, cement, and ceramics or in human-produced nonmetallic polymeric materials. (*Note:* Some metals occur in elemental form in nature but most do not.) Since metals are frequently combined (alloyed) with other metallic and some nonmetallic elements to produce alloys (metal combinations with certain desired properties), we will refer to all metallic materials in this chapter as “alloys” with the understanding that often pure or nearly pure metal elements may be used in design.

1.2 Purpose

The purpose of this chapter is to create a sufficient understanding of alloys so that selection of them for specific designs will be appropriate. The primary intent will be to cover alloy selection for structural purposes, that is, where the alloy must support its weight and, probably, the additional loads of a design. The chapter will provide sufficient information for the selector to work with designers to create successful components as well as to evaluate the capability of alloy providers and manufacturers to meet the required end uses of the design. To this end, mechanical, physical, and environmental property behavior that can influence alloy selection will be described.

There is no cookbook for alloy selection. Proprietary alloys and/or proprietary/restricted processing can create conditions and properties not listed in a handbook or catalog of available alloys. Critical applications may require a selector to work with one or more manufacturers to develop an understanding of what is available and to determine what one can expect from a chosen alloy. At times it may be necessary to develop new or adapt different manufacturing processes for the utilization of alloys for specific applications.

2 COMMON ALLOY SYSTEMS

While there are many metallic elements which are used to produce alloys, the more industrially important alloys in structural design are iron and its alloys (called ferrous alloys) or other (nonferrous) alloys based on copper, aluminum, magnesium, nickel, cobalt, titanium, and a handful of other metallic elements. Some special elements (e.g., zirconium, beryllium) also may find structural use in applications such as nuclear reactors or other devices. Precious metals (e.g., gold, platinum, silver) are used for applications from jewelry to jet engines! Zinc-based alloys are important in die casting of small articles. [*Note:* The words *article* or *component* may be used interchangeably to indicate a designed item which, in service, will likely be part of a collection of items (e.g., a gas turbine). A gas turbine high-pressure turbine blade would be an article or component.]

3 WHAT ARE ALLOYS AND WHAT AFFECTS THEIR USE?

Alloys, for purposes of this chapter, are solid entities of a given chemical composition, crystal structure, and metallurgical structure at the temperature of use. The range of temperature use can be from near absolute zero to many thousands of degrees. Alloys are made from metallic elements (and some nonmetallic ones added in minor amounts) which are recovered from various ores. In the process of recovery from ores and transfer to desired products, alloys most often are subject to melting (liquification) casting, and/or mechanical deformation processes. This chapter is not concerned with extraction from ores or the subsequent purification of alloy elements prior to the creation of specific alloys for structural use.

Alloys normally exist as a crystalline arrangement of individual atoms (see Fig. 1). Aggregates of multiples of the basic crystalline individual units (e.g., face-centered cubic, body-centered cubic) are termed *grains*. These grains have the same arrangement/orientation of unit cells of the given alloy across their dimension. The mechanical properties of alloys are normally affected by chemistry and intrinsic unit-cell capability, grain size, grain shape and grain orientation, temperature, and certain other factors. Typically, properties of interest are tensile properties (Fig. 2), fatigue properties (Fig. 3), and high-temperature time-dependent properties such as creep rupture (Fig. 4). Modulus of elasticity is another mechanical property used in design and additional properties such as toughness or crack propagation characteristics can be incorporated into structural design, though such properties are not always available.

The methods of preparing alloys can significantly affect their resultant properties. The preparation of an alloy normally will result from melting of appropriate elements/alloys followed by pouring (casting) the molten alloy into a mold to produce an electrode for further primary melting or an ingot for remelting or for deformation processing. Generic mold shapes may be used to produce ingots if the cast alloy is to be remelted and cast into a specific mold shape (e.g., a blade for use in a gas turbine engine). Specific mold shapes may be used if articles are to be created directly by casting. The electrode, ingot, or component produced will show a “cast” structure which will be influenced by the casting process and subsequent treatments applied to create the desired alloy properties.

Often, an alloy may be processed by one or more deformation processes, that is, a billet cut from an ingot may be formed to shape or mostly to shape by hot rolling, forging, and so on, to produce a “wrought” structure. There are a variety of possible cast structures as well as a variety of wrought structures. By examining a component under a microscope, microstructure (appearance at 100x magnification and up) can be viewed. Alloys also can be examined at low magnification for macrostructure (probably 1x to 10x magnification) Subsequent to production of a

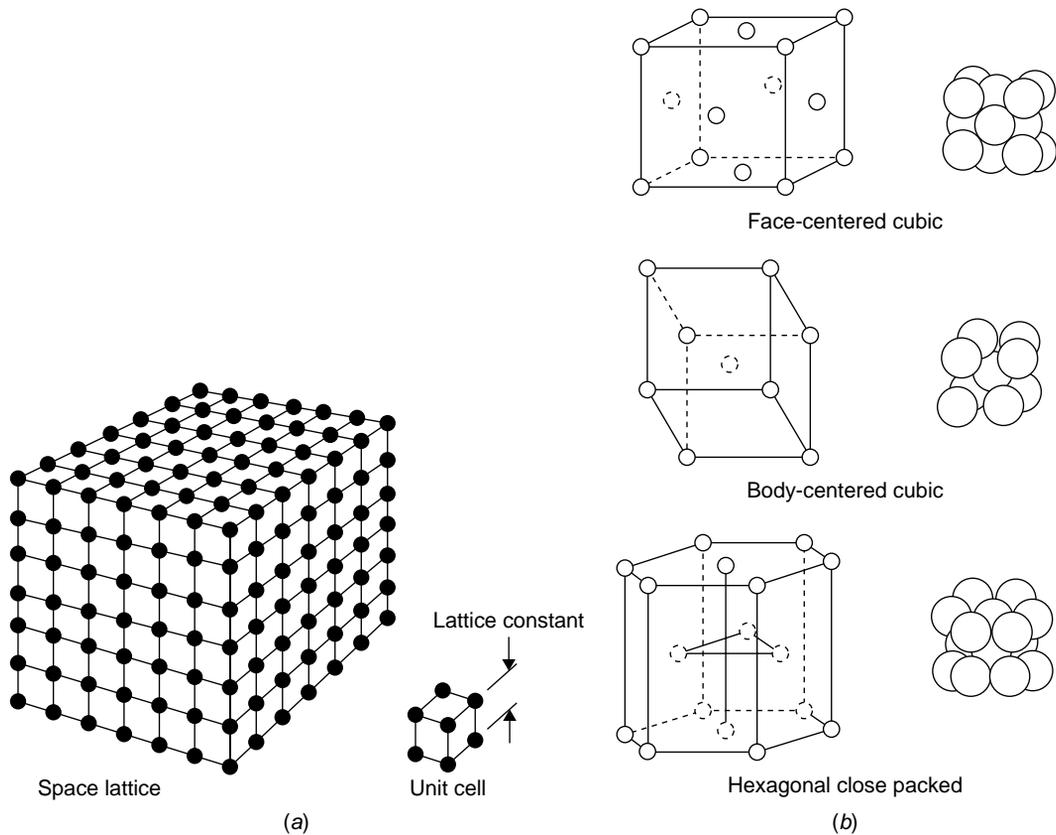

Fig. 1 (a) Simple cubic lattice. Atoms are represented by solid spheres and, in this lattice, atoms are located at the corners of cubes which repeat indefinitely in three-dimensional space. (b) Common lattice structures for most metals/alloys.

component, the application of special heating cycles (heat treatment) often is used to convey certain property values or characteristics to alloys. In-process heat treatments may be used during the shaping of the component.

4 WHAT ARE THE PROPERTIES OF ALLOYS AND HOW ARE ALLOYS STRENGTHENED?

Metals are crystalline as noted above and, in the solid state, the atoms of a metal or alloy may arrange themselves in various crystallographic groupings, often occurring as cubic structures. Some crystal structures tend to be associated with better property characteristics than others. Crystalline structure normally is a characteristic of the major (base) alloy element in an alloy. In addition to basic crystal structure, crystalline aggregates of atoms have orientation relationships in space. As noted, crystalline aggregates are called grains and, in an alloy, there are usually many grains with random orientation directions within each

manufactured article. Metal alloy articles with multiple random grain directions are known as polycrystalline (frequently referred to as having equiaxed grain structure), often having roughly equal dimensions in all directions. However, columnar-shaped grains (with one relatively longer axis) are common in polycrystalline cast products.

Properties of alloys may be mechanical, physical, or chemical. Mechanical behavior encompasses the strength properties determined in appropriate tests and tend to be the more important properties for selection of alloys for structural applications. Some mechanical properties of alloys are tensile or compressive strength (e.g., onset of plasticity, yielding strength, fracture strength under normal stress loading), fatigue strength (i.e., cycles to first crack or fracture or stress for a specific number of failure cycles), modulus of elasticity, and so on, which are measured primarily at lower to intermediate temperatures of operation. In addition, high-temperature mechanical properties such as creep or creep rupture strength, fatigue strength, and thermally induced fatigue capability are of concern but

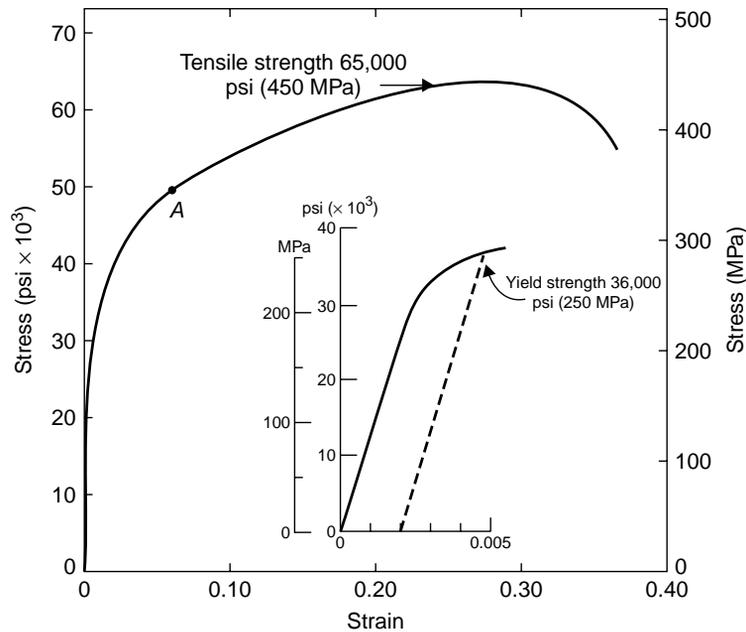

Fig. 2 Ultimate tensile strength, UTS or TS, and defined yield strength at 0.2% offset (inset), TY or YS. Young's modulus is the slope of the elastic region before plastic deformation begins.

primarily at temperatures above about 0.5 of the absolute melting point of an alloy. At high temperatures, mechanical properties may be influenced by sequences of cyclic loading and time as well as frequency of load application in addition to temperature of testing.

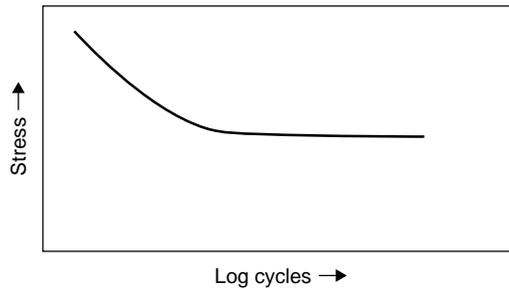

Physical properties include heat capacity, electrical conductivity, thermal conductivity, and magnetic properties. Chemical properties may be of most concern in environmental attack when alloys for structural applications are considered. Intrinsic chemical properties of alloys are modified (as are mechanical properties) by chemical changes during alloy invention and by heat treatment of alloys during processing. In addition, surface chemical properties frequently are modified by surface changes induced, for example, by coatings.

While the physical properties to a major extent depend upon the chemistry of the alloy, the mechanical properties are dependent not only on the chemistry of an alloy but more importantly on the microstructure. Microstructure is assumed to mean grain shape, orientation, grain size, and so on, and the presence, absence, type, and location of new crystal phases in the alloy. The mechanical properties result from the interaction of imperfections such as dislocations with the microstructural components.

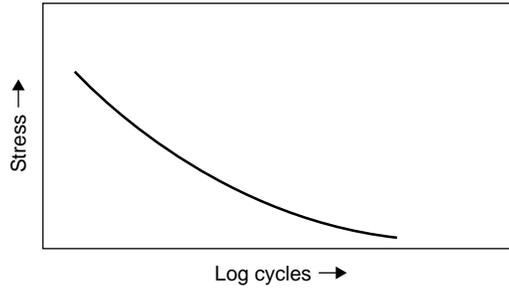

The peripheral surface of a grain is called a grain boundary. Aggregates of atoms without grain boundaries are rarely created in nature. However, alloys without internal grain boundaries (i.e., single crystals) or alloys with aligned boundaries (i.e., columnar grained

structures) can be produced in some systems by appropriate manufacturing techniques. The introduction of different atom types and new crystal phases and/or the manipulation of grain boundaries plus the use of stored energy of deformation enable inhibition of the movement of the imperfections (e.g., dislocations) that enable deformation to occur.

It is quite important for the engineer selecting alloys to have a realistic understanding of the strengthening process in alloys as the mechanical properties of alloys can be modified considerably by processing to manipulate the strengthening level achieved. The energy of mechanical deformation (working) can be stored in an alloy (work hardening), producing higher strengths than the unworked (e.g., soft, annealed) alloy. Alloys such as steels (ferrous alloys) can have increased strengths produced by the introduction of fine structure from transformations of crystal lattices. This fine structure usually results from the formation of nonequilibrium martensite phases (in preference to the expected equilibrium phases). The fine structure produced by the martensitic reaction acts to restrict deformation by dislocation movements. This type of hardening often produces very high strengths (as in iron alloys) but much reduced ductility. Subsequent heat treatment (tempering) normally is used to enhance ductility at the expense of strength in transformation hardened alloys. Industrial use of martensite to strengthen alloys is most prevalent with iron-base alloys (containing carbon) or in titanium alloys.

Typical fatigue curve at low temperature

Typical fatigue curve at high temperature

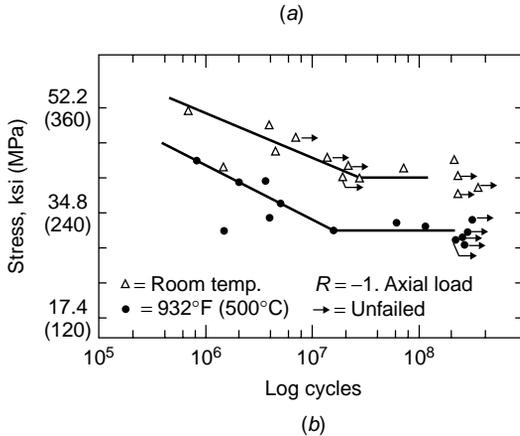

Fig. 3 (a) Typical fatigue response at high temperature versus that at low temperature. (b) Actual fatigue curves at room and one elevated temperature for specific nickel-base superalloy.

Dislocation movement at lower temperatures is reduced not only by fine structure but also by smaller grain sizes. Ultimate tensile strength is not particularly affected by grain size changes, although ductility effects are noticed. As operating temperatures increase, fine grain size material usually becomes less strong than coarse-grained material. Increased temperatures and time at high temperatures may cause recrystallization (new grain formation and subsequent

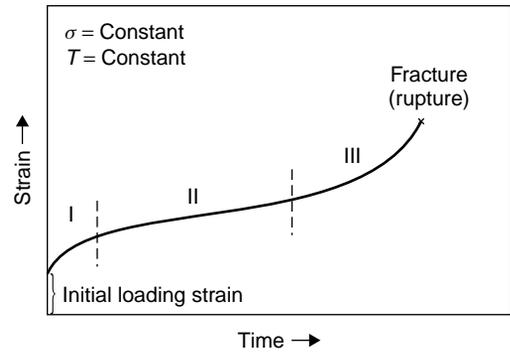

Fig. 4 Time-dependent deformation under constant load at constant high temperature followed by rupture. All loads below short-time yield strength.

loss of stored energy) and/or grain growth. Consequently, work hardening to increase strength has upper limits of application since the high-strength benefit of (cold) work may be lost with time at higher operating temperatures.

Some alloys derive their strength from solid-solution hardeners (elements dissolved in the basis metal) as well as from secondary precipitates that form in the matrix (principal) phase and produce precipitation (age) hardening from the dispersed particles. Precipitates may be phases or they may be zones of enrichment in one of the alloy elements present. In lower temperature use alloys, such as aluminum, age hardening may be from zones or phases. In higher temperature use alloys, precipitated phases are the norm. Principal strengthening precipitate phases vary with alloy but in nickel-base and iron-nickel-base superalloys they are ordered particles of γ' , η , and/or γ'' . Phases such as carbides may provide limited direct strengthening (e.g., through dispersion hardening) or, more commonly, indirectly (e.g., by stabilizing grain boundaries against movement at high temperature). In some instances, ceramic (e.g., silica, yttria) or other phases may be dispersed mechanically instead of metallurgically in a matrix to produce dispersion hardening. Thus the hardening of alloys can consist of:

- Solid-solution hardening
- Work hardening
- Dispersion/precipitate hardening (sometimes with ordered precipitates)
- Transformation (martensite) hardening
- Grain size/morphology (shape/orientation) hardening

The results of hardening vary by alloy and by the temperature of testing. Improvements in lower temperature short-time strength may not necessarily be transferred to high-temperature ranges of operation.

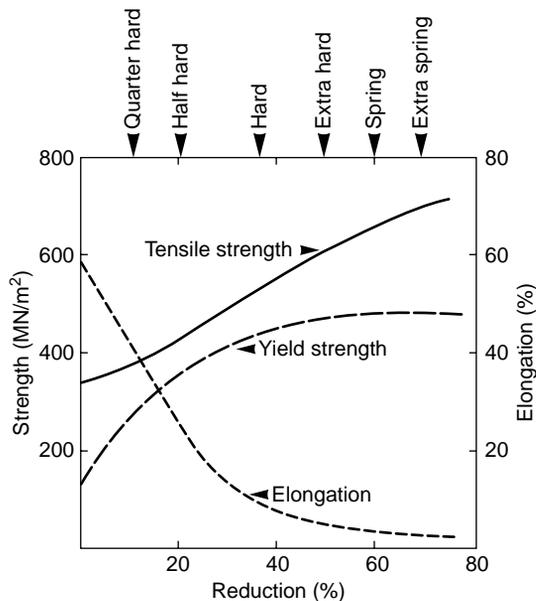

Fig. 5 Terms used in copper industry to indicate degree of cold working are shown at top of plot.

Control of grain structure can significantly influence mechanical properties. The extent to which the secondary phases contribute directly to strengthening depends on the alloy and its processing. It should be noted that improper distributions of phases such as carbides and precipitate phases can be detrimental to properties. Work hardening is an important characteristic of alloys since work hardening may be used to strengthen an alloy (Fig. 5) but also may contribute to the need for intermediate heating (in-process annealing) during forging/forming of an article to prevent cracking of the article or damage to fabrication equipment.

5 MANUFACTURE OF ALLOY ARTICLES

Appropriate compositions of most alloy types can be worked, that is, they can be forged, rolled to sheet, or otherwise deformed mechanically into a variety of shapes. More highly alloyed compositions may be processed as castings. Castings may be less costly than equivalent forgings. Large and small castings can be made. Fabricated alloy structures can be built up by combining (joining) separate article pieces, particularly by welding or brazing, but the more highly alloyed the composition, the more difficult it may be to join an alloy.

Many alloys may be available and used in cast or wrought form. In the latter situation, alloys may be available in extruded, forged, or rolled form. Bar stock, strip, sheet, plate, wire, and other wrought forms/sizes may be obtained. Deformation of alloys may be performed hot or cold. Often, higher strength or "exotic"

alloys are only able to be produced and used in the cast condition. Powder metallurgy processing is an accepted method to produce articles of difficult-to-process alloys in "wrought" conditions. However, simple components of ordinary alloys, particularly of ferrous metals, are often produced by powder metallurgy for reduced cost compared to conventional cast or wrought processing.

As noted above cold deformation (work hardening), for example, by cold rolling, may be used to increase short-time strength properties for applications at low to intermediate temperatures. Energy stored by deformation processing is an accepted method for improving alloy mechanical properties below a use temperature of about 0.5 of the absolute melting point. As noted above, heat treatment (heating of components in sometimes multiple and complex steps) is frequently used to obtain desired mechanical property values.

6 ALLOY INFORMATION

There is no substitute for consultation with alloy producers or manufacturers about the forms (cast, wrought, powder metallurgy) which can be provided and the exact chemistries/properties available in alloys. It should be understood that not all alloys are readily available as off-the-shelf items. While many thousands of alloy compositions have been evaluated, some for over a century, only a relative handful are routinely produced. Moreover, some alloys are not available for use in all forms and sizes. Sometimes the highest strength alloys will be useful only as powder metal products or as castings. In many instances, specific alloy compositions may only be available at limited times in a production cycle.

Design data for alloys are not intended to be conveyed here, but Tables 1–9 offer limited information on some typical properties for a few alloy classes. Design properties should be obtained from internal testing if possible. Data from producers or other validated sources may be substituted if sufficient test data are not available in-house. Typical properties are merely a guide for comparison. Exact alloy chemistry, article section size, heat treatment, and other processing steps must be known to generate adequate property values for design.

The alloy selector needs to be aware that processing treatments such as forging conditions, heat treatment, and coatings for corrosion protection dramatically affect properties of alloys. All data should be reconciled with the actual manufacturing specification and processing conditions expected. Alloy selectors should work with competent metallurgical engineers to establish the validity of data intended for design as well as to specify the processing conditions that will be used for component production.

Application of design data must take into consideration the probability of components containing locally inhomogeneous regions under some circumstances. Short-time properties such as tensile strength

may be little affected by local inhomogeneities. Time- or cyclic-dependent properties at high temperatures and cyclic properties at low to intermediate temperatures can be detrimentally affected by inhomogeneities. For wrought alloys, the probability of occurrence of such regions (which are highly detrimental to fatigue life) is principally dependent upon the melting method selected to produce the cast ingot for subsequent processing. For alloys, whether used as cast or in the wrought form, the degree of inhomogeneity and the likelihood of defects such as porosity are related to the alloy composition, the casting technique used, and the complexity of the final component. Defects may be detected by metallurgical surface examination, radiography, or sonic inspection, but all methods have limitations on the defect size that can be detected.

For sources of property data other than data from the producers (e.g., melters, forgers) of an alloy or from an alloy selector's own institution, one may refer to organizations such as ASM International which publish compilations of data that may form a basis for

the development of design allowables for many alloys. A list of some trade and professional organizations where alloy information may be obtained is provided at the end of this chapter.

Standards organizations such as the American Society for Testing and Materials (ASTM) publish information about alloys, but that information does not ordinarily contain design data. It is important to note that the same nominal alloy chemistry may have some composition modification made from one manufacturer or customer to another. Sometimes this extends from one country to another. Tweaking of the casting or "wroughting" processes or the heat treatment often associated with what seem to be minor composition changes can cause significant variations in properties. All facets of chemistry and processing need to be considered when selecting an alloy for an application.

There are instances when different heat treatments may be applied to the same nominal alloy composition with resultant differences in properties. An illustration of this is shown in Fig. 6 where a wrought superalloy

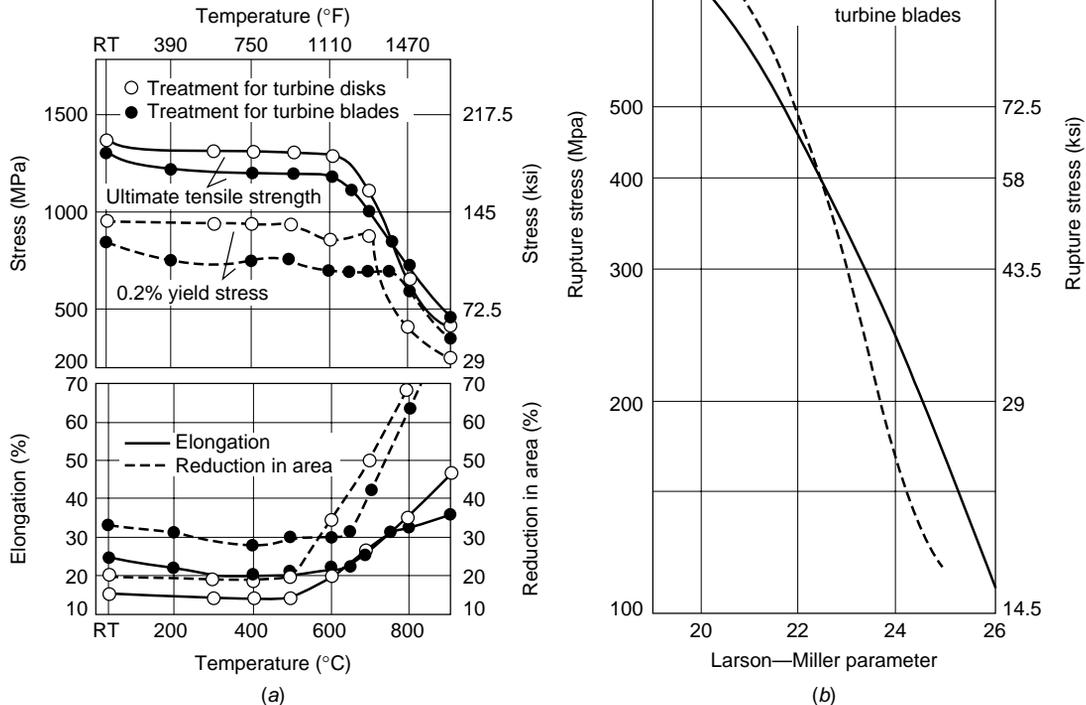

Fig. 6 Heat treatment for two different applications showing how (a) tensile properties and (b) rupture properties differ; $P_{LM} = T(C + \log t)$, where $C = 20$ is Larson-Miller constant, T is absolute temperature (K), and t is time in hours. RT = room temperature.

(Waspaloy) was produced for two different gas turbine engine parts, a disk and a turbine blade. Note the changes in properties. It also is not unusual for the heat treatments applied to cast parts of the same alloy composition to differ from the heat treatments for wrought products of the same alloy.

7 METALS AT LOWER TEMPERATURES

7.1 General

Alloy strengths at lower temperatures (usually considerably below $0.5T_m$) are not a function of time under normal conditions. Environmental attack (general overall corrosion, selective corrosion, etc.) can be significant and will be a function of time, temperature, and environment. Presence of notches and/or cyclic conditions may cause premature failure of a component. Consequently, in addition to evaluation of tensile (e.g., ultimate, yield strengths) properties, possible environmental considerations should be checked and the fatigue (low cycle/high cycle, smooth/notched) strengths, crack propagation characteristics, and toughness behavior should be reviewed.

7.2 Mechanical Behavior

Temperature or time of load application may influence the property behavior, including failure mode, of an article in mechanical testing. Failure may be defined as initiation of a crack or of fracture of an article into two or more pieces. In the case of short-time tensile properties (yield strength, ultimate strength), strengths usually are reduced as temperatures increase from absolute zero to higher temperatures near about 0.5 of the absolute melting temperature. Figure 7 illustrates the trends in tensile strength and ductility of alloys as temperatures increase.

Ductility of an alloy, as measured by elongation at fracture or reduction of area in cross section after fracture, tends to increase with temperature. Sometimes ductility or toughness of an alloy is measured by energy absorbed during impact tests. Strength properties tend to appear in design calculations while ductility values do not. Ductility is considered important in actual alloy use since limited ductility may cause an alloy article to fail with no immediate prior indication of likelihood of failure. The “forgiveness” of higher ductility alloys makes designers more comfortable with application of some alloys. Attempts to build “ductility” considerations into alloy selection and design resulted in various types of fracture toughness property concepts being developed and applied to alloy selection. Fracture toughness (critical fracture toughness) is one concept for which design data may be available for alloys. Higher fracture toughness is most desirable, as is higher ductility.

Some alloys may exhibit a “ductile-to-brittle” transition. This concept occurs when an alloy undergoes a rapid transition to much lower failure ductility over a very small temperature range on cooling of the alloy.

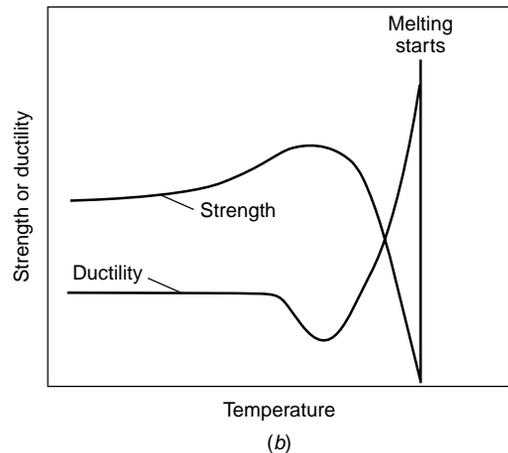

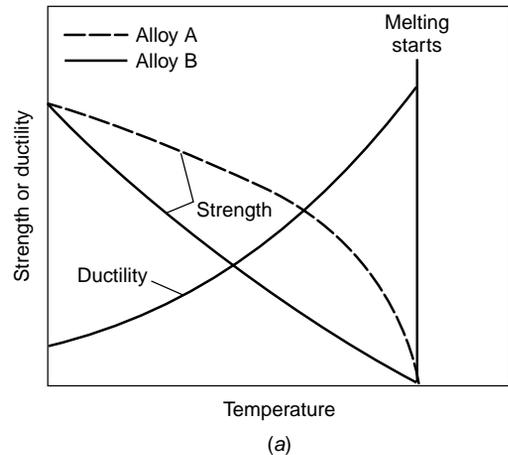

Fig. 7 (a) Most metals and alloys show a decrease in strength and increase in ductility as temperatures increase. (b) Superalloys precipitation hardened by γ' particles often show peak in strength and minimum in ductility as temperatures increase.

Steels, for example, may show a ductile-to-brittle transition, particularly at temperatures below room temperature. Figure 8 illustrates how toughness, as measured by ductility, for steels drops as temperature decreases (and carbon content increases).

Hardness properties (usually measured by means of standard indentation tests) may be used to judge an alloy's strength capability at lower temperatures and confirm the results of heat treatment but play no role in design.

8 METALS AT HIGH TEMPERATURES

8.1 General

While material strengths at low temperatures are usually not a function of time, at high temperatures

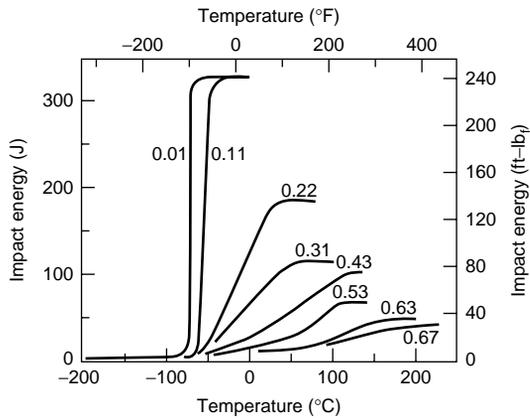

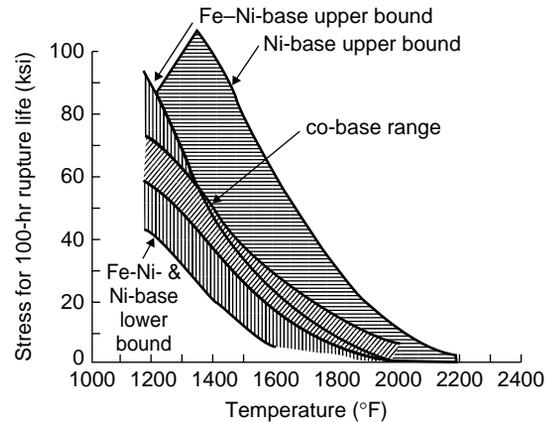

Fig. 8 Charpy V-notch energy versus temperature behavior for steel.

the time of load application becomes very significant for mechanical properties. Concurrently, environmental attack by oxygen and/or other elements at high temperatures accelerates the conversion of some of the metal atoms to oxides or other compounds. Environmental attack proceeds much more rapidly at high temperatures than at room or lower temperatures. Environmental considerations can vary significantly with different types of environment and different temperatures, in some instances, showing a greater rate of attack at one temperature than the attack of the same alloy at a higher temperature. As in the case of lower temperatures, presence of notches and/or cyclic conditions may cause premature failure of a component. Thus, in addition to evaluation of short-time tensile (e.g., ultimate, yield strengths) properties, creep rupture properties, fatigue, and thermomechanical fatigue (smooth/notched) strengths, crack propagation characteristics, toughness behavior, and possible environmental considerations should be checked.

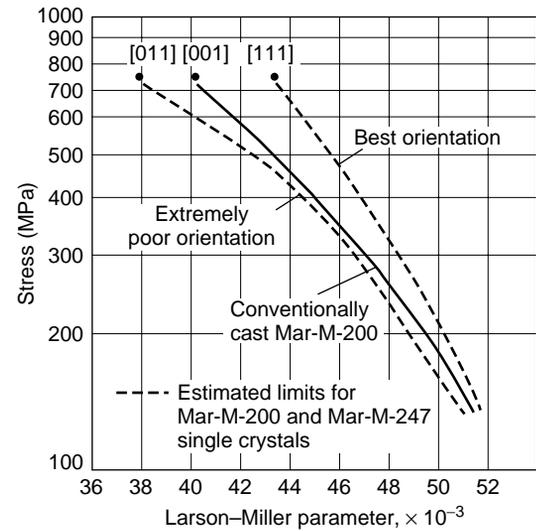

8.2 Mechanical Behavior

In the case of short-time tensile properties (yield strength, ultimate strength), the mechanical behavior of alloys at higher temperatures is similar to that at room temperature, but with alloys becoming weaker as the temperature increases. However, when steady loads below the normal yield or ultimate strength (determined in short-time tests) are applied for prolonged times at higher temperatures, the situation is different. Figure 4 illustrates the way in which most alloys respond to steady extended-time loads at high temperatures.

Owing to the higher temperature, a time-dependent extension (creep) is noticed under load. If the alloy is exposed for a long time, the alloy eventually fractures (ruptures). The degradation process is called creep or, in the event of failure, creep rupture (sometimes stress rupture) and alloys for elevated temperature use

(a)

(b)

Fig. 9 (a) Stress for 100-hr rupture life for three classes of superalloys. (b) Log failure stress versus Larson-Miller parameter for single-crystal nickel-base superalloys in three possible test orientations ($P_{LM} = \text{actual } P_{LM} \times 1.8$). $P_{LM} = T(C + \log t)$, where $C = 20$ is Larson-Miller constant, T is absolute temperature (K), and t is time in hours.

are selected on their ability to resist creep and creep rupture failure. Data for superalloys frequently are provided as the stress which can be sustained for a fixed time (e.g., 100-hr rupture) versus the temperature. Figure 9 shows such a plot with ranges of expected performance for various superalloy families.

One of the contributory aspects to elevated-temperature failure is that alloys tend to come apart at the grain boundaries when tested for long times above about 0.5 of their absolute melting temperature. Thus,

fine-grained alloys which are usually favored for lower temperature applications may not be the best materials for creep-rupture-limited applications at high temperatures. Elimination or reorientation/alignment of grain boundaries is sometimes a key factor in maximizing the higher temperature life of an alloy.

A factor in mechanical behavior not often recognized is that the static modulus (e.g., Young's modulus E) is affected by increases in temperature. This should be obvious from the above discussion about creep. The dynamic modulus of alloys shows a decrease with increasing temperatures. However, dependent on rate of load application, as test temperatures increase, static moduli determined by measurements from a (short-time) tensile test tend to gradually fall below moduli determined by dynamic means. Since moduli are used in design and may affect predictions of life and durability, every effort should be made to determine the dynamic, not just static, moduli of alloys for high-temperature applications. Table 10 shows dynamic moduli of cast superalloys for illustration.

Moduli of cast alloys also may be affected dramatically by the orientation of grains or by use of single crystals. Thus, a columnar grain nickel-base superalloy will show a dynamic modulus parallel to the growth direction of the columnar grains that is around 18×10^6 psi (124.1 GPa) at 70°F (21°C). This is much lower than the polycrystalline (random-orientation) value of around 30×10^6 psi (206.8 GPa). A more accurate method of depicting moduli would be to use the appropriate single-crystal elastic constants (three needed) of an alloy, but these are rarely available.

Cyclically applied loads that cause failure (fatigue) at lower temperatures also cause failures in shorter times (lesser cycles) at high temperatures. For example, Fig. 3 shows schematically how the cyclic resistance is

degraded at high temperatures when the locus of failure is plotted as stress versus applied cycles ($S-N$) of load. From the $S-N$ curves shown, it should be clear that there is not necessarily an endurance limit for metals and alloys at high temperatures.

Cyclic loads can be induced not only by mechanical loads in a structure but also by thermal changes. The combination of thermally induced and mechanically induced loads leads to failure in thermomechanical fatigue (TMF). TMF failures occur in a relatively low number of cycles. Thus TMF is a low-cycle fatigue (LCF) process (less than about 10^5 cycles). LCF can be induced by high repeated mechanical loads while lower stress repeated mechanical loads lead to fatigue failure in a high number of cycles (HCF greater than 10^6 cycles). Dependent on application, LCF failures in structures can be either mechanically induced or TMF type. In airfoils for the hot section of gas turbines, TMF is a major concern. In highly mechanically loaded parts such as gas turbine disks, mechanically induced LCF is the major concern. HCF normally is not a problem with alloys unless a design error occurs and a component is subjected to a high-frequency vibration that forces rapid accumulation of fatigue cycles. Although $S-N$ plots are common, the designer should be aware that data for LCF and TMF behavior frequently are gathered as plastic strain (ϵ_p or $\Delta\epsilon_p$) versus applied cycles. The final component application will determine the preferred method of depicting fatigue behavior.

While life under cyclic load ($S-N$ behavior) is a common criterion for design, resistance to crack propagation is an increasingly desired property. Thus, the crack growth rate (da/dn) versus a fracture toughness parameter is required. The toughness parameter in this instance is the stress intensity factor K range ΔK over an incremental distance which a crack has grown. A

9 MELTING AND CASTING PRACTICES

9.1 Melting

In order to produce most alloys, the appropriate chemistries are made liquid; mixing occurs (if more than one element or master alloy is present) and then the liquid is poured into containers (molds) to produce the desired shape. Most alloys have melting points sufficiently low that they can be melted and cast to shapes economically and with acceptable purity and quality. Melting consists of providing a furnace with an appropriate (usually ceramic-lined) crucible to contain the molten-metal charge and a power source (usually gas or electricity) to produce the appropriate temperatures for melting. For common industrial alloys (white metals, magnesium, aluminum, copper, steels, and superalloys), the melting range needed probably varies from around 800°F to about 2500°F. Melting temperatures for some alloys such as titanium alloys range higher than this.

As indicated earlier, there are occasions when a primary alloy to eventually be used in a final article

shape is cast into an electrode or an ingot one or more times before an article is produced. Electrodes are the precursors to final forged or deformation processed articles. They are intended to be remelted by electrical energy to refine chemistry, microstructure, and so on, prior to being cast as ingots to be delivered to the manufacturer who may cut the ingots to billets from which to make the (raw shape at least) final article by deformation processing. Cast ingots may be remelted without additional processing for use in the direct casting of articles. Alloys produced using the variety of available furnaces in ambient air environments satisfy most common needs. Vacuum melting and similar processes produce higher quality alloys and usually are the production melting methods of choice for applications such as those in aerospace.

For metals such as titanium alloys and superalloys, melting is done under vacuum to retain and/or enhance an alloy's properties. Ordinarily, most alloys to be cast into articles or ingots (which are then processed into billets for wrought processing) are melted open to the atmosphere (air) except for the use of slags on the molten-alloy surface to minimize pickup of gases or loss of elements from the molten alloy or to introduce elements to the alloy from the slag. Furnaces may be resistance wire heated, gas fired heated, arc heated, or induction heated. For more sophisticated melting, especially where vacuum is required, alloys may be heated by induction, arc, electron beam, or plasma. The latter three processes can produce higher local heat input and so may be used to melt alloys such as titanium. The more sophisticated the melting techniques, the higher the cost but, generally, the better the quality.

Vacuum induction melting (VIM) is used for superalloys and, in some instances, stainless steels. The VIM furnace consists of a ceramic-lined crucible built up around water-cooled induction coils. The crucible is mounted in a vacuum chamber. The vacuum chamber may have several vacuum ports (of various sizes) built into it so that, without breaking vacuum,

- charge material may be introduced into the crucible,
- molds may be introduced into the chamber, and
- systems for removing slag from the pour stream (tundish) may be introduced.

Sampling of the molten metal is required for chemistry control in primary alloy production and when the VIM unit is producing ingot for subsequent processing. VIM is more costly than electric arc furnace or other routine processes for melting alloys. A major advantage of VIM is excellent control of chemistry and reduction of impurities such as gases (oxygen, nitrogen) and detrimental tramp elements. Sometimes, in lieu of VIM, an alloy (e.g., of steel) may be vacuum degassed (VD) after melting but before pouring into molds. Improved properties result from VIM or VD processing. The essence of selecting a melting

process to create the desired composition and electrode/ingot/cast article structure hinges on the correct choice and adaptation of melting principles and attention to detail in processing.

Consumable vacuum arc remelting (CVAR, most often referred to as VAR) is used to primary melt and to remelt titanium and to remelt superalloys. High heat inputs can be achieved and the alloys are cast into water-cooled molds. No slag is used but rather the ultrahigh vacuum acts to protect the alloy. An electrode is used to strike an arc between the consumable electrode of the alloy and a striker plate in the water-cooled mold. The molten metal produced from the electrode by the arc drips into a pool and solidifies in characteristic ways related to alloy composition, melt rate, mold size, and so on. Generally the mold is larger than the electrode. Molds for VAR processing are circular. Sometimes multiple VAR is applied to an alloy.

Another melting process is electroslag remelting (ESR), which uses an arc within the slag to produce heat that melts the face of an electrode. In ESR, current is applied to an electrode situated inside a water-cooled crucible containing a molten-slag charge. The intended circuit of current is from the electrode, through the molten slag, through the solidifying ingot, through the water-cooled stool, and back to the electrode. The molten droplets from the electrode face fall through the slag to a molten pool and then solidify. Changes in chemistry can be effected in ESR to a greater degree than in VAR processing. There are subtle aspects of the processing for both VAR and ESR which may be discussed with a knowledgeable alloy producer. For superalloy primary melting, where larger ingot sizes of highly alloyed materials are needed, VAR is used in preference to ESR.

VAR and ESR are secondary melting processes (following primary VIM melting to produce electrodes). Several producers of critical rotating superalloy components in the gas turbine industry have adopted the use of a hybrid secondary melt process. Primary melting by VIM to ensure production of a low-oxygen, precise chemistry, initial electrode is followed by ESR. The ESR electrode will be clean and sound. The clean, sound electrode is then remelted by VAR. The improved cleanliness and soundness of the electrode facilitate VAR control. This product is referred to as "triple melt" and has a much reduced frequency of defect occurrence compared to double-melt (VIM + VAR) superalloy product. The cost of the triple-melt process is clearly higher than double melt (VIM + VAR or VIM + ESR).

As noted, alloy-melting practices may be classified as either primary (the initial melt of elemental materials and/or scrap which sets the composition) or secondary (remelt of a primary melt for the purpose of making larger electrodes, controlling the solidification structure, etc.). The melt type or combination of melt types selected depends upon both the alloy composition and intended application (mill form and

size desired, properties desired, sensitivity of the final component to localized inhomogeneity in the alloy, economics, etc.).

Although not widely used owing to economic considerations, the use of electron beams or plasma melting on the surface of an electrode and on the molten pool provides an alternative source for clean melting of some specialty alloys.

9.2 Casting to Prepare for Subsequent Processing

When alloys are cast, the resulting object may be (a) an electrode for remelting, (b) an ingot to be melted (in whole or in part) later and then cast into articles, (c) a cast article of commerce, or (d) an ingot for processing into billet. This section discusses the casting of ingot for later use, not directly into articles of commerce.

From the billet, wrought shaped articles may be formed. Also from billet stock, mill products may be produced. Mill products would be bar, plate, sheet, wire, and so on, which might later be deformation processed into a shape or used directly. For example, bar stock might be machined into fasteners while wire might be sold and used with no further processing. Alloys usually not only are available in standard mill forms (plate, sheet, and bar, from which components may be machined) but also may be produced as specific component shapes by the use of forging (or casting). It is critically necessary that the property requirements of a component be fully understood in order to maximize properties and minimize costs. For instance, a component selected to resist corrosive attack may not need to be melted by a process that assures maximum fatigue resistance.

The most critical feature of melt process selection is the size of the component to be manufactured from an ingot. Larger components require larger ingot sizes. The higher the melting point of an alloy and the more highly alloyed the chemistry of the alloy, the greater may be the restrictions of maximum ingot size. For forged components consideration must be made not only of the final component size but also of the capability of the ingot to be sufficiently deformed so as to develop the properties characteristic of a forged structure. Internal ingot cleanliness is also a consideration in selecting the melting route.

Many alloys will have no special cyclic requirements and routine melting and casting to ingots is the rule. However, for more sensitive applications (e.g., aircraft structures), more stringent requirements will exist. Generally, for fatigue-sensitive components, a melt practice is selected which will guarantee the best structure. The needs of sensitive applications may require the generation of specific structure in an ingot cast and machined to billet. For example, a specific grain size may be required by the wrought processor in order to obtain the ultimate customer's specific properties after a forging process and subsequent heat treatment. Specific grain sizes and/or ingot surface finish

may be required in order to maximize the effectiveness of ultrasonic or etch inspections. The processes for producing ingot for sensitive wrought-product applications will require that the alloy selector work closely with the melter and forger on the melt-to-ingot-to-billet-to-article sequence. Those selecting materials for less critical articles may be able to rely on standard "mill" practices to generate adequate product.

9.3 Casting Practices for Producing Articles

Generally, cast articles are made by remelting ingots of the desired alloy. Articles may range from grams (ounces) in weight for jewelry (e.g., rings) to tens or hundreds of pounds (machinery, vehicle applications, power turbine components, aircraft gas turbine components). The casting invariably is done in a foundry. The alloy generally is melted in smaller versions of the furnaces used to do primary/secondary melting to produce ingots. Melting in the furnace is done in crucibles which are almost always ceramic-lined containers. In order to cast an article after it has been designed, a copy of the design must be replicated as a negative cavity in a mold. Obviously the mold must be resistant to attack by the molten alloy to be poured into it.

Multiple molds generally are prepared, dependent on the weight/size of the intended cast article. The molds must be connected in such a way that transfer of liquid alloy to them is easy. Design of molds is critical to successful casting. The cavity in the mold must be slightly larger than the intended article to provide for the shrinkage that occurs in the solidification of alloys. There will be a basin or tundish into which the molten metal is poured and from which the metal is dispersed to the individual molds. In order to transfer the metal and properly feed the cavities, various channels (sprues, risers, runners, etc.) are needed. The final mold assembly must have sufficient rigidity to be stored and to be moved into place for casting at the appropriate time.

Different media are used for molds. Sand is a common and inexpensive molding material and plaster and other similar compositions may be used. Surface finish and dimensions are affected by the molding material as is the cost of the casting process. In some instances, molten metal can be melted and injected into water-cooled metal dies producing fine definition with die-cast articles. The alloys used for such processing are lower melting alloys but work has been done to cast high-temperature alloys this way. Cost will be a factor and die casting is more commonly a process for large runs of small- to moderate-size articles such as medals cast in moderate-melting-range alloys.

Complex shapes can be produced by casting. Often the article shape is such that cores must be added to the negative cavity to produce desired passages and holes in the finished casting. Most routine casting will not require extra thin article walls or extra high tolerances. However, for aircraft or power gas turbine parts, in particular, very high tolerances are required

and wall thicknesses (nickel-base superalloys) may drop to 0.040 in. (0.101 cm) or so.

The principal casting practice for high-precision casting is investment casting (also known as the lost-wax process). A reverse-cast model of the desired component is made and wax is solidified in the resultant die. Then a series of these wax models are joined to a central wax-pouring stem. The assembly is coated (invested) with appropriate ceramic, processed to remove wax, and fired to strengthen the invested ceramic mold. A small percentage of a (VIM) alloy ingot is remelted and cast into the mold. Upon solidification a series of components in the desired form are created, attached to the central pouring stem. These objects, frequently gas turbine hot-section airfoil components, are removed and then machined and processed to desired dimensions. Superalloy investment-cast cases now are available up to about 40 in. (101.6 cm) in diameter. Titanium alloys similarly can be cast in large sizes using investment-casting techniques. Turbine airfoils can now be cast not only in smaller sizes for aircraft gas turbines but also with airfoil lengths of several feet for land-based power turbines.

Most investment-cast articles are of conventional, polycrystalline structure with more or less randomly oriented grains. Mechanical properties are nominally random but may show some directionality. Increased high-temperature property strength levels have been achieved in nickel-base superalloys by columnar grain directional solidification (CGDS), which removes grain boundaries that are perpendicular to the applied principal load in turbine airfoils. The ultimate solution for optimum high-temperature strength is single-crystal directional solidification (SCDS) to produce a superalloy with no grain boundaries. Maximum creep rupture strength in nickel-base superalloys now is achieved with SCDS alloys. SCDS has been applied not only to aircraft gas turbine engines but also to large-frame land-based gas turbines. Most alloy systems used commercially have not shown a need for increases in the high-temperature strength which might be produced by single-crystal casting. Such processing would considerably increase cost and property improvements with SCDS depend on alloy chemistry. Certain nickel-base superalloys are the only alloys where acceptable cost-benefit trades are possible.

9.4 Casting Considerations in Alloy Selection

Alloy selection for cast articles generally will be on the basis of alloy type needed (e.g., copper, aluminum) and then on specific alloys within the selected type so as to provide the desired properties. Not all alloys are equally good for casting. In many alloys systems, compositions of casting alloys differ from those of alloys used for wrought applications. Depending on the application, there may be more or less tolerance for lesser quality castings. Need for pressure tightness, for example, might dictate a casting process different from that for another application. Casting defects occur and

vary with alloy composition, article shape, and dimensions as well as casting practice. Oxide (dross) carried over from the alloy-melting production process may cause surface and internal inclusion problems in some alloy systems. Porosity is another major concern, especially with large castings. Porosity may be controlled by mold design and pouring modifications. In some alloy systems where articles for critical applications are required, non-surface-connected porosity may be closed by hot isostatic pressing (HIP) of the cast articles. Surface porosity in large castings may be repaired by welding. Other casting concerns may include surface finish intergranular attack (IGA) caused during chemical removal of molding materials, selectively located coarse grains in PC materials, and so on. Sometimes alloys may be modified in chemistry to optimize product yield but with a possible compromise in properties. Product yield is an important determinant of final component cost.

10 FORGING, FORMING, POWDER METALLURGY, AND JOINING OF ALLOYS

10.1 Forging and Forming

Forging is one of the most common methods of producing modest production lots of wrought articles for alloy applications. Mill products such as bar stock and wire generally are produced in greater quantities than forgings but, for the most part, are used to make non-complex shapes. The most demanding applications use wrought forged ingot metallurgy components. One or more intermediate shape stages usually are involved when conventional forging is practiced. Special processing by isothermal (usually superplastic) forging may enable the forging to go directly from billet to final stage in one step using a closed die.

A billet is the precursor to a forging in large-sized articles. Billets are transformed (forged) to shapes approximating the final desired shapes with the approximation dimensions being dependent on the alloy system and known issues in the forging process. Multiple reductions may be needed and blocker dies (open dies) may be needed before closed die forging to final dimension/shape. Forging may be accomplished with one or a group of dies and in open or closed dies. While closed dies better define the final form of a forging, the cost of using such dies exceeds that of open dies. Some dies may be just flat platens that are used to transfer the forging load. The more complex the dies, the more difficult it becomes to extract heat. Significant costs can be incurred for die design and procurement.

Forging is usually a process carried out at elevated temperatures with the temperature being determined by alloy composition, amount of reduction needed, and so on. Forging always requires significant deformation of the alloy as it is transformed from billet to article. Sometimes the forging deformation is retained to increase strength; sometimes forging is used to modify the microstructure of the article when forging is combined with appropriate heat treatments. In the case of

high-performance superalloys, the objectives of a forging cycle may be:

- Uniform grain refinement
- Control of second-phase morphology
- Controlled grain flow
- Structurally sound component

Hot forging is a multistep process with several to many cycles of heating to forge temperature, then forging, followed again by heating, forging, and so on.

Forming, while containing elements of deformation, generally restricts itself mostly to sheet that, for example, may be bent or formed to a mandrel or other forming die. Forming of automotive hoods from sheet metal would be an example. Deformation induced in forming may not be extreme and forming is not used to control microstructure and properties of alloys. Basically, forming produces relatively two-dimensional shapes while forging produces three-dimensional shapes with distinct properties. Roll forming is often used to produce small shapes from bar stock or rod.

There are two major types of forging: open die and closed die. Open-die forgings are less expensive but in general require more stock removal by machining to get to the final dimensions. Closed-die forgings are more costly but reduce the machining needed to achieve final dimensions in the article. In forging, alloy billets are squeezed between two platens or dies using an appropriately sized press. Several to many forging steps may be needed to bring the billet to the approximate article shape and dimensions. A great deal of skill is necessary not only in die design but by the operators of the forge presses in order to achieve optimum properties and cost balances. As alloy strengths increase, it becomes increasingly difficult to move an alloy around during forging. When higher forging pressures are required, defects become more probable.

Superplastic forming became available in the 1960s and was first used to produce aluminum alloy door panels, for example, for high-end automotive vehicles. Superplastic forging was introduced for superalloys when the strengths of alloys were bumping up against metallurgical limits and forging was becoming too difficult. A process called superplastic forming/diffusion bonding was developed in the air frame business to produce large articles with better properties than existing technology could produce. This is a high-technology process without applicability to processing of routine materials.

10.2 Powder Metallurgy Processing

Powder metallurgy (PM) has been in use for many decades, dating back over 50 years. The principal intent of PM was/is to produce alloy articles at less cost. However, since the latter part of the twentieth century, PM also has meant a way to create billets of the highest strength alloys (without casting) and

subsequent forging of billets to final parts. Different powder production manufacturing processes exist for alloys. A common practice is gas atomization where a prealloyed ingot is remelted and then blasted by a jet of air/argon/helium to produce powder in a chamber. The powder is recovered and classified for size, for example. Powder production generally is a batch process.

Molds (dies) for making PM parts are made to the shape of the planned article and then filled with powder, tapped, pressed, and sintered (high-temperature heated) or otherwise metallurgically bonded (by heat/pressure) to increase density and properties. The process often can be automated. Dimensions of dies will need to reflect the expansion coefficient of the die material and the alloy powder. There are different process variables in PM, including multiple methods of powder production. Compaction consists of processes such as cold pressing or vacuum hot pressing or HIP, among others. Some high-strength superalloys are made only by PM methods. Because powder articles made by other than HIP are not 100% dense, there will be porosity in the form of very small voids in the powder article compact. For the most part, a small number of defects such as holes do not significantly affect the properties of alloys, at least in static tests. For fatigue-limited applications, higher quality production processes would need to be used.

A relatively new aspect of the use of PM is in the superalloy field where alloys, which can be cast in relatively small parts such as turbine blades, are not workable by cogging, forging, and so on, to produce a billet for disk forging. By using powder of the desired alloy, a compact of the desired article can be made by HIP or extrusion and then the compact can subsequently be worked (usually forged) to final shape and machined to produce a higher strength wrought article than can be produced from conventional wrought-alloy ("ingot metallurgy") procedures.

10.3 Forging/Working Considerations in Alloy Selection

The stronger the alloy to be utilized in design, the more difficult it will be to manipulate by mechanical working forces. In addition to working difficulties, problems with ordinary forgings can arise from many sources. Poor grain size control, grain size banded areas, poor second-phase morphology/distribution, internal cracking, and surface cracking are among the sources for rejection of forged parts. Limits exist on the capability of an alloy to be worked without cracking, encountering other defects, or stalling a forge or extrusion press. Some shaping equipment such as rotary forging devices may be better able to change the shape of the stronger alloys than other equipment. Powder metallurgy offers an alternative processing route for high-strength alloys such as superalloys used for rotating disks, shafts, hubs, and so on, in aircraft and power generation turbines. Powder production reflects an art

that is not always directly transferable from one producer or one alloy to another. Powder components are best made by producing an ingot from powder and then forging the ingot to component shape. Extensive work with an alloy melt shop and an associated powder producer may be necessary to create a satisfactory metal powder of a high-strength/high-performance alloy selected for design.

10.4 Joining

Welding, soldering, and brazing are used to manufacture articles in many instances. Soldering is a lower temperature, less than 800°F (427°C), process of letting molten metal be drawn into a very tight crevice between the components to be joined and then allowing it to be solidified. Brazing is accomplished in the same general way, but the braze alloys melt above about 800°F (427°C). Braze alloys produce stronger bonds than solder alloys. Solder finds extensive use in the electronics industry. Brazing is more often found in structures which require relatively high strength. Such structures might be aircraft gas turbine stator assembly parts, for example.

Welding produces a metallurgical bond between components of an article. There are many welding processes. The simplest definition is solid-state bonding versus fusion welding. Relative to fusion welding, resistance welding techniques are low-cost methods to join parts such as tabs on sheet metal. Arc welding is perhaps the most common fusion welding technique with higher quality associated with gas-tungsten arc or gas-metal arc welding. There are other techniques used for massive structures and also specialized techniques that produce maximum-quality welds. Those techniques use electron beams, laser beams, or plasmas to heat the weld metal. Relative to solid-state welding, a number of techniques exist, including friction or inertia bonding, diffusion bonding, and ultrasonic bonding. The success of these techniques is dependent on clean surfaces and optimum bonding areas.

Many complex articles in devices such as gas or steam turbines were/are combinations of components joined to produce a larger article. In some applications, when the joined article is not too large or complex, efforts have been made to replace such articles with cast components. However, surface-connected defects often are found in large superalloy castings. In addition to large superalloy castings, many articles produced in industry can have production defects. If defects can be repaired, articles may be acceptable for service. Consequently, repair welding is employed with great frequency, dependent on the dollar value of the article and other economic and availability aspects.

10.5 Considerations in Joining Process Selection

An alloy selector will need to consider the weldability or joinability of an alloy before suggesting initial production use of joining techniques and/or their

use in repair. Many nickel-base superalloys are not weldable. High-performance alloys such as titanium alloys and sheet metal of cobalt-base, solid-solution-strengthened nickel-base and lower hardener content nickel-base alloys can be joined as can iron–nickel-base alloys. Aluminum alloys can be welded with high-heat input welding techniques. Some techniques such as electron beam welding (EBW) may be best for high-performance materials owing to the vacuum environments of the processes and the very narrow fusion zone that is created in the process. High-vacuum EBW and similar joining processes may not find wide use in production of large quantities of consumer goods owing to the cost of the process. On the other hand, the use of nonvacuum electron beam welding (NVEBW) has been shown to be cost effective for steels used in auto frames.

11 SURFACE PROTECTION OF MATERIALS

11.1 Intrinsic Corrosion Resistance

Most alloys are not intrinsically resistant to surface attack by corrosion. Precious metal alloys containing gold or platinum may be chemically stable. Most alloys consist of metallic elements which want to revert to compounds (e.g., oxides) in chemical states such as those in which the elements are found naturally. Corrosion is the interaction of elements in an alloy with the environment to produce chemical compounds. Surface attack occurs most frequently since the surface is the primary interface with the surroundings of an article in use. Most typically, articles “see” oxygen from the air and a water-based environment owing to humidity in the air. The processes of uniform corrosion in aqueous environments and with selected other environments are fairly well understood. Corrosion also can take place in nonuniform ways through the action of or development of pits, crevices, or cracks. Under some circumstances, individual alloy elements may be selectively removed from an alloy.

Using an understanding of the nature of the corrosion process, metallurgists have developed alloys which have improved resistance to corrosion in a variety of environments. In fact, many alloys containing certain elements such as chromium or aluminum demonstrate natural resistance to corrosion in oxidizing environments. However, alloys which are corrosion resistant in oxidizing environments often are not resistant in reducing environments, especially when attacked in the presence of halide elements such as chlorine. Some alloys/elements are more noble with respect to other alloys/elements. One representation of the corrosion sensitivity of alloys is the “galvanic series of alloys/elements.” Alloys/metals that do not corrode or are more corrosion resistant in aqueous environments are called noble or cathodic while more corrosion prone alloys/elements are called active or anodic. Table 11 shows a galvanic series for some commercial alloys and metals in seawater. Note that some more common alloys other than those of the precious elements are near the top. Specifically titanium

Table 11 Galvanic Series of Selected Commercial Metals and Alloys in Seawater^a

Noble, or cathodic	Platinum
	Gold
	Graphite
	Titanium
	Silver
	Stainless steel, austenitic, P (18% Cr, 8% Ni, low C)
	Stainless steel, ferritic, P (10–30% Cr, high C)
	Nickel–chromium–iron alloy, P (80% Ni, 13% Cr, 7% Fe)
	Nickel, P
	Silver solder
	Nickel–copper alloy (70% Ni, 30% Cu)
	Copper–nickel alloys (60–90% Cu)
	Copper–tin bronzes
	Copper–zinc brasses
	Nickel–chromium–iron alloy, A (80% Ni, 13% Cr, 7% Fe)
	Nickel, A
	Tin
	Lead
	Lead–tin solders
	Stainless steel, austenitic, A (18% Cr, 8% Ni, low C)
	Stainless steel, ferritic, A (10–30% Cr, high C)
	Cast iron
	Steel
	Aluminum alloys, precipitation hardened
	Cadmium
	Aluminum, commercially pure
	Zinc
Active, or anodic	Magnesium and magnesium alloys

^aP indicates passive condition; A indicates active condition.

and its alloys are very resistant to aqueous corrosion. Similarly, titanium alloys display excellent corrosion resistance in body fluids. Consequently, titanium alloys are often choices for applications such as prostheses for bone implants or in dental work. Commercially pure titanium find extensive use in the chemical processing industry.

Although cast iron and steel are near the bottom of the series and so are active (steels rust in most instances of environmental exposure), chromium additions to iron can produce a passive layer that inhibits oxidation. Hence alloys of iron with sufficient chromium additions became “stainless.” Stainless steels are near the top (cathodic end) of the galvanic series and perform very well in a variety of commercial applications. Some construction steels are alloyed to produce a rust-resistant finish and are used for uncoated/unpainted steel work on bridges, guard rails, and so on.

Different alloys may display varying behavior dependent on the environment. In some instances, alloys that display good aqueous corrosion resistance (general corrosion attack resistance) show tendencies to selective attack such as that which occurs in stress corrosion. Connections between anodic and cathodic alloys in service invariably lead to accelerated attack of the anodic element/alloy.

Some alloys have moderate resistance to corrosion. That is, they form discolored surface layers but do not have surface recession at a great rate. A case in point would be copper or copper alloy flashing often seen on roofs at chimney lines. The alloys degrade owing to formation of a surface patina, but there is no significant surface recession and the copper retains its cross section and hence strength integrity for a long time.

Some alloys show adequate corrosion resistance so long as the surface of the article is not degraded. However, surface erosion or inadvertent scratching or similar degradation can cause corrosion to accelerate. Pitting and similar corrosion owe their existence to such tendencies.

Some alloy elements confer better corrosion resistance in certain temperature/environment regimes than in others. Nickel-base superalloys oxidize at elevated temperatures. Nickel was alloyed with chromium in the early twentieth century to produce oxidation-resistant materials used for electrical resistance wires. In the mid-twentieth century, the nickel–chromium alloys were adapted for use as superalloys for gas turbine engines. In the early years of use, these chromium-containing alloys showed excellent oxidation resistance. Later, as temperatures went higher, alloys with higher amounts of aluminum (and reduced chromium) than in the early superalloys showed improved high-temperature oxidation resistance.

Generally, as temperatures increase, corrosion attack increases. However, for some forms of environmental attack, the kinetics of the attack process may be such that a specific type of attack begins at a certain temperature and increases with increased temperature but then drops again to lower rates at still higher temperatures. Nickel-base superalloys exposed to sulfur and/or halide-containing environments may show lower temperature hot-corrosion rates that are greater than the hot-corrosion attack seen at higher temperatures.

In addition to general corrosion, grain boundary oxidation/corrosion or the selective attack of some secondary phases in an alloy can create notches. Coatings will help protect against such attack. Other types of chemical attack are more subtle. For example, brass (copper–zinc) alloys can be susceptible to stress corrosion cracking. In this instance, the attack may be on/in the grains and cause cracking owing to a residual or applied stress on an article made of the alloy. In the early days of manufacture of cartridge brass (70 Cu and 30 Zn), cases would crack or be embrittled by stress corrosion cracking and would burst on firing. Stress corrosion cracking can be found in titanium

alloys and some stainless steels among other materials. Reduced residual stresses help to alleviate the problem for brass.

11.2 Coatings for Protection

From early use of steel, the concept of rust was prevalent. At first no alloys were made that were rust resistant, but it was discovered that, if one could protect the iron or low-carbon steels from the environment, then there was no attack. In the automotive industry, this concept was applied to bumpers by electroplating coatings onto the bumpers. First a nickel plate was applied, then a high-reflectivity chromium was plated over the nickel. So long as the nickel did not develop a pore or scratch or suffer a similar breakdown, the steel bumper did not rust. Similarly, prior to the widespread use of polymer trash cans, steel cans were coated with a sacrificial layer of zinc, an element anodic to iron. The trash cans did not rust because the zinc corroded preferentially to the steel. These two illustrations show the use of impervious coatings or anodic coatings to protect materials.

Corrosion at lower temperatures is not the same as corrosion at high temperatures where the interaction of an alloy with oxygen can cause an oxide to form with consequent reduction in the cross-sectional area of an alloy. If the oxide itself is essentially protective, e.g., chromium oxide at temperatures below about 1500–1600°F (816–871°C) or aluminum oxide above about 1800°F (982°C), then the alloy is protected from oxygen attack for some time. It was reasoned that the production of a deliberately introduced chromium-oxide-forming or aluminum-oxide-forming coating on alloys for high-temperature use would increase their resistance to oxidation.

Such coatings were introduced and applied by a number of methods. The early coatings were diffusion coatings on cobalt- or nickel-base superalloys and were created by pack aluminizing or slurry application. The chemistry of the coating was determined by the chemistry of the alloy. Some high-temperature protective aluminide coatings were applied by painting or by spray processes. Later (second-generation) coatings were produced by overlaying a specific chemistry of a protective nature on the surface of the component using physical vapor deposition (evaporation of elements of an alloy by using an electron beam and redeposition of the elements on the target alloy's surface). Overlay coatings are generally more expensive than diffusion coatings. However, vapor-transported diffusion-type coatings can coat internal (non-line-of-sight) surfaces while overlay coatings can only coat external line-of-sight surfaces that can be seen by the coating apparatus. Some commercial diffusion coating processes are available, but most overlay coating processes are proprietary, having been developed by users such as aircraft gas turbine manufacturers.

Of course, for lower temperature use, spray or electrodeposited coatings may provide adequate protection for many alloys and overlay coatings might be overkill.

Despite the coatings on high-temperature superalloys, oxidation (or other corrosion) continues but at a markedly lower rate. Since the coating is being used up over time, eventually the coating will not be sufficient protective and the surface of the alloy must be recoated. This concept of eventual coating degradation will apply at both high temperatures in oxidation and lower temperature corrosion (e.g., aqueous corrosion). Depending on the alloy's structural application, the cost to replace the article that is coated, and the cost of recoating, a decision will need to be made about continued use of the article in its application. Generally, replating or recoating of articles is more apt to occur if the cost of the article's replacement is very high. So, gas turbine airfoils which may cost in the \$100–\$1000 range to make as castings are more apt to be recoated and reused than a car bumper that has rusted.

11.3 Coating Selection

Coating selection is based on knowledge of oxidation/corrosion behavior in laboratory, pilot-plant, and field tests. Attributes that are required for successful coating selection include:

- High resistance to general oxidation/corrosion
- Ductility sufficient to provide adequate resistance to thermal mechanical fatigue if the article sees high temperatures since coatings are not particularly ductile and coating cracking/spalling could occur
- Compatibility with the base alloy to be coated (important anywhere but especially for high-temperature operation)
- Low rate of interdiffusion with the base alloy (if used at high temperatures)
- Ease of application and low cost relative to improvement in component life
- Ability to be stripped and reapplied without significant reduction of base-metal dimensions or degradation of base-metal properties

12 POSTSERVICE REFURBISHMENT AND REPAIR

One important aspect of modern alloy use is the concern for maximizing service life of articles. Manufacturers do not wish articles or devices to fail in less than the warranted life. Selection of alloys for design should include concern for potential early removal and repair or refurbishment. Surface degradation and mechanical property loss are major economic factors in applications of articles. These factors have become of greater interest as the base cost of materials and subsequent components has risen dramatically over the

past 40 years. (As this chapter is being written, for example, the price of nickel, a common base material or alloy element, has risen 10-fold in 3 years!)

Although initial cost has usually prevailed in alloy selection for consumer devices and articles, as the cost of machinery (nonelectronic) has increased owing to various factors, more attention in alloy selection has been given not only to initial ability to produce a viable article but also with regard to future life and refurbishment/repair concerns. In practice, when public safety consideration limits or product integrity design limits are reached, costly components may be withdrawn from use. Some components may appear to be unaffected by service time. For economic reasons there may be incentives to return these components to service.

Other components after service may have visible changes in appearance. For example, a gas turbine high-pressure turbine blade may be missing a coating in the hottest regions of the airfoil or a crack may develop in a vane airfoil. Seals may be worn. It is highly desirable that damage can be repaired so that the costly parts can be returned to service.

If possible, alloys would be selected on the basis of restoration of capability after initial capability has (apparently) been reduced by service exposure of the component. However, most applications do not permit alloy selection on that basis. Many applications have limited lifetimes to reduce initial cost (and, possibly, to improve the likelihood that new products will be purchased). The best alloy from a property and initial economic viewpoint is usually the choice. However, it is common practice with certain applications to refurbish or repair many components which have visible external changes.

Stripping and recoating of turbine airfoils is one example of refurbishment and repair practice. Oxidation- and corrosion-resistant coatings and thermal barrier coatings may be reapplied (after appropriate surface-cleaning treatments) to restore resistance of the surface to heat and gaseous environments. When a high-performance article made of a superalloy is to be refurbished by recoating, all traces of the original coating should be removed before recoating is attempted. In the case of missing, eroded, cracked, and/or routed material, welding traditionally has been used to fill the gaps for some alloys and components. Care must be taken to assure that no additional alloy degradation occurs owing to the refurbishment and repair practice.

The restoration of mechanical properties degraded by creep and/or fatigue is not clear-cut. In the laboratory, reheat treatment has been shown to restore the mechanical properties of some superalloys after service exposure. The degree of restoration is a function of the mechanical history of the component. Results of reheat treatment of service exposed parts are variable. Most postservice procedures for high-cost flight safety articles do not provide for mechanical property restoration.

It is important to recognize that refurbishment or repair may not result in cost-effective performance.

13 ALLOY SELECTION: A LOOK AT POSSIBILITIES

13.1 General

Selection of alloys for design may require a comprehensive review of the design and potential materials or, as noted below, may rely on prior use to dictate alloy selection. On the assumption that a design will start from scratch with no preconceived notions of alloy usage, several questions need to be answered:

- What is the expected temperature of use?
- What is the expected environment (gas, liquid, moving, static, etc.)?
- What strength levels are required?
- Is there a cyclic component to any loads?
- Are elastic properties likely to be a criterion?
- Will loading be uniform or will some directions within the article see different loads?
- Are there special characteristics at issue, for example, heat capacity, electrical, magnetic?
- For how long must the article to be designed and manufactured last?
- Will successful operation depend on special cooling or other conditions?
- What weight or dimensional levels must not be exceeded?
- Is there an aesthetic component to the application of the desired article?

Assuming that the above questions can be answered in a definitive way, referral to general alloy characteristics will narrow the choices available. For example, operating temperatures above about 1000°F (538°C) will eliminate aluminum, magnesium, and zinc alloys since alloys of those metals will be molten at such operating temperatures. Elastic modulus concerns might further limit alloys. For example, if it would appear that materials for a given article would need Young's modulus of near 30×10^6 psi (206.8 GPa), then titanium alloys would be eliminated since their moduli are less than 20×10^6 psi (137.9 GPa). Would the application be in oxidizing gases above 1000°F (538°C)? Then iron would be ruled out owing to its lower oxidation resistance compared to other alloys at those temperatures. Stainless steels might be possible but creep rupture strength might be too low, thus moving the likely candidates to superalloys, those of cobalt, iron-nickel, or nickel base.

Now, attention would need to be directed to the manufacturing ability of alloys to be considered. If the alloy is to be mechanically deformed to reach its near final shape, ductility/workability will need to be considered. Is the article complex, with internal cooling

passages and thin walls? Then investment casting may be the best production method! Consideration must also be given to the fact that some processing methods produce or permit improved property levels over other processing methods. For example, investment-cast superalloys are superior in creep rupture strength to wrought superalloys and SCDS investment-cast superalloys are superior to polycrystal investment-cast superalloys.

At this point, alloy families will have been reduced considerably from the total matrix of alloys to one or two alloy types, for example, cobalt-base or nickel-base superalloys that can be investment cast. Design now will hinge on strength (static and/or dynamic-cyclic). A review of strength requirements might show creep rupture capability requirements on the order of 24 hr life at 1850°F/36 ksi (1010°C/248.2 MPa). Cobalt alloys cannot reach those levels so nickel-base superalloys become the choice. Now the selection may hinge on specific alloy chemistry, past experience with an alloy, and investment-casting experience with the alloys from which selection needs to be made. Economics of the basic alloy chemistry, economics of the investment-casting route (polycrystalline, columnar grain, single crystal) to be used, ease of applying surface coatings (if required), minimum alloy properties which are needed, and perhaps other factors need to be considered.

The final selection will need to be verified by actual manufacturing and device testing in simulated or (preferably) actual service. Refurbishment procedures may need to be considered if the article is particularly costly and can have its life extended by suitable and timely refurbishment.

It may be seen that the alloy selection in this instance is not exactly a case of working from "ground zero" to scientifically evaluate the likely candidates. Rather, the selection has depended on real engineering data and judgment and would have involved potential alloy suppliers and manufacturing specialists as soon as possible. A great deal of "alloy selection" that appears in the literature has been done in retrospect, that is after some particular article has been manufactured (e.g., a skateboard), scientific approaches to the evaluation of the actual article show the requirements which were met to produce it. There is nothing in principle wrong with scientific alloy selection. However, the general lack of data (not enough, maybe virtually no, property data), no or limited manufacturing experience, insufficient awareness of the "shop" climate (what furnaces might be available for heat treating the articles and how would the treatment impact the shop schedule), and so on, can cause unacceptable delays or even inability to manufacture an acceptable article.

Assuming that minimum alloy property data will be available, the key to alloy selection is to find knowledgeable engineers in-house and engage them and other knowledgeable persons from the manufacturing pipeline in conversation early on in the selection process.

13.2 Impact of Materials' Data Validity on Selection

There ought to be one basic rule for alloy selection and that is: "Do not believe all you see or hear" (from your fellow employees or from persons purveying new alloys, coatings, or processes). The most common type of statement from alloy/process developers with whom one talks (the "sellers") at the start of new alloy (or process) evaluation is: "This is our average product/property." Translated, this statement should probably be treated by the alloy selectors (the "buyers" in this instance) as meaning: "It's the best we have gotten!" One needs to be skeptical and inquisitive about statements from the seller!

One should be especially wary of selective use of data. There was a situation where an alloy (never used in production) was claimed to have property levels up to 150°F (94°C) better than any other similar alloy then existent. Unfortunately, when a laboratory program was run at a different laboratory (lab 2) than the laboratory (lab 1) of alloy invention, results were troublingly low. On inquiry to the "inventor of the alloy," the question was raised as to how he got such good results. The answer? The inventor only cut out good material to test.

At that point, it was reported to the manager of lab 2 that, with careful work in the laboratory, one might get a "100°F (62.5°C)" improvement over the best existing alloy but never 150°F (94°C). And, it was said that, in a production shop, the best improvement might be no better than 50°F (31°C). The latter projection was proven true when maximum alloy improvement turned out in production to be only 47°F (29.4°C).

Engineers have been known to discard data that are not as good as what they expect (and occasionally get). There need to be valid reasons for excluding data. When much data (properties, results of processing, etc.) get discarded, the discarded data often come back to haunt the user of the alloy/production process. Dig into the database for anything you use in your alloy selection. Assure yourself that there are no hidden items which may appear again in production.

In an instance of mechanical property tests of a new wrought nickel-base superalloy to be used for a gas turbine disk, low creep rupture test results were routinely discarded. The alloy (as a disk) went into production and most of the first production run began to fail the creep rupture acceptance tests in the shop, with test values almost identical to those which had been routinely discarded during alloy development. A modification of heat treatment was necessary to bring the alloy creep rupture life back to the range promised in development and much time and money were spent in the recovery operation.

14 LEVEL OF PROPERTY DATA

Different organizations have different ways to treat property data. Generally minimum and typical properties are desired by design engineers. Minima can vary

in definition (-2σ , -3σ deviations are used). One of the cardinal rules of alloy property development is that enough data will never be generated to truly determine a statistically valid property level over all possible property space. Data cost money! Estimates are made and may often be used in design. If these estimates are conservative and can be justified by alloy data on the alloy of interest and similar alloys, satisfactory designs with the selected alloy usually result.

Not all properties require minimum values. Some property values used for design are typical values. While minima may be used in design, estimates of typical behavior of a component made in order to track its operation may require typical property values.

15 THOUGHTS ON ALLOY SYSTEMS

15.1 General

Melting temperatures for homogenous alloys range near but generally below the melting temperature for the major (base) element. Natural segregation of alloy elements during solidification can lead to even lower melting temperatures. The incipient melting temperatures (lowest melting point of an alloy after solidification can be many tens of degrees less than an alloy's nominal melting temperature. While some homogenization may occur with heat treatment or with wrought processing and heat treatment, it is possible for alloys, particularly cast alloys, to still show incipient melting. This factor needs to be kept in mind during processing and use of a given alloy. Some alloy elements cause significant depression of the melting temperatures of an alloy system while others show relatively little effect. For example, boron, carbon, zirconium, and hafnium depress the melting temperatures of nickel-base superalloys. Since these elements were added primarily to enhance grain boundary strength/ductility in cast versions of many alloys, the introduction of single-crystal nickel-base superalloys enabled most or all of those elements to be removed from the alloy chemistry. The resultant melting temperature increase enabled enhanced heat treatments and optimized strength properties in these alloys.

Another aspect of alloys is the effect of alloy elements on the density of the base metal of an alloy. When much lighter elements than the base metal are introduced, significant density reductions occur. Such additions may or may not be beneficial. For example, early nickel-base superalloys tended to have densities of about 0.3 lb/in.³ (8.3 g/cm³). Some inventors added vanadium, a relatively light metal, to an alloy and reduced the density of the alloy to about 0.28 lb/in.³ (7.75 g/cm³). When first introduced, the vanadium-containing alloy seemed destined to become an excellent turbine blade airfoil performer. However, the introduction of vanadium made the alloy sensitive to hot-corrosion degradation and it was dropped from consideration. Major changes in alloy density for an application may often be achieved but often only by selecting a different base alloy.

Alloy costs today are much more variable than they have been historically. Alloy selection needs to consider the possibility of alloy and processing cost increases during the lifetime of a component design. Alloy costs can be significantly impacted by local conditions in areas of the world where the base-metal ore is found. Dramatic increases in prices have occurred when wars, embargoes, or significant new manufacturing restrictions are imposed. Sometimes such cost increases have led to changes in alloy selection for a component or to chemistry modification to reduce the amount of costly or strategic element used in the alloy. In the mid-1970s, the price of cobalt shot up by a factor of 10 (the price eventually dropped). Cobalt was a principal ingredient in many superalloys used for gas turbines. Corporate managements were appalled by this state of affairs and decreed that cobalt be removed as soon as possible from the manufacturing process. As a result, a particular iron-nickel-base superalloy, IN 718 (alloy with no cobalt), became the world standard for applications which previously employed cobalt-containing alloys. It behooves the alloy selector to consider strategic and economic conditions when recommending an alloy for design.

As mentioned earlier, there are limited numbers of alloy systems available for structural applications. Iron is the most common and least expensive. Aluminum, copper, magnesium, and titanium follow iron in volume of structural alloy application. Nickel and superalloys are widely used as well. Alloys from all of the systems mentioned can be welded, although some alloys or systems may require special attention. High-strength, high-temperature nickel-base superalloys generally are not weldable owing to a tendency to cracking, particularly in the heat-affected zone.

15.2 Iron

Iron alloys consist of cast iron, wrought iron, low-carbon steel, alloy steel, stainless steel, precipitation-hardening steels, and so on. Iron has been around for several millennia. Steel, the name commonly applied to many iron alloys, is the most widely used metallic material. The range of property levels achievable in iron alloys is quite broad and the general availability of iron makes it a relatively inexpensive alloy base for structural design. Steels are hardenable by solid-solution strengthening, grain size hardening, work hardening, precipitation hardening, and transformation hardening (martensite or bainite formation). Very high short-time strengths, up to over 200 ksi (1379 MPa), can be produced in steels. Stainless steels provide significant corrosion protection in many environments. Many steels are forgeable and formable with much steel sheet going into vehicle production. Automobiles can contain nearly 60% of their weight in steel. Steels are ubiquitous, being found in tall buildings, aircraft, cars, trucks, small and large internal combustion engines, hand tools and large machine tools, garden implements,

kitchen utensils, pots, pans, and so on. Iron-base superalloys are used in gas and steam turbines. Much iron wire was used to fence the western United States in the late 1800s and iron boilers, rails, and rail cars were standard on trains. Iron has a density of 0.285 lb/in.³ (7.89 g/cm³) but alloys can range as high as 0.3 lb/in.³ (8.3 g/cm³) or above. Steels have elastic moduli in the range of about 30×10^6 psi (207 GPa). Iron melts at 1220°F (660°C) but steels melt at lower temperatures. Steels can be plated, painted, or coated to enhance corrosion protection. The alloys can be joined with relative ease depending on alloy composition, and economics favors iron alloys as materials of choice in many instances.

Other than for certain stainless grades, steel normally is considered an alloy of iron and carbon plus other elements. Now some modern steels incorporate very important changes, for example, interstitial-free steels where carbon is considered an impurity and vacuum-degassed steels with extra low oxygen content. The application of carbon and alloy steels is related largely to the ability to get the desired mechanical properties ("hardness") where we want it. The selection of steels will need to consider the hardenability (maximum thickness at which one can achieve the desired hardness/strength) of the selected alloy with respect to the requirements for strength in the article being designed. Combinations of alloy content and processing can almost always enable the strength (hardness) to be achieved. There are more steels from which to choose than any other alloy class. Strength in steels is frequently referred to in terms of hardness (e.g., on a Rockwell C scale or some other scale). There are sophisticated tools available to determine the likelihood of success in getting an alloy with the correct hardenability.

The properties of steels are modified not only by chemistry changes but also by heating for various times at various temperatures. This heat treatment of steels is effective because iron has a phase transition as it heats up and the lower (room temperature) body-centered-cubic ferrite phase changes to the face-centered-cubic austenite phase. Of course, carbides continue to exist in steels as appropriate to the temperatures and times at which the steel has been held. On cooling, the steel can change back to the preferred lower temperature structure in many ways (not all ways are possible with all steels). Essentially the austenite, which absorbs a lot of carbon at its high temperature of formation, rejects the carbon and tries to transform back to ferrite. Sometimes the austenite forms a nonequilibrium body-centered-tetragonal phase, martensite. Martensite then exists along with carbides. Sometimes austenite transforms to bainite and carbides and sometimes austenite transforms to pearlite (a special form of ferrite and carbide aggregate). The result of these various possibilities is the ability of steels to possess a range of possible properties. Selection of a particular steel is an

exercise in estimating the strength needs for a particular property and finding one steel from the multitude of available steels that will get the properties where they are wanted, along with any other desired properties such as corrosion resistance, and at the lowest cost.

Plain carbon steels are used for routine and lower temperature applications. For elevated-temperature applications (e.g., tubing/piping in a steam turbine), higher alloy contents are needed and carbon content is only a part of the selection process. Chromium is often added in small amounts to low-alloy steels used at moderate temperatures. With sufficient chromium, scaling of steels can be prevented. When corrosion is meant to be almost entirely prevented, chromium is added above about 12 wt %, sometimes going up above 20 wt % for certain stainless steels.

Stainless steels are intended to promote integrity of the surface while retaining reasonable strength at high temperatures. The chromium oxide film which forms on stainless steels conveys a passivity and provides corrosion resistance to the alloy. Stainless steels not only see high-temperature service but also find much use at lower temperatures in aqueous or other nongaseous environments. To an extent, stainless steels for elevated-temperature service form a continuum with the iron-nickel- and nickel-base superalloys as well as the heat-resistant and nickel-base corrosion-resistant alloys. The so-called precipitation-hardened steels are chromium-containing steels with special additives to bring out precipitates for hardening, much like aluminum alloys or nickel-base superalloys. It is important to note that the stainless nature of stainless steels is promoted by chemically oxidizing environments. Reducing environments, particularly environments containing halogens, can have devastating effects on stainless steels.

15.3 Copper

Copper is a system which also has been around for millennia. The bronze age was the age of tin alloyed with copper to produce strong (by the standards of the day) alloys. The bronze age was followed by the iron age. There are many benefits to copper compared to iron-base alloys and other systems. The copper alloy systems do not compete solely on a strength basis since copper alloys normally are weaker than iron alloys. However, there are areas where copper alloys show sufficient strength and unique other properties (corrosion resistance, nonsparking characteristics when struck, etc.) to compete with steels. A major property of pure or relatively pure copper alloys is their high electrical and thermal conductivity. Specially strengthened copper alloys find use as electrodes and similar current-carrying articles where high temperatures and surface wear resistance are significant. Copper has a moderately high melting point, 1981°F (1083°C); this is less than the melting points of iron alloys but much greater than the melting points of aluminum and magnesium alloys.

Copper is strengthened by solid-solution hardening, grain size hardening, work hardening, and precipitation hardening. Copper is moderately abundant and copper alloys such as the brasses offer reasonable strength with good formability and corrosion resistance. The modulus of copper is 17×10^6 psi (115 GPa); this is less than the modulus of steels and nickel alloys, higher than the modulus of aluminum, and comparable to the moduli of titanium alloys. Most wrought alloys are available in work-hardened conditions and typically find use in moderate to small parts such as springs, fasteners, hardware, gears, and cams. Copper is very formable and forgeable though forming is more apt to be used than forging to manufacture articles of copper alloys. Casting can be used to create copper articles as well. A major use is in conductivity devices (e.g., wire). Copper alloys find wide use in plumbing. Copper, brasses, bronzes, and cupronickels are used for pipes, valves, and fittings in transporting water. The density of copper alloys is around 0.32 lb/in.³ (8.86 g/cm³) for many compositions.

15.4 Aluminum

The aluminum industry is relatively new and got its start in the late 1800s. Aluminum alloys became available in the early part of the twentieth century. Aluminum melts at 1220°F (660°C) and owes its popularity to corrosion-resistant, moderately high strength alloys with a substantially lower density, 0.098 lb/in.³ (2.77 g/cm³), than most other structural alloys. Strong aluminum alloys can be produced for operation up to about several hundred degrees Fahrenheit. Aluminum is strengthened by solid solution and work hardening but the highest strength aluminum alloys are precipitation (age) hardened. Cast aluminum is often used. Aluminum alloys have become synonymous with lightweight articles of acceptable strength when age-hardened aluminum is used. The density is considerably less than the density of steel. Figure 11 shows the effect of density on the specific strength of several alloy systems. Note that, despite the much greater strength of iron and nickel alloys, at room temperature the specific strength of aluminum alloys makes them competitive with iron alloys.

Aluminum is thermodynamically a reactive metal, as is magnesium. However, it has excellent resistance to corrosion in water (including salt water), atmospheric environments, oils, and many chemicals. Aluminum owes its excellent corrosion resistance to the aluminum oxide film that forms naturally but can be enhanced by artificial means. When the excellent corrosion resistance of aluminum alloys in many environments plus the excellent formability/forgeability of aluminum alloys is considered, their high specific strength can make them alloys of choice. In weight-sensitive applications at low to moderate temperatures, aluminum alloys perform very well. The modulus of aluminum alloys is about 10×10^6 psi (69 GPa) and so the alloys are not as stiff as iron, copper, or nickel

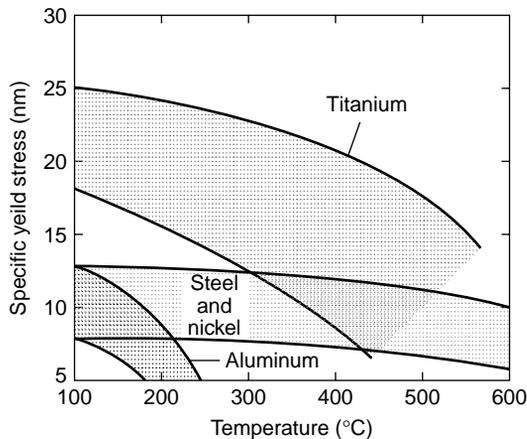

Fig. 11 In certain circumstances lower densities can make somewhat less strong alloys the materials of choice.

alloys. They find use in aircraft structures, however, and aluminum beams have been used in construction. Aluminum is nontoxic and is found as pots/pans, utensils, and beverage cans and in other uses.

Although aluminum alloys generally are corrosion resistant in atmospheric environments, some alloys are corroded in special localized environments. Exfoliation, intergranular corrosion, stress corrosion cracking, and similar problems can exist. Some alloy types within the aluminum alloy family are less corrosion resistant than other aluminum alloys. However, alloy choice, the availability of anodizing and similar finishing processes, plus the process of cladding aluminum alloys with pure aluminum can provide good corrosion resistance for aluminum alloy systems. Alclad aluminum alloys generally are sheet and tube. Because of the nature of artificially formed aluminum oxide coatings on aluminum alloys, the anodized alloys can be colored. In addition to household goods, aluminum siding provides colorful protection for many homes while resisting denting. Aluminum find use as ladders and in many outdoor activities where its intrinsic corrosion-resistant oxide surface skin protects it better than iron alloys. Aluminum alloys are extensively used in aircraft structures.

15.5 Magnesium

Magnesium alloys became available in the early twentieth century. Magnesium alloy applications are fueled by its density of 0.063 lb/in.^3 (1.74 g/cm^3), which is the lowest of any commercially used metal. The melting point of magnesium of 1202°F (650°C) is competitive with that of aluminum. The modulus of magnesium is about $6.5 \times 10^6 \text{ psi}$ (45 GPa), which is considerably less than aluminum or steel. However, owing to its low density, magnesium can have better specific rigidity than the latter alloys. For rectangular steel, aluminum, and magnesium sections of equal

rigidity, calculations show that the magnesium article will weigh only about 71% as much as the aluminum article and 41% as much as the steel article. Magnesium alloys have good strength and very good strength when their density is factored into the selection process. Magnesium alloys generally are forged/formed at elevated temperatures and forgings can be produced in the same general variety of shapes and sizes as forgings of other metals. However, most magnesium articles are produced as castings. Commercial applications have included luggage, ladders, materials handling equipment, as well as aerospace applications.

Magnesium is the most active element in the galvanic series of elements/alloys and so normally should not be coupled with any more cathodic alloy in an application. (Magnesium is used in hot-water tanks to provide cathodic protection.) Under extreme conditions of galvanic corrosion, rapid corrosion results. However, magnesium alloys generally are used with limited corrosion problems. Magnesium rapidly forms an oxide layer when exposed to corrosion conditions such as atmospheric moisture. The oxide is not too protective but neither is alloy section loss excessive. Use of high-purity magnesium reduces problems and anodizing, chromate coatings, and polymeric coatings have been developed to increase magnesium alloy protection from the environment.

15.6 Titanium

Titanium became commercially available at the start of the last half of the twentieth century. Titanium owes its industrial use to two significant factors: It has exceptional room temperature resistance to a variety of corrosive media and a relatively low density of 0.163 lb/in.^3 (4.51 g/cm^3) and can be strengthened to achieve outstanding properties when compared with competitive materials on a strength-to-density basis. Limited numbers of titanium alloys have been invented and marketed, perhaps owing to the greater cost of the product compared to the metal systems covered thus far. Titanium is produced by a batch process and must be further processed by expensive vacuum-melting techniques if its use is desired for aerospace applications.

There are three main classes of titanium alloys, α , $\alpha-\beta$, and β alloys. Property levels and processing capability vary with class of alloy in addition to specific composition. Titanium has a melting point of 3035°F (1668°C). The high melting point of titanium induced inventors to assume that high-strength alloys comparable to those of iron-, nickel-, and cobalt-base alloys would be capable of being produced. Unfortunately, titanium alloys are not able to operate at very high temperatures. Thus, while titanium and its alloys have melting points higher than those of steels, their maximum upper useful temperatures for structural applications generally range from as low as 800°F (427°C) to the region of about $1000-1100^\circ\text{F}$ ($538-595^\circ\text{C}$), depending on composition. Normally the alloys are used well below about

1000°F (538°C). However, titanium alloys are capable of being strengthened to high levels and, combined with their reduced densities relative to iron alloys and excellent corrosion resistance, they were able to replace iron alloys extensively in aircraft gas turbines.

The modulus of titanium is 15.0×10^6 psi (103 GPa). However, titanium undergoes an allotropic transformation on heating and changes from a low-temperature hexagonal-close-packed crystal structure (α) to one that is body-centered cubic (β). On cooling back to lower temperatures, a martensitic reaction can occur or the β can transform to α with varying degrees of fine structure. If a titanium alloy has a β structure at room temperature, the modulus of the alloy will differ from the modulus of an α alloy. The modulus will vary with chemistry and processing. Texturing in rolling processes can further change the effective modulus depending on grain alignment and the amount of β or α present. In addition to the variation of modulus with chemistry and processing, titanium alloy density will vary with the amount and type of alloy elements in a given composition. Many β -forming elements are significantly heavier than titanium while the α -forming element, aluminum, is lighter.

One alloy, Ti-6Al-4V, has been the workhorse of the titanium industry and, for many years, claimed over 50% of the titanium market. This alloy can be used up to the order of 500°F (260°C) to 600°F (316°C). Ti-6Al-4V is an α - β alloy with good all-around properties. Generally α - β alloys are the most used titanium alloys. However, titanium α alloys have better high-temperature properties and β alloys have superior tensile properties and improved fabricability. Titanium alloys have found use in the chemical processing industry, as golf clubs and eyeglass frames, in dental applications, and as structural implants (e.g., hip replacements) in the human body, in addition to their widespread aerospace use. The alloys have greater high-temperature capability than aluminum alloys and are better in specific strengths than iron alloys, facts which ensure their continued use. A large amount of titanium production is used in aerospace applications. Large fan disks in high-bypass-ratio gas turbines and wing spars for aircraft are made of these alloys.

15.7 Nickel

Nickel has been available as an alloy element since the late-nineteenth century. It has exceptional value as an alloy element in steels and other elements as well as being the basis for the high-performance superalloys and heat-resistant alloys used in the aerospace and nuclear industries. Superalloys are covered below. Nickel alloys other than superalloys tend to be more or less relatively pure nickels used in food processing equipment, chemical processing, or some aerospace components. There is another class of nickel alloys which have applications other than those just mentioned—specifically nickel-copper alloys (trade-names begin with Monel), which are characterized by

high strength, good weldability, and excellent corrosion resistance at room temperatures in aqueous conditions. Some of these alloys are age hardened. Monels have applications in pumps, valves, storage tanks, heat exchangers, waveguides, screw machine products, fasteners for nuclear applications, and other uses.

15.8 Superalloys

Superalloys came into early use about 1940, with use motivated in large part by military concerns. Stainless steels and cobalt alloys were modified to provide improved creep rupture capability at higher temperatures such as those found in piston engine superchargers. Concurrently, a few nickel-base superalloys such as Inconel X were created and made available. The terminology “superalloys” did not take hold until the late 1940s when the more widespread use of gas turbine engines prompted a search for improved alloys. Eventually, the addition of more precipitation-creating elements such as aluminum into the basic Nichrome (80 nickel-20 chromium) chemistries plus continued work on modified stainless steels with titanium and other additions led to a class of alloys generally called superalloys. Superalloys are iron-, iron-nickel-, cobalt-, or nickel-based alloys which have exceptional high-temperature strength properties from about 1000°F (538°C) to about 2000°F (1093°C).

Cast nickel-base superalloys have the best strength in creep rupture at high temperatures above about 1300°F (704°C) while wrought iron-nickel and nickel-base superalloys have the best combination of properties below about 1300°F (704°C). Iron-base superalloys have acceptable properties below about 1000°F (538°C) and are the least expensive superalloys. Cobalt-base superalloys are used for long-time, high-temperature, and somewhat lower stress applications. For highest tensile properties, the nickel- or iron-nickel-base alloys stand out. For best forgeability, iron-nickel-base superalloys such as IN718 are outstanding.

Superalloy articles up to 48 in. (122 cm.) in length are cast as blades for gas turbines by the investment casting process, sometimes using SCDS technology. CGDS blades are made as well. Both types are stronger than polycrystalline castings but decidedly more expensive. Large relatively thin walled case castings up to nearly 48 in. (122 cm) in diameter are made of IN718. Gas turbine disks up to nearly 36 in. (~ 1 m) in diameter are forged or powder metallurgy processed and forged from IN718 and nickel-base alloys. Oxidation/corrosion-resistant coatings are used to protect surfaces of the hottest parts (turbine airfoils) from environmental attack. Superalloys are normally melted with various vacuum-melting techniques using induction or other high-technology furnaces. They may have as many as a dozen or more alloy elements controlled in the alloy and are subject (as is titanium) to extensive surveillance during the melting, casting, and forging operations.

Parts as small as thumb size or as large as gas turbine diffuser cases can be cast in superalloys. Investment-casting techniques produce exceptionally high quality alloy articles with maximum property capability. Most alloys are available to potential customers through normal channels. However, certain manufacturers of gas turbine engine hardware have invented proprietary alloys and these most likely would not be available for public purchase in the foreseeable future.

16 SELECTED ALLOY INFORMATION SOURCES

16.1 General

In the selection of alloys for structural applications, selectors may have access to prior related designs from company records or data from public records that may be applicable to the planned design. Consequently, at least a class of alloys and, possibly, a specific alloy or two may be readily apparent as alloy selection starts. However, more information on alloy types, properties, economics, and availability will most certainly be required eventually. It is beyond the scope of this chapter to provide information on all alloy classes, let alone specific compositions which might be used for alloy selection within the alloy classes. However, many organizations, technical and sales, exist to promote specific elements and alloys of such elements as well as to promote processes for the manufacture of specific alloys into useful articles.

The number of organizations available to provide alloys, alloy property data, produce articles, and so on, is very large. The following list of websites is provided as a starting point to help alloy selectors determine possible alloy types, properties, economics, and availability. This list almost certainly will change with time and should only be used as a guide to locate potential information providers. Hopefully the resources at these and similar sites will enable a selector and the designer to come up with an appropriate alloy for a planned design.

It is vital to remember in alloy selection that many alloys are not off-the-shelf consumer items and that properties may vary with material specification for the alloy. Alloys often are made to user specification which may vary from user to user and time to time. While a selector may be able to use common readily available alloys, often he or she may not be able to do so. When working with any specialty alloys, diligence in working with the producers will pay dividends in obtaining optimum properties and reducing difficulties for users of alloys. This concept is more costly than buying off the shelf but invariably leads to best quality and more reliable articles in design.

16.2 Selected Websites for Alloy Selection

The following is only a partial list. More information as to websites, locations, and so on, may be available. Not all companies or institutions active in any given

technology are represented. No recommendation is made or implied by this list.

1 INTRODUCTION

Plastics or polymers are ubiquitous. Through human ingenuity and necessity natural polymers have been modified to improve their utility and synthetic polymers developed. Synthetic polymers in the form of plastics, fibers elastomers, adhesives, and coatings have come on the scene as the result of a continual search for man-made substances that can perform better or can be produced at a lower cost than natural materials such as wood, glass, and metal, which require mining, refining processing, milling, and machining. The use of plastics can also increase productivity by producing finished parts and consolidating parts. For example, an item made of several metal parts that require separate fabrication and assembly can often be consolidated to one or two plastic parts. Such increases in productivity have led to fantastic growth in macromolecules. Indeed, the use of plastics has increased almost 20-fold in the last 30 years. Today there is a tremendous range of polymers and formulated plastics available which offer a wide range of performance. This chapter presents concise information on their synthesis, structure, properties, and applications.

1.1 Classification of Plastics

The availability of plastic materials for use in various applications is huge.¹⁻⁵ There are various ways to categorize or classify plastics that facilitate understanding similarities and difference between materials. The two major classification are thermosetting material and thermoplastics materials.⁵⁻⁷ As the name implies, thermosetting plastics, or thermosets, are set, cured, or hardened into a permanent shape.^{5,6} The curing, which usually occurs rapidly under heat or ultraviolet (UV) light, leads to an irreversible crosslinking of the polymer. Thermoplastics differ from thermosetting materials in that they do not set or cure under heat.⁵ When heated, thermoplastics merely soften to a mobile, flowable state where they can be shaped into useful objects. Upon cooling, thermoplastics harden and hold their shape. Thermoplastics can be repeatedly softened by heat and shaped.

Another major classification of thermoplastics is as amorphous or semicrystalline plastics.^{5,6} Most polymers are either completely amorphous or have an amorphous component as part of a semicrystalline polymer. Amorphous polymers are hard, rigid glasses below a fairly sharply defined temperature, which is known as the glass transition temperature, or T_g . Above the T_g the amorphous polymer becomes soft and flexible and can be shaped. Mechanical properties show profound changes near the glass transition temperature.

Semicrystalline polymers have crystalline melting points T_m that are above their glass transition temperature. The degree of crystallinity and the morphology of the crystalline phase have an important effect on mechanical properties. Crystalline plastics will become

less rigid above their glass transition temperature but will not flow until the temperature is above its T_m .

Many mechanical and physical properties of plastics are related to their structure. In general, at ambient temperatures, amorphous polymers have greater transparency and greater dimensional stability over a wide temperature range. In semicrystalline plastics the ordering and packing of the polymer chains make them denser, stiffer, stronger, and harder. Semicrystalline plastics also have better inherent lubricity and chemical resistance and during molding will tend to shrink more and have a greater tendency to warp.

Another important class of polymeric resins is elastomers. Elastomeric materials are rubberlike polymers with glass transition temperatures below room temperature. Below that glass transition temperature an elastomer will become rigid and lose its rubbery characteristics.

1.2 Chemical/Solvent Resistance

The solvent or chemical resistance of plastics is a measure of the resin's ability to withstand chemical interaction with minimal change in appearance, weight, dimensions, and mechanical properties over a period of time.⁸ When polymers are exposed to chemical environments, they can dissolve in the solvent, absorb the solvent, become plasticized by the solvent, react with the solvent or chemical, or be stress cracked.⁶ Hence mechanical properties can be reduced and dimensions of molded parts changed.

Qualitative comments are made in this chapter about the chemical resistance of various plastics. Generally, these comments are based on laboratory screening that the manufacturers have reported. The stress level of the test part has a very significant influence on the performance of the material. When the stress level increases, resistance to chemicals and solvents decreases. Sources of stress can occur from injection molding, applied loads, forming, and assembly operations.

When an application requires exposure to or immersion in chemicals or other harsh environments, it is of prime importance to use prototypes of suitable stressed material for testing under actual operating conditions.⁸

1.3 Plastics Additives

The wide variety of synthetic polymers offers a huge range of performance attributes.⁹⁻¹³ Additives play a key role in optimizing the performance of polymers and transforms them into commercially viable products. Additives are materials that are added to a polymer to produce a desired change in material properties or characteristics. A wide variety of additives are currently used in thermoplastics to enhance material properties, expand processability, modify aesthetics, and/or increase environmental resistance. Enhancement of properties include thermal stability, flame retardancy, impact resistance, and UV light stability. Reinforcing fiber (i.e., high-strength, inert fibrous material such

as glass and carbon fibers can be incorporated in the polymer matrix to improve modulus and strength while lowering the coefficient of thermal expansion and unusually lowering impact and increasing density. Particulates of flake fillers usually increase stiffness as well as lower costs.¹³ Plasticizers lower modulus and enhance flexibility. Thus additives are found in most commercial plastics and are an essential part of the formulation in which performance is tailored for specific applications.⁹⁻¹³

This chapter focuses on properties of the base resins with very few additives other than stabilizers. Properties for plastics that contain glass fiber (GF) are listed for those plastics that routinely use such reinforcing fibers.

1.4 Properties

Plastic materials can encounter mechanical stress, impact, flexure, elevated temperatures, different environments, and the like. Hence various properties are measured and reported to give an indication of a material's ability to perform under various conditions. Properties are determined on standard test parts and are useful for comparative purposes. A description of properties used in the chapter would be instructive and are listed below.

Density: The mass per unit volume of a material at 73°F (23°C).

Tensile Modulus: An indicator of the stiffness of a part. It is basically the applied tensile stress, based on the force and cross-sectional area, divided by the observed strain at that stress level.

Tensile Strength: The amount of force required to elongate the plastic by a definite amount. Higher values mean the material is stronger.

Elongation at Break: The increase in length of a specimen under tension before it breaks under controlled test conditions. Usually expressed as a percentage of the original length. Also called "strain."

Flexural Modulus: The ratio of applied stress to the deflection caused in a bending test. It is a measure of the stiffness of a material during the first part of the bending process.

Flexural Strength: The maximum stress that can be applied to a beam in pure bending before permanent deformation occurs.

Izod Impact Strength: The amount of impact energy required to cause a test specimen to break completely. The specimen may be notched or unnotched.

Heat Deflection Temperature (HDT, also called deflection temperature under load, or DTUL): Gives an indication of a material's ability to perform at higher temperatures while supporting a load. It shows the temperature at which a test specimen will deflect a given distance under a given load in flexure under specific test conditions, usually at 1.82 and/or 0.42-MPa loads.

Vicat Softening Temperature: A measure of the temperature at which a plastic starts to soften at specific test conditions according to International Organization for Standardization (ISO) 306. It gives an indication of a material's ability to withstand limited short-term contact with a heated object.

Relative Thermal Index (RTI, formerly called continuous-use temperature): The continuous operating temperature of plastics materials used in electrical applications, as specified by Underwriter's Laboratories (UL). It is the maximum temperature at which the material retains at least 50% of the original value of all properties tested after the specific amount of time. The RTI tests are important if the final product is to receive UL recognition.

UL94 VO: Classification of flammability of plastic materials that follows the UL 94 standard, vertical burning test. The VO rating is where the total burn time for the five specimens after two 10-sec applications of flame is ≤ 50 sec. Sample thicknesses on VO-rated test specimens are reported. A rating on thin samples would suggest possible utility in applications requiring thin walls.

Oxygen Index: A flammability test that determines the minimum volumetric concentration of oxygen that is necessary to maintain combustion of a specimen after it has been ignited.

Hardness: The resistance of a material to indentation under standardized conditions. A hard indenter or standard shape is pressed into the surface of the material under a specific load. The resulting area of indentation or the depth of indentation is measured and assigned a numerical value. For plastics, the most widely used methods are Rockwell and Shore methods and Ball hardness.

Coefficient of Thermal Expansion (CTE): A measure of how much a material will lengthen (or shorten upon cooling) based on its original length and the temperature difference to which it is exposed. It becomes important when part dimensions are critical or when two different materials with different CTEs are attached to each other.

Shrinkage: The percentage of reduction in overall part dimensions during injection molding. The shrinkage occurs during the cooling phase of the process.

Water Absorption/Moisture Absorption: The percentage weight gain of a material after immersion in water for a specific time at a specific temperature. Low values are preferred and are important in applications requiring good dimensional stability. As water is absorbed, dimensions of the part tend to increase and physical properties can deteriorate. In addition, low water absorption is very important for most electrical properties.

Relative Permittivity (formerly called dielectric constant): A measure of the amount of electrical energy stored in a material. It is equal to the capacitance of a material divided by the capacitance of a dimensionally equivalent vacuum. Important

for high-frequency or power applications in order to minimize power losses. Low values indicate a good insulator. Moisture, frequency, and temperature increases may have adverse effects.

Dissipation Factor (also called “loss tangent”): A measure of the dielectric characteristics of a plastic resin. Moisture, frequency, and temperature increases may have adverse effects.

2 POLYOLEFINIC THERMOPLASTICS

2.1 Polyethylene

Polyethylene (PE) plastics are lightweight, semicrystalline thermoplastics that are prepared by the catalytic polymerization of ethylene.^{14–16} Depending on the temperature, pressure, catalyst, and use of a comonomer, three basic types of polyethylene can be produced: high-density polyethylene (HDPE), low-density polyethylene (LDPE), and linear low-density polyethylene (LLDPE). LDPE and LLDPE contain branching. This branching results in decreased crystallinity and lower density. Most properties of PEs are a function of their density and molecular weight. As density decreases, the strength, modulus, and hardness decrease and flexibility impact, and clarity increase. Hence HDPE exhibits greater stiffness, rigidity, improved heat resistance, and increased resistance to permeability than LDPE and LLDPE.

LDPE is prepared under more vigorous conditions, which results in short-chain branching. The amount of branching and the density can be controlled by the polymerization conditions.

LLDPE is prepared by using an α -olefin comonomer during polymerization. Hence branching is introduced in a controlled manner and where the chain length of the branching is uniform. In general, the comonomers are 1-butene, 1-hexene, 1-octene, and 4-methyl-1-pentene (4M1P).

Polyethylene polymers are versatile and inexpensive resins that have become the largest volume use of any plastics. They exhibit toughness, near-zero moisture absorption, excellent chemical resistance, excellent electrical insulating properties, low coefficient of friction, and ease of processing. They are not high-performance resins. Their heat deflection temperatures are reasonable but not high. Specialty grades of PE include very low density (VLDPE), medium-density (MDPE), and ultrahigh-molecular-weight PE (UHMWPE).

Some typical properties of HDPE and LDPE are listed in Table 1. Properties of the various copolymers of LLDPE appear in Table 2.

Uses HDPE’s major use is in blow-molded containers (milk, water, antifreeze, household chemical bottles), shipping drums, carboys, automotive gasoline tanks; injection-molded material-handling pallets, crates, totes, trash and garbage containers, and household and automotive parts; and extruded pipe products (corrugated, irrigation, sewer/industrial, and gas distribution pipes).

LDPE/LLDPEs find major applications in film form for food packaging as a vapor barrier film including stretch and shrink wrap; for plastic bags such as

Table 1 Typical Properties of HDPE, LDPE, LLDPE, and UHMWPE

Property	HDPE	LDPE	LLDPE	UHMWPE
Density (g/cm ³)	0.94–0.97	0.915–0.935	0.91–0.92	0.93

grocery, laundry, and dry cleaning bags; for extruded wire and cable insulation; and for bottles, closures, and toys.

2.2 Polypropylene

Polypropylene (PP) is a versatile semicrystalline thermoplastic offering a useful balance of properties that are typically higher than for HDPE. It is prepared by the catalyzed polymerization of propylene.^{17,18} Crystallinity is key to the properties of PP. The degree of crystallinity is a function of the degree of geometric orientation (stereoregularity) of the methyl groups on the polymer chain (backbone). There are three possible geometric forms of PP. Isotactic PP has predominantly all the methyl groups aligned on the same side of the chain (above or below the chain). In syndiotactic PP the methyl groups alternate above and below the polymer chain. Finally, atactic PP has the methyl groups randomly positioned along the chain. Both isotactic and syndiotactic PP will crystallize when cooled from the molten states; however, commercial PP resins are generally isotactic.

Isotactic PP is highly crystalline thermoplastic that exhibits low density; rigidity; good chemical resistance to hydrocarbons, alcohols, and oxidizing agents; negligible water absorption; excellent electrical properties; and excellent impact/stiffness balance. PP has the highest flexural modulus of the commercially available polyolefins. In general, PP has poor impact resistance. However, PP-elastomer blends have improved impact strength. Unfilled PP has poor flame resistance and is degraded by sunlight. Flame-retardant and UV-stabilized grades are available. Typical properties appear in Table 3.

Uses End uses for PP are in blow-molding bottles and automotive parts, injection-molded closures, appliances (washer agitators, dishwasher components), house wares, automotive parts, luggage, syringes, storage battery cases, and toys. PP can be extruded into fiber and filament for use in carpets, rugs, and

cordage. In addition, PP can be extruded into film for packaging applications.

2.3 Polymethylpentane

Polymethylpentane (PMP) is prepared by the catalytic polymerization of 4-methyl-1-pentene.¹⁴ PMP is a semicrystalline thermoplastic that exhibits transparency (light transmission up to 90%), very low density, chemical resistance, negligible water absorption, and good electrical properties. PMP resins are available as homopolymers and copolymers with higher α -olefins. The homopolymer is more rigid and the copolymers have increased ductility. PMP is degraded by sunlight and high-energy radiation. Moreover, strong oxidizing acids attack it. PMP grades are available with increased radiation resistance as well as with reinforcing fillers. Properties appear in Table 4.

Uses Applications for PMP resins cover a wide spectrum of end uses. These include medical (hypodermic syringes, disposable cuvettes, blood-handling equipment, respiration equipment, laboratory ware), packaging (microwave and hot-air-oven cookware, service trays, coated paper plates), and miscellaneous (transparent ink cartridges for printers, light covers, sight glasses, lenses, liquid level and flow indicators, fluid reservoirs).

3 SIDE-CHAIN-SUBSTITUTED VINYL THERMOPLASTICS

3.1 Polystyrene

The catalytic or thermal polymerization of styrene yields general-purpose or crystal polystyrene (PS).^{19,20} The designation of "crystal" refers to its high clarity. PS is an amorphous polymer (atactic geometric configuration) and exhibits high stiffness, good dimensional stability, moderately high heat deflection temperature, and excellent electrical insulating properties. However, it is brittle under impact and exhibits very poor resistance to surfactants and a wide range of solvents.

The three main categories of commercial PS resins are crystal PS, impact PS, and expanded PS foam.

Copolymerization of styrene with a rubber, polybutadiene, results in the rubber being grafted onto the PS. This impact-modified PS has increased impact strength, which is accompanied by a decrease in rigidity and heat deflection temperature. Depending on the levels of rubber, impact polystyrene (IPS) or high-impact polystyrene (HIPS) can be prepared. These materials are translucent to opaque and generally exhibit poor weathering characteristics.

PS find wide use in styrofoam. Typically, styrofoam is produced from expandable styrene (EPS) beads, which contain a blowing agent. When heated, the blowing agent vaporizes and expands the PS and forms a low-density foam. The density of the foam is controlled by the amount of blowing agent.

Typical properties for PS, IPS, and HIPS appear in Table 5.

Uses Ease of processing, rigidity, clarity, and low cost combine to support applications in toys, displays, consumer goods (television housings), medical (labware, tissue culture flasks) and housewares such as food packaging, audio/video consumer electronics, office equipment, and medical devices.

EPS can readily be prepared and is characterized by excellent low thermal conductivity, high strength-to-weight ratio, low water absorption, and excellent energy absorption. These attributes have made EPS of special interest as insulation boards for construction (structural foam sections for insulating walls), protective packaging materials (foamed containers for meat and produce), insulated drinking cups and plates, and flotation devices.

3.2 Syndiotactic Polystyrene

Syndiotactic polystyrene (SPS) is a semicrystalline polymer and is produced via metallocene-catalyzed polymerization of styrene.²¹ By comparison

to general-purpose, amorphous polystyrene (PS, HIPS), SPS has stereoregularity in its structure, which facilitates crystallization. In SPS the phenyl groups alternate above and below the polymer chain. Hence SPS has a high crystalline melt point and good chemical resistance.

The slow rate of crystallization and high T_g of SPS typically require an oil-heated tool when injection molding and longer cycle times to maximize physical properties. Typical properties appear in Table 6.

Uses SPS is targeted at automotive under-the-hood and specialty electronic applications. It will compete with polyamides, thermoplastic polyesters, and polyphenylene sulfid (PPS).

3.3 Styrene/Acrylonitrile Copolymer

Copolymerization of styrene with a moderate amount of acrylonitrile (AN) provides a clear, amorphous polymer (SAN).²⁰ The addition of the polar AN group gives increased heat deflection temperature and chemical resistance compared to PS. Other benefits of SAN are stiffness, strength, and clarity. Like PS the impact resistance is still poor. SAN is chemically resistant to hydrocarbons, bases, most detergents, and battery acid. However, SAN has poor resistance to chlorinated and aromatic solvents, esters, ketones, and aldehydes. The composition and molecular weight can be varied to change properties. An increase in AN will increase SAN's physical properties but will make melt processing more difficult and will decrease the transparency. In general, the AN level in SAN does not exceed 30% for molding applications. Typical properties appear in Table 7.

Uses SAN is utilized in typical PS-type applications where a slight increase in heat deflection temperature and/or chemical resistance is needed. Such applications include appliances (refrigerator compartments, knobs, blender and mixer bowls), electronics (cassette cases, tape windows, meter lenses), packaging (bottle jars, cosmetic containers, closures), medical (syringe

components, dialyzer housings), and other (glazing, battery cases, pen barrels).

3.4 Acrylonitrile/Butadiene/Styrene Polymers

ABS is a generic name for a family of amorphous ter polymer prepared from the combination of acrylonitrile, butadiene, and styrene monomers.²² Acrylonitrile (A) provides chemical resistance, hardness, rigidity, and fatigue resistance and increases the heat deflection temperature. Butadiene (B) provides toughness and low-temperature ductility but lowers the heat resistance and rigidity. Styrene (S) provides rigidity, hardness, gloss, aesthetics, and processing ease. This three-monomer system offers a lot of flexibility in tailoring ABS resins. Optimization of these monomers can enhance a desired performance profile. Because of the possible variations in composition, properties can vary over a wide range.

Typical resin grades in this product family consist of a blend of an elastomeric component and an amorphous thermoplastic component. Typically the elastomeric component is the polybutadiene-based copolymer (ABS with high B). The amorphous thermoplastic component is SAN.

ABS plastics offer a good balance of properties centering on toughness, hardness, high gloss, dimensional stability, and rigidity. Compared to PS, ABS offers good impact strength, improved chemical resistance, and similar heat deflection temperature. ABS is also opaque. ABS has good chemical resistance to acids and bases but poor resistance to aromatic compounds, chlorinated solvents, esters, ketones, and aldehydes. ABS has poor resistance to UV light. Typical properties are shown in Table 8.

Table 8 Typical Properties of ABS Resins

Property	General Purpose	High Heat	High Impact
Density (g/cm ³)	1.05	1.05	1.04

CTE (10 ⁻¹⁵ /°C)	8.82	7.92	9.45
Shrinkage (in./in.)	0.006	0.006	0.006

Uses ABS materials are suitable for tough consumer products (refrigerator door liners, luggage, telephones, business machine housings, power tools, small appliances, toys, sporting goods, personal care devices), automotive (consoles, door panels, various interior trim, exterior grills and lift gates), medical (clamps, stopcocks, blood dialyzers, check valves), and building and construction (pipes, fittings, faucets, conduit, shower heads, bathtubs).

3.5 Acrylonitrile/Styrene/Acrylate Polymers

Acrylonitrile/styrene/acrylate (ASA) ter polymers are amorphous thermoplastics and are similar to ABS resins. However, the butadiene rubber has been replaced by an acrylate-based elastomer, which has excellent resistance to sunlight. Hence ASA offers exceptional durability in weather-related environments without painting. In outdoor applications, ASA resins retain color stability under long-term exposure to UV, moisture, heat, cold, and impact. In addition, ASA polymers offer high gloss and mechanical properties similar to those of ABS resins. ASA has good chemical resistance to oils, greases, and salt solutions. However, resistance to aromatic and chlorinated hydrocarbons, ketones, and esters is poor.

ASA resins exhibit good compatibility with other polymers. This facilitates its use in polymer blends and alloys and as a cost-effective, cap-stock (overlayer) to protect PS, polyvinyl chloride (PVC), or ABS in outdoor applications.

Various grades are available for injection molding, profile and sheet extrusion, thermoforming, and blow molding. Typical properties appear in Table 9.

Uses ASA resins have applications in automotive/transportation (body moldings, bumper parts, side-view mirror housings, truck trailer doors, roof luggage containers), building/construction (window lineals, door profiles, downspouts, gutters, house

siding, windows, mail boxes, shutters, fencing, wall fixtures) sporting goods (snowmobile and all-terrain vehicle housings, small water craft, camper tops, windsurfer boards), and consumer items (garden hose fittings and reels, lawnmower components, outdoor furniture, telephone handsets, covers for outdoor lighting, spa and swimming pool steps and pumps, housings for garden tractors).

3.6 Poly(methyl methacrylate)

The catalytic or thermal polymerization of methyl methacrylate yields poly(methyl methacrylate) (PMMA). It is often referred to as acrylic. PMMA is a strong, rigid, clear, amorphous polymer. The optical clarity, rigidity, colorability, and ability to resist sunlight and other environmental stresses make PMMA ideal for glass replacement.

In addition, PMMA has low water absorption and good electrical properties.

Acrylics have fair chemical resistance to many chemicals. However, resistance to aromatic and chlorinated hydrocarbons, ketones, and esters is poor. PMMA properties appear in Table 10.

Uses PMMA is used in construction (glazing, lighting diffusers, domed skylights, enclosures for swimming pools and buildings), automotive (exterior lighting lenses in cars and trucks, nameplate, medallions, lenses on instrument panels), household (laboratory, vanity and counter tops, tubs), medical (filters blood pumps), and others (appliances, aviation canopies and window, outdoor signs, display cabinets).

3.7 Styrene/Maleic Anhydride Copolymer

Styrene/maleic anhydride (SMA) resins are copolymers of styrene and maleic anhydride (MA) and offer

Table 10 Typical Properties of PMMA, SMMA, and SMA Resins

Relative permittivity at 1 kHz	3.3	—	—

increased heat deflection temperatures, strength, solvent resistance, and density compared to PS.²⁰ SMA resins are usually produced via catalyzed bulk polymerization. There is a strong tendency to form the 1 : 1 styrene-MA copolymer. Random SMA resins containing 5–12% MA are produced via starve feeding, i.e., keeping the MA concentration low during the polymerization. SMA resins are brittle and have poor UV resistance. Impact-modified grades and terpolymers (grafting rubber into polymer during polymerization) are available. Typical properties for SMA prepared with 9% MA appear in Table 10.

Uses SMA copolymers have been used in automotive (instrument panels, headliners) food service items, plumbing, and electrical applications.

3.8 Styrene/Methyl Methacrylate Copolymer

Styrene/methyl methacrylate (SMMA) copolymers are prepared by the catalyzed polymerization of styrene and methyl methacrylate (MMA). The advantages of SMMA over PS include improved outdoor weathering and light stability, better clarity, increased chemical resistance, and improved toughness. Properties for SMMA prepared with 30% MMA appear in Table 10.

Uses Applications for SMMA plastics are in small appliances and kitchen and bathroom accessories.

3.9 Polyvinyl Chloride

The catalytic polymerization of vinyl chloride yields polyvinyl chloride (PVC).²³ It is commonly referred to as PVC or vinyl and is second only to PE in volume use. Normally, PVC has a low degree of crystallinity and good transparency. The high chlorine content of the polymer produces advantages in flame resistance, fair heat deflection temperature, and good electrical properties. The chlorine also makes PVC difficult to process. The chlorine atoms have a tendency to split out under the influence of heat during processing and heat and light during end use in finished products, producing discoloration and embrittlement. Therefore, special stabilizer systems are often used with PVC to retard degradation.

PVC has good chemical resistance to alcohols, mild acids and bases, and salts. However, PVC is attacked by halogenated solvents, ketones, esters, aldehydes, ethers, and phenols.

There are two major classification of PVC: rigid and flexible (plasticized). In addition, there are also foamed PVC and PVC copolymers. Typical properties of PVC resins appear in Table 11.

Rigid PVC PVC alone is a fairly rigid polymer, but it is difficult to process and has low impact strength. Both of these properties are improved by the addition of elastomers or impact-modified graft copolymers, such as ABS and ASA resins. These improve the melt flow during processing and improve the impact strength without seriously lowering the rigidity or the heat deflection temperature.

Uses With this improved balance of properties, rigid PVCs are used in such applications as construction (door and window frames, water supply, pipe, fittings, conduit, building panels and siding, rainwater gutters and downspouts, interior molding and flooring) packaging (bottles, food containers, films for food wrap), consumer goods (credit cards, furniture parts), and other (agricultural irrigation and chemical processing piping).

Plasticized PVC The rigid PVC is softened by the addition of compatible, nonvolatile, liquid plasticizers. The plasticizers are usually used in > 20 parts per hundred resins. It lowers the crystallinity in PVC and acts as internal lubricant to give clear, flexible plastics. Plasticized PVC is also available in liquid formulations known as plastisols or organosols.

Uses Plasticized PVC is used for construction (wire and cable insulation, interior wall covering), consumer goods (outdoor apparel, rainwear, upholstery, garden hose, toys, shoes, tablecloths, sporting goods, shower curtains), medical (clear tubing, blood and solution bags, connectors), and automotive (seat covers). Plastisols are used in coating fabric, paper, and metal and rotationally cast into balls, dolls, and the like.

Foamed PVC Rigid PVC can be foamed to a low-density cellular material that is used for decorative moldings and trim. Foamed PVC is also available via foamed plastisols. Foamed PVC adds greatly to the softness and energy absorption characteristics already inherent in plasticized PVC. In addition, it gives rich, warm, leatherlike material.

Table 11 Typical Properties of PVC Materials

Property	General Purpose	Rigid	Rigid Foam	Plasticized	Copolymer
Density (g/cm ³)	1.40	1.34–1.39	0.75	1.29–1.34	1.37

Dissipation factor at 1 kHz	0.081	—	—	—	—

Uses Upholstery, clothing, shoe fabrics, handbags, luggage, and auto door panels and energy absorption for quiet and comfort in flooring carpet backing, auto headliners, and so forth.

PVC Copolymers Copolymerization of vinyl chloride with 10–15% vinyl acetate gives a vinyl polymer with improved flexibility and less crystallinity than PVC, making such copolymers easier to process without detracting seriously from the rigidity and heat deflection temperature. These copolymers find primary applications in flooring and solution coatings.

3.10 Poly(vinylidene chloride)

Poly(vinylidene chloride) (PVDC) is prepared by the catalytic polymerization of 1,1-dichloroethylene. This crystalline polymer exhibits high strength, abrasion resistance, high melting point, better than ordinary heat resistance (100°C maximum service temperature), and outstanding impermeability to oil, grease, water vapor, oxygen, and carbon dioxide. It is used in films, coatings, and monofilaments.

When the polymer is extruded into film, quenched, and oriented, the crystallinity is fine enough to produce high clarity and flexibility. These properties contribute to widespread use in packaging film, especially for food products that require impermeable barrier protection.

PVDC and/or copolymers with vinyl chloride, alkyl acrylate, or acrylonitrile are used in coating paper, paperboard, or other film to provide more economical, impermeable materials. Properties appear in Table 12.

Uses PVDC is used in food packaging where barrier properties are needed. Applications for injection-molding grades are fitting and parts in the chemical industry. PVDC pipe is used in the disposal of waste acids. PVDC is extruded into monofilament and tape that is used in outdoor furniture upholstery.

4 POLYURETHANE AND CELLULOSIC RESINS

4.1 Polyurethanes

Polyurethanes (PUs) are prepared from polyols and isocyanates.^{24,25} The isocyanate groups react with the hydroxyl groups on the polyol to form a urethane bond. The polyol can be a low-molecular-weight polyether or polyester. The isocyanate can be aliphatic or aromatic and in the preparation of linear PU is typically difunctional. However, isocyanates with greater functionality are used in preparing rigid foam PUs. The family of PU resins is very complex because of the enormous variation in the compositional features of the polyols and isocyanates. This variety results in a large number of polymer structures and performance profiles. Indeed, PUs can be rigid solids or soft and elastomeric or have a foam (cellular) structure.

The majority of PU resins are thermoset (PUR). However, there are also important thermoplastic polyurethane resins (TPU). Polyurethanes offer high impact strength, even at low temperatures, good abrasion resistance, excellent heat resistance, excellent resistance to nonpolar solvents, fuels, and oils, and resistance to ozone, oxidation, and humidity.

TPUs are generally processed by injection-molding techniques. PURs are processed by reaction injection molding (RIM) and various foaming techniques. A major use of PUR is in the production of flexible, semirigid, and rigid foams. In addition, PUs can be used as fibers, sealants, adhesives, and coatings.

Typical properties of PUs appear in Table 13.

Uses Typical applications for PUs are in consumer goods (furniture padding, bedding, skateboard and roller blade wheels, shoe soles, athletic shoes,

ski booths, backing on carpets and tiles), automotive (padding, seals, fascias, bumpers, structural door panels), and miscellaneous (tubing, membranes, bearings, nuts, seals, gaskets).

4.2 Cellulosic Polymers

Cellulose-based plastics are manufactured by the chemical modification of cellulose.^{26–29} Cellulose does not melt and hence is not a thermoplastic material. However, esterification of cellulose gives organic esters of cellulose, which are thermoplastic. These include cellulose acetate (CA), cellulose acetate butyrate (CAB), and cellulose propionate (CP). Cellulosics are noted for their wide range of properties, which include clarity (up to 80% light transmission), abrasion resistance, stress crack resistance, high gloss, and good electrical properties. CA offers good rigidity and hardness. CAB and CP offer good weatherability, low-temperature impact strength, and dimensional stability.

In general, cellulosic esters are resistant to aliphatic hydrocarbons, ethylene glycol, bleach, and various oils. However, alkaline materials attack them. Cellulosic esters have high water absorption and low continuous-use temperatures. Typical properties appear in Table 14.

Uses Typical applications for cellulosic plastics are automotive (steering wheels, trim), film (photographic, audio tape, pressure-sensitive tape), home furnishings (table edging, Venetian blind wands), packaging (tubular containers, thermoformed containers for nuts, bolts, etc.), and miscellaneous (tool and brush handles, toys, flaments for toothbrushes, eye glass frames, lighting fixtures).

5 ENGINEERING THERMOPLASTICS: CONDENSATION POLYMERS

Engineering thermoplastics comprise a special-performance segment of synthetic plastics that offer

enhanced properties.^{2,3} When properly formulated, they may be shaped into mechanically functional, semiprecision parts or structural components. Mechanically functional implies that the parts may be subjected to mechanical stress, impact, flexure, vibration, sliding friction, temperature extremes, hostile environments, and the like, and continue to function.

As substitutes for metal in the construction of mechanical apparatus, engineering plastics offer advantages such as transparency, light weight, self-lubrication, and economy in fabrication and decorating. Replacement of metals by plastic is favored as the physical properties and operating temperature ranges of plastics improve and the cost of metals and their fabrication increases.

5.1 Thermoplastic Polyesters

Thermoplastic polyesters are prepared from the condensation polymerization of a diol and typically a dicarboxylic acid. Usually the dicarboxylic acid is aromatic, that is, terephthalic acid. As a family of polymers thermoplastic polyesters are typically semicrystalline and hence have good chemical resistance. An important attribute of a semicrystalline polymer is a fast rate of crystallization, which facilitates short injection-molding cycles.

Poly(butylene terephthalate) Poly(butylene terephthalate) (PBT) is prepared from butanediol with dimethyl terephthalate.^{29–31} PBT is a semicrystalline polymer that has a fast rate of crystallization and rapid molding cycles. PBT has a unique and favorable balance of properties between polyamides and polyacetals. PBT combines high mechanical, thermal, and electrical properties with low moisture absorption, extremely good self-lubricity, fatigue resistance, very good chemical resistance, very good dimensional stability, and good maintenance of properties at elevated temperatures. Dimensional stability and electrical properties are unaffected by high-humidity conditions.

PBT has good chemical resistance to water, ketones, alcohols, glycols, ethers, and aliphatic and chlorinated hydrocarbons at ambient temperatures. In addition, PBT has good resistance to gasoline, transmission fluid brake fluid greases, and motor oil. At ambient temperatures PBT has good resistance to dilute acids and bases, detergents, and most aqueous salt solutions. It is not recommended for use in strong bases or aqueous media at temperatures above 50°C.

PBT grades range from unmodified to glass-fiber reinforced to combinations of glass fiber and mineral filler that enhance strength, modulus, and heat deflection temperature. Both filled and unfilled grades of PBT offer a range of UL and other agency compliance ratings.

A high-density PBT combines the inherent characteristics of PBT with the advantages of high levels of mineral reinforcement. This combination provides

a balance of mechanical, thermal, and electrical properties, broad chemical and stain resistance, low water absorption, and dimensional stability. In addition, the smooth, satin finish and heavy weight offer the appearance and quality feel of ceramics while providing design flexibility injection-molding processing advantages, and recycling opportunities which are common in engineering thermoplastics. Properties appear in Table 15.

Uses Applications of PBT include automotive components (brake system parts, fuel injection modules, grill-opening panels), electrical/electronic components (connectors, smart network interface devices, power plugs, electrical components, switches, relays, fuse cases, light sockets, television tuners, fiber-optic tubes), medical (check valves, catheter housings, syringes), consumer goods (hair dryer and power tool housings, iron and toaster housings, food processor blades, cooker-fryer handles), and miscellaneous (gears, rollers, bearing, housings for pumps, impellers, pulleys, industrial zippers). High-density PBT is being used in kitchen and bath sinks, countertops, wall tiles, shower heads, speaker housings, medical equipment, and consumer goods.

PBT/PC Alloy PBT/PC resins are thermoplastic alloys of PBT and polycarbonate (PC). The amorphous PC provides impact resistance and toughness while the PBT provides enhanced chemical resistance and thermal stability. Impact modification completes the balanced performance profile by providing both low- and high-temperature durability. Hence high levels of impact strength are achieved at low temperatures, below -40°C.

PBT/PC resins offer a balance of performance characteristics unique among engineering thermoplastics with their optimal combination of toughness, chemical resistance, dimensional stability, lubricity, and

high heat distortion temperature. In addition, this family of resins offers very good aesthetics, lubricity, UV resistance, and color retention. Originally developed for the automotive industry, PBT/PC resins are designed to provide resistance to various automotive fluids—gasoline, greases, oils, and the like. In general, the higher the amount of PBT in the resin blend, the higher the resin's chemical resistance. Hence resistance to gasoline may vary from grade to grade. PBT/PC resins generally are not very hydrolytically stable. Properties appear in Table 16.

Uses Applications for PBT/PC resins include automotive bumpers/fascia, tractor hoods and panels, components on outdoor recreational vehicles, lawn mower decks, power tool housings, material-handling pallets, and large structural parts.

Poly(ethylene terephthalate) Poly (ethylene terephthalate) (PET) is prepared from the condensation polymerization of dimethyl terephthalate or terephthalic acid with ethylene glycol.^{29–31} PET is a semicrystalline polymer that exhibits high modulus, high strength, high melting point, good electrical properties, and moisture and solvent resistance. The crystallization rate of PET is relatively slow. This slow crystallization is a benefit in blow-molding bottles where clarity is important. Indeed, a small amount of a comonomer is typically added during polymerization of PET. The function of the comonomer is to disrupt the crystallinity and lower the rate of crystallization. However, in injection-molding applications the slow rate of crystallization will increase the molding cycle time.

For most injection-molding applications PET generally contains glass fiber or mineral filler to enhance properties. Typical properties appear in Table 17.

Uses Primary applications of PET include blow-molded beverage bottles; fiber for wash-and-wear, wrinkle-resistant fabrics; and film that are used in food packaging, electrical applications (e.g., capacitors), magnetic recording tape, and graphic arts. Injection-molding application of PET include automotive (cowl vent grills, wiper blade supports) and electrical (computer fan blades, fuse holders and connectors).

Poly(trimethylene terephthalate) Poly(trimethylene terephthalate) (PTT) is prepared from 1,3-propanediol and terephthalic acid. PTT is a semicrystalline polymer that exhibits properties between PET and PBT. In particular, it offers high modulus, high strength, good electrical properties, and moisture and solvent resistance. Its crystallization rate is slower than PBT but faster than PET.³² Properties appear in Table 18.

Uses Initial applications for PTT were in carpet fiber where it offers a softer feel in combination with stain resistance and resiliency. Other fiber markets include textiles and monofilaments. Injection-molding applications would be various automotive parts.

5.2 Polyamides (Nylon)

Polyamides, commonly called nylons, are produced by the condensation polymerization of dicarboxylic acids and diamines or the catalytic polymerization of a lactam monomer (a cyclic amide).^{33,34} In general, polyamides are semicrystalline thermoplastics. Polyamides are a class of resins characterized by broad chemical resistance, high strength, and toughness. In addition, polyamides absorb high levels of water. Moisture from the atmosphere diffuses into the polymer and hydrogen bonds to the amide groups. This absorbed water causes dimensional changes where the molded part will increase in size and weight. The higher the amount of amide groups in the polymer, the greater the moisture uptake. In addition, the water acts as a plasticizer and lowers the rigidity and strength. Polar solvents such as alcohols are also absorbed into the nylon.

There are numerous dicarboxylic acids and diamines that can be used to make polyamides. The shorthand method for describing the various types of polyamides uses a number to designate the number of carbon atoms in each starting monomer(s). In the case of terephthalic and isophthalic acids T and I are used, respectively.

Polyamide 6/6 and 6 The two major types of polyamides are polyamide 6/6, or nylon 6/6 (PA6/6), and polyamide 6, or nylon 6 (PA6).^{33,34} PA6/6 is made from a six-carbon dicarboxylic acid and a six-carbon diamine—that is, adipic acid and hexamethylene diamine. PA6 is prepared from caprolactam. Both PA6/6 and PA6 are semicrystalline resins.

Key features of nylons include toughness, fatigue resistance, and chemical resistance. Nylons do exhibit a tendency to creep under applied load. Nylons are resistant to many chemicals, including ketones, esters, fully halogenated hydrocarbons, fuels, and brake fluids. Nylons have a relatively low heat deflection temperature. However, glass fiber or mineral filler are used to enhance the properties of polyamides. In

Relative permittivity at 1 MHz	—	3.8	3.6	—
Dissipation factor at 1 MHz	—	0.022	0.02	—

addition to increasing the heat deflection temperature, the fibers and fillers lessen the effect of moisture and improve the dimensional stability. Properties of PA6/6 and PA6 appear in Table 19.

Uses The largest application of nylons is in fibers. Molded applications include automotive components (electrical connectors, wire jackets, fan blades, valve covers, emission control valves, light-duty gears), electronic (connectors, cable ties, plugs, terminals, coil forms), related machine parts (gears, cams, pulleys, rollers, boat propellers), and appliance parts.

Polyamide/PPE Alloys Polyamide/polyphenylene ether (PA/PPE) alloys are compatible blends of amorphous PPE and a semicrystalline PA that have a microstructure in which the PA is the continuous phase and the PPE is the discrete phase.^{3,35-37} The PPE acts as an organic reinforcing material. This technology combines the inherent advantages of PPE (dimensional stability, very low water absorption, and high heat resistance) with the chemical resistance and ease of processing of the PA. This combination results in a chemically resistant material with the stiffness, impact

resistance, dimensional stability, and heat performance required for automotive body panels that can undergo online painting.

PA/PPE alloys offer broad environmental resistance to commonly used automotive fuels, greases, and oils. In addition, this family of alloys is resistant to detergents, alcohols, aliphatic and aromatic hydrocarbons, and alkaline chemicals.

Since PPE does not absorb any significant amount of moisture, the effect of moisture on properties is reduced. Indeed, the moisture uptake in PA/PPE alloys is lower. Hence PA/PPE alloys minimize the effect of moisture on rigidity, strength, and dimensional stability vis-à-vis PA.^{35,36} In addition, heat deflection temperatures have been enhanced by the PPE. Properties are shown in Table 20.

Uses PA/PPE alloys are used in automotive body panels (fenders and quarter panels), automotive wheel covers, exterior truck parts, under-the-hood automotive parts (air intake resonators, electrical junction boxes and connectors), and fluid-handling applications (e.g., pumps).

Polyamide 4/6 (PA4/6) Nylon 4/6 is prepared from the condensation polymerization of 1,4-diaminobutane and adipic acid.³³ PA4/6 has a higher crystalline melting point, greater crystallinity, and a faster rate of crystallization than other PAs. In comparison to PA6/6 and PA6, PA4/6 offers high tensile strength and heat deflection temperature; however, it has higher moisture uptake, which can affect properties and dimensional stability. Properties appear in Table 21.

Uses Application for PA4/6 include under-the-hood automotive parts, gears, bearings, and electrical parts.

Semiaromatic Polyamide (PA6/6T, PA6I/6T)

Semiaromatic PAs have been developed in order to increase the performance over that of PA6/6 and

PA6.³³ In general, these resins are modified copolymers based on poly(hexamethylene terephthalate), or PA6/T. Pure nylon 6/T exhibits a very high T_m of 370°C and a T_g of 180°C. This high T_m is above its decomposition temperature. PA6/T copolymers have been prepared using additional monomers such as isophthalic acid, adipic acid, caprolactam, or 1,5-hexyl diamine, which lower the crystalline melting point to useful ranges for melt processing. These terpolymers exhibit T_m values of 290–320°C and T_g values of 100–125°C and offer enhanced performance (i.e., stiffer, stronger, greater thermal and dimensional stability) over PA6/6 and 6. Melt processing requires higher temperatures and often an oil-heated mold (> 100°C). These semicrystalline PAs have good chemical resistance, good dielectric properties, and lower moisture absorption and are more dimensionally stable in the presence of moisture than PA6 and PA6/6. Properties appear in Table 22.

Uses High heat application, automotive (radiator ventilation and fuel supply systems), electrical/electronic (housings, plugs, sockets, connectors), recreational (tennis rackets, golf clubs), mechanical (industrial and chemical processing equipment, bearings, gears), appliance and plumbing parts, and aerospace components.

Aromatic Polyamides Polyamides prepared from aromatic diamines and aromatic diacids give very high heat aromatic nylons or aramides. Examples are poly(*p*-phenyleneterephthalamide) (PPTA) and poly(*m*-phenyleneisophthalamide) (MPIA). These wholly aromatic PAs have high strength, high modulus, high chemical resistance, high toughness, excellent dimensional stability, and inherent flame resistance. MPIA has a T_g of 280°C and is difficult to melt process. Typically it is spun into fibers. PPTA has very high T_g and T_m of 425 and 554°C, respectively. In addition,

PPTA exhibits liquid crystalline behavior and is spun into highly oriented, very high modulus, crystalline fibers. Properties appear in Table 23.

Uses PPTA fibers have uses in bullet-resistant apparel, composites, brake and transmission parts, gaskets, ropes and cables, sporting goods, tires, belts, and hoses.

MPIA fiber have uses in heat-resistant and flame retardant apparel, electrical insulation, and composite structures.

5.3 Polyacetals

Polyacetal homopolymer, or polyoxymethylene (POM), is prepared via the polymerization of formaldehyde followed by capping each end of the polymer chain with an ester group for thermal stability. Polyacetal copolymer (POM-Co) is prepared by copolymerizing trioxane with relatively small amounts of a comonomer such as ethylene oxide.²⁹ The comonomer functions to stabilize the polymer to reversion reactions. POM and POM-Co are commonly referred to as acetals and are also semicrystalline resins.

Polyacetals exhibit rigidity, high strength, excellent creep resistance, fatigue resistance, toughness, self-lubricity/wear resistance, and solvent resistance. Acetals are resistant to gasoline, oils, greases, ethers,

alcohols, and aliphatic hydrocarbons. They are not recommended for use with strong acids.

Properties are enhanced by the addition of glass fiber or mineral fillers. Properties of POM and POM-Co appear in Table 24.

Uses Applications of polyacetals include moving parts in appliances and machines (gears, bearings, bushings, rollers, springs, valves, conveying equipment), automobiles (door handles, fasteners, knobs, fuel pumps, housings), plumbing and irrigation (valves, pumps, faucet underbodies, shower heads, impellers, ball cocks), industrial or mechanical products (rollers, bearings, gears, conveyor chains, housings), consumer products (A/V cassette components, toiletry articles, zippers, pen barrels, disposable lighters, toy parts), and electronic parts (key tops, buttons, switches).

5.4 Polycarbonate

Most commercial PCs are derived from the reaction of bisphenol A and phosgene.^{29,38–40} PCs are amorphous resins that have a unique combination of outstanding clarity and high impact strength. In addition, PCs offer high dimensional stability, resistance to creep, and excellent electrical insulating characteristics. Indeed, PCs are among the stronger, tougher, and more rigid thermoplastics available. PC is a versatile material and a popular blend material used to enhance the performance of ABS, ASA, and polyesters (PBT).

PCs offer limited resistance to chemicals. PC properties are shown in Table 25.

Uses Applications of PC include glazing (safety glazing, safety shields, nonbreakable windows), automotive parts (lamp housings and lenses, exterior parts, instrument panels), packaging (large water bottles, reusable bottles), food service (mugs, food processor bowls, beverage pitchers), ophthalmic (optical

lenses, corrective eyewear, sun wear lenses), medical/laboratory ware (filter housings, tubing connectors, eyewear, health care components), consumer (various appliance parts and housings, power tool housings, cellular phone housings, food processor bowls, lighting), media storage [compact discs (CDs), digital video discs (DVDs)], and miscellaneous (electrical relay covers, aircraft interiors, building and construction). Extruded PC film is used in membrane switches.

5.5 Polycarbonate/ABS Alloy

Polycarbonate/ABS alloys are amorphous blends of PC and ABS resins. They offer a unique balance of properties that combines the most desirable properties of both resins.⁴¹ The addition of ABS improves the melt processing of PC/ABS blends, which facilitates filling large, thin-walled parts. Moreover, the ABS enhances the toughness of PC, especially at low temperatures, while maintaining the high strength and rigidity of the PC. In addition, PC/ABS offers excellent UV stability, high dimensional stability at ambient and elevated temperatures, and the ability for chlorine/bromine-free flame retardance.

Table 26 Typical Properties of PC/ABS Blends

Property	At Selected PC/ABS Ratio (wt/wt)			
	0/100	50/50	80/20	100/0
Density (g/cm ³)	1.06	1.13	1.17	1.20

HDT at 1.81 MPa (°C)	80	100	113	132

The properties are a function of the ABS-to-PC ratio. Properties appear in Table 26.

Uses Automotive (interior and exterior automotive applications as instrument panels, pillar, bezel, grills, interior and exterior trim), business machines (enclosures and internal parts of products such as lap- and desk-top computers, copiers, printers, plotters, and monitors), telecommunications [mobile telephone housings, accessories, and smart cards (GSM SIM cards)], electrical (electronic enclosures, electricity meter covers and cases, domestic switches, plugs and sockets and extruded conduits), and appliances (interior and external parts of appliances such as washing machines, dryers, and microwave ovens).

5.6 Polyester carbonates

Polyester carbonate (PEC) resins have iso- and terephthalate units incorporated into standard bisphenol A polycarbonate.³⁸ This modification of the polymer enhanced the performance between that of PC and polyarylates. Thus, PECs have properties similar to PC but with higher heat deflection temperature and better hydrolytic performance. Higher levels of iso- and terephthalate units result in higher heat deflection temperatures and continuous-use temperatures. Properties of PECs with different heat deflection temperatures appear in Table 27.

Uses PEC is marketed into typical polycarbonate applications that require slightly higher heat deflection temperature and continuous-use temperatures, such as consumer goods, electrical/electronic, and automotive parts.

5.7 Polyarylates

The homopolymers of bisphenol A and isophthalic acid or terephthalic acids are semicrystalline.⁴² The semicrystalline polyarylates (PARs) have a high crystalline melting point and very slow crystallization rates. Hence oil-heated molds and long cycle times would have made commercialization unattractive. Amorphous PARs are prepared from a mixture of isophthalic and terephthalic acids and bisphenol A and can be melt processed without difficulty. They are

Table 27 Typical Properties of PECs

Property	PEC-1	PEC-2

clear, slightly yellow in color, dimensionally stable, and resistant to creep, have excellent electrical properties, are rigid, and have good impact strength.

PARs have poor chemical resistance to ketones, esters, and aromatic and chlorinated hydrocarbons. Typical properties appear in Table 28.

Uses PARs are marketed into applications requiring a higher heat deflection temperature than PC. These include electrical/electronic and automotive applications.

5.8 Modified Polyphenylene Ether

Poly(2,6-dimethylphenylene ether), or PPE, is produced by the oxidative coupling of 2,6-dimethyl phenol.⁴³⁻⁴⁶ PPE is an amorphous thermoplastic. The

Relative permittivity at 1 MHz	2.62	3.8

PPE polymer has a very high heat deflection temperature, good inherent flame resistance, outstanding dimensional stability, and outstanding electrical properties. In addition, PPE has one of the lowest moisture absorption rates found in any engineering plastic.

PPE by itself is difficult to process; hence, PPE is commonly blended with styrenics (e.g., HIPS, ABS) to form a family of modified PPE-based resins.⁴⁴⁻⁴⁶ What is truly unique about the PPE/PS blends is that the PPE and PS form a miscible, single-phased blend. Most polymers have limited solubility in other polymers. Modified PPE resins cover a wide range of compositions and properties.

Modified PPE resins are characterized by ease of processing, high impact strength, outstanding dimensional stability at elevated temperatures, long-term stability under load (creep resistance), and excellent electrical properties over a wide range of frequencies and temperatures. Another unique feature of modified PPE resins is their ability to make chlorine/bromine-free flame-retardant grades.

Modified PPE resins are especially noted for their outstanding hydrolytic stability—they do not contain any hydrolyzable bonds. Their low water absorption rates—both at ambient and elevated temperatures—promote the retention of properties and dimensional stability in the presence of water and high humidity and even in steam environments. In addition, modified PPE resins are also virtually unaffected by a wide variety of aqueous solutions—slats, detergents, acids, and bases. PPE is a versatile material and is used in alloys with PA to enhance the performance and decrease the moisture absorbance of the PA.

The chemical compatibility with oils and greases is limited. It is not recommended for contact with ketones, esters, toluene, and halogenated solvents. Typical properties appear in Table 29.

Uses Applications include automotive (instrument panels, trim, spoilers, under-the-hood components, grills), telecommunication equipment (TV cabinets, cable splice boxes, wire board frames, electrical connectors, structural and interior components in electrical/electronic equipment), plumbing/water handling (pumps, plumbing fixtures), consumer goods (microwavable food packaging, appliance parts), medical, and building and construction.

6 HIGH-PERFORMANCE MATERIALS

High-performance resins arbitrarily comprise the high end of engineering plastics and offer premium performance. Typically high-performance resins will be used in tough metal replacement applications or replacement of ceramic materials. Such materials offer greater resistance to heat and chemicals, high RTIs, high strength and stiffness, and inherent flame resistance. These resins have higher cost and the processing can be more challenging.

6.1 Polyphenylene Sulfide

The condensation polymerization of 1,4-dichlorobenzene and sodium sulfid yields a semicrystalline polymer, polyphenylene sulfid (PPS).⁴⁷ It is characterized by high heat resistance, rigidity, excellent chemical resistance, dimensional stability, low friction coefficient, good abrasion resistance, and electrical properties. PPS has good mechanical properties, which remain stable during exposure to elevated temperatures. Water absorption for PPS is very low and hydrolytic stability is very high. PPS resins are inherently flame resistant.

PPS has excellent chemical resistance to a wide range of chemicals. Indeed, even at elevated temperatures PPS can withstand exposure to a wide range of chemicals, such as mineral and organic acids and alkali. However, it is attacked by chlorinated hydrocarbons.

Depending on the polymerization process, PPS can be a linear or branched polymer. The branched polymer is somewhat more difficult to process due to the very high melting temperature and relatively poor flow characteristics.

PPS resins normally contain glass fiber or mineral fillers. Properties appear in Table 30.

Uses Applications for PPS resins include industrial (parts requiring heat and chemical resistance, submersible, vane, and gear-type pump components), electrical/electronic (high-voltage electrical components), automotive (electrical connectors, under-the-hood components), appliance parts (hair dryers, small cooking appliances, range components), medical (hydraulic components, bearing cams, valves), and aircraft/aerospace.

6.2 Polyarylsulfones

Polyarylsulfones are a class of amorphous, high-end-use-temperature thermoplastics that characteristically exhibit excellent thermo-oxidative stability, good solvent resistance, creep resistance, transparency, and high heat deflection temperatures.⁴⁸⁻⁵⁰ Polyarylsulfones have excellent hydrolytic stability even in saturated steam; they can be repeatedly steam sterilized. Typically the polyarylsulfone families of resins have low resistance to weathering and are degraded by UV light. There are three major categories of aromatic polyarylsulfone resins: polysulfone (PSU), polyphenylsulfone (PPSU), and polyethersulfone (PES).

PSU is prepared by nucleophilic aromatic displacement of the chloride on bis(*p*-chlorophenyl)sulfone by the anhydrous disodium salt of bisphenol A. This amorphous polymer has a T_g of 190°C.

PPSU is higher performing than PSU. This wholly aromatic resin is prepared from biphenol and bis(*p*-chlorophenyl)sulfone.⁵⁰ The lack of aliphatic groups in this all-aromatic polymer and the presence of the biphenyl moiety impart enhanced chemical/solvent resistance, outstanding toughness, greater resistance to combustion, greater thermo-oxidative stability, and a T_g of 220°C. PPSU has excellent resistance to mineral acids, caustic, salt solution, and various automotive fluids. Exposure to esters, ketones, and polar aromatic solvents should be avoided.

PES consists of a diphenyl sulfone unit linked through an ether (oxygen) unit. Again the lack of aliphatic groups results in higher thermo-oxidative stability. PES offers high heat (T_g of 230°C), chemical/solvent resistance, and improved toughness over PSU. PES is chemically resistant to most inorganic

gasoline. However, esters, ketones, methylene chloride, and polar aromatic solvents attack PES.

Typical properties of PSU, PPSU, and PES appear in Table 31.

Uses Typical applications of polyarylsulfones include medical/laboratory (surgical equipment, laboratory equipment, life support parts, autoclavable tray systems, suction bottles, tissue culture bottles, surgical hollow shapes), food handling (microwave cookware, coffee makers, hot-water and food-handling equipment, range components), electrical/electronic

(components, multipin connectors, coil formers, printed circuit boards), chemical processing equipment (pump housings, bearing cages), and miscellaneous (radomes, alkaline battery cases).

6.3 Liquid Crystalline Polyesters

Liquid crystalline polymers (LCPs) have a rigid rod-like aromatic structure. The rodlike molecules arrange themselves in parallel domains in both the melt and solid states. In the molten state the molecules readily slide over one another, giving the resin very high flo

under shear. Most commercially important polyester LCPs are based on *p*-hydroxybenzoic acid (HBA). An example would be the copolyester of HBA and hydroxynaphthanoic acid (HNA) with a molar ratio of 73/27.

LCPs are highly crystalline, thermotropic (melt-orienting) thermoplastics. Because of the possibility of melt orientation during molding, LCPs can have anisotropic properties; that is, properties can differ in the direction of flow and perpendicular to the flow direction. LCPs offer high strength, rigidity, dimensional stability, inherent flame resistance, and high heat resistance. LCPs have high flow and can deliver exceptionally precise and stable dimensions in very thin walled applications.

LCPs are resistant to weathering, burning, γ -radiation, steam autoclaving, and most chemical sterilization methods. They have outstanding strength at elevated temperatures.

LCPs are resistant to virtually all chemicals, including acids, organic hydrocarbons, and boiling water. It is attacked by concentrated, boiling caustic but is unaffected by milder solutions. Typical properties of the HBA-HNA LCPs appear in Table 32.

Uses Typical applications of LCPs include electrical/electronic (stator insulation, rotors, boards for motors, burn-in sockets, interface connectors, bobbins, switches, chip carriers and sensors), medical (surgical instruments, needleless syringes, dental tools, sterilizable trays and equipment, drug delivery systems and diagnostics), industrial (chemical process and oil field

equipment), and packaging (food packaging requiring barrier properties).

6.4 Polyimides

Polyimides are a class of polymers prepared from the condensation reaction of a carboxylic acid anhydride with a diamine.⁵¹ Polyimides are among the most heat-resistant polymers. Poly(pyromellitimide-1,4-diphenyl ether) is prepared from pyromellitic anhydride (PMDA) and 4,4'-oxydianiline (ODA). PMDA-ODA has a T_g of 360°C or higher. This very high T_g does not lend itself to standard melt-processing techniques. PMDA-ODA resins are available as film and direct-formed parts from formulated resin. PMDA-ODA has excellent thermal stability, useful mechanical properties over a very wide temperature range, creep resistance, high toughness, and excellent wear resistance. PMDA-ODA had excellent electrical properties to a broad range of chemicals. However, it will be attacked by 10% and stronger solutions of sodium hydroxide. Typical properties appear in Table 33.

Uses PMDA-ODA film are used as wire and cable wrap, motor-slot liners, flexible printed circuit boards, transformers, and capacitors. Molded parts are used in application requiring resistance to thermally harsh environments such as automotive transmission parts, thermal and electrical insulators, valve seats, rotary seal rings, thrust washers and discs, bushings, and the like.

6.5 Polyetherimides

Polyetherimides (PEIs) are prepared from the polymerization of aromatic diamines and etherdianhydrides.^{52,53} PEI is an amorphous thermoplastic that contains repeating aromatic imide and ether units. The rigid aromatic imide units provide PEI with its high-performance properties at elevated temperatures, while the ether linkages provide it with the chain flexibility necessary to have good melt flow and processability by injection molding and other melt-processing techniques.

PEI resins offer high strength, rigidity, high heat resistance, inherent flame resistance, low smoke generation, excellent processability with very tight molding tolerances, heat resistance up to 200°C, RTI of 170°C, excellent dimensional stability (low creep sensitivity and low coefficient of thermal expansion), superior torque strength and torque retention and stable dielectric constant and dissipation factor over a wide range of temperatures and frequencies.

PEIs have excellent hydrolytic stability, UV stability, and radiation resistance. They are well suited for repeated steam, hot air, ethylene oxide gas, and cold chemical sterilizations. In addition, PEIs have proven property retention through over 1000 cycles in industrial washing machines with detergents and compliance with Food and Drug Administration (FDA), European Union (EU), and national food contact regulations.

In addition PEI resins are resistant to a wide range of chemicals, including alcohols, hydrocarbons, aqueous detergents and bleaches, strong acids, mild bases, and most automotive fuels, fluids, and oils. Chlorinated hydrocarbons and aromatic solvents can attack PEI resins. Typical properties appear in Table 34.

Uses Automotive (transmission components, throttle bodies, ignition components, sensors, thermostat housings), automotive lighting (headlight reflectors, fog light reflectors, bezels, light bulb sockets), telecommunications (molded interconnect devices, electrical control units, computer components, mobile phone

internal antennae, radio frequency (RF) duplexers or microfilters, fiber-optic connectors), electrical (lighting, connectors to reflectors) heating, ventilation, and air conditioning (HVAC)/fluid handling (water pump impellers, expansion valves, hot-water reservoirs, heat exchange systems), tableware/catering (food trays, soup mugs, steam insert pans or gastronome containers, cloches, microwavable bowls, ovenware, cooking utensils, reusable airline casseroles), medical (reusable medical devices such as sterilization trays, stopcocks, dentist devices, and pipettes), and aircraft (air and fuel valves, food tray containers, steering wheels, interior cladding parts, semistructural components).

6.6 Polyamide Imides

Polyamide imides (PAIs) are prepared from trimellitic anhydride and various aromatic diamines.⁵⁴ PAIs are tough, high-modulus thermoplastics capable of high continuous-use temperatures. In addition, they have inherent flame resistance and very high strength. PAIs have very broad chemical resistance but are attacked by aqueous caustic and amines. PAIs have high melt temperature and require very high processing temperatures. PAIs contain an amide group and hence will absorb moisture, which can affect dimensional stability. Properties appear in Table 35.

Uses Automotive (housings, connectors, switches, relays, thrust washers, valve seats, bushings, wear rings, rollers, thermal insulators), composites (printed wiring boards, radomes), and aerospace (replacement of metal parts).

6.7 Aromatic Polyketones

Aromatic polyketones are a family of semicrystalline high-performance thermoplastics that consist of a combination of ketone, ether, and aromatic units.⁵⁵ The absence of aliphatic groups results in outstanding high-temperature performance, exceptional thermal stability, excellent environmental resistance, high

mechanical properties, resistance to chemical environments at elevated temperatures, inherent flame resistance, excellent friction and wear resistance, and impact resistance. In addition, aromatic polyketones have high chemical purity suitable for applications in silicon chip manufacturing.

There are two major aromatic polyketone resins: polyetherketone (PEK) and polyetheretherketone (PEEK). Typical properties appear in Table 36.

Uses Applications are in the chemical process industry (compressor plates, valve seats, pump impellers, thrust washers, bearing cages), aerospace (aircraft fairings, radomes, fuel valves, ducting),

and electrical/electronic (wire coating, semiconductor wafer carriers).

7 FLUORINATED THERMOPLASTICS

Fluoropolymers or fluoroplastics are a family of fluorine-containing thermoplastics that exhibit some unusual properties.^{56,57} These properties include inertness to most chemicals, resistance to high temperatures, extremely low coefficient of friction, weather resistance, and excellent dielectric properties. Mechanical properties are normally low but can be enhanced with glass or carbon fiber or molybdenum disulfide fillers. Properties are shown in Table 37.

7.1 Poly(tetrafluoroethylene)

Poly(tetrafluoroethylene) (PTFE) is a highly crystalline polymer produced by the polymerization of tetrafluoroethylene. PTFE offers very high heat resistance (up to 250°C), exceptional chemical resistance, and outstanding flame resistance.⁵⁶ The broad chemical resistance includes strong acids and strong bases. In addition, PTFE has the lowest coefficient of friction of any polymer.

PTFE has a high melting point and extremely high melt viscosity and hence cannot be melt processed by normal techniques. Therefore PTFE has to be processed by unconventional techniques (PTFE powder is compacted to the desired shape and sintered).

Uses Typically PTFE is used in applications requiring long-term performance in extreme-service environments. PTFE applications include electrical (high-temperature, high-performance wire and cable insulation, sockets, pins, connectors), mechanical

(bushings, rider rings, seals, bearing pads, valve seats, chemical resistance processing equipment and pipe, nonlubricated bearings, pump parts, gaskets, and packings), nonstick coatings (home cookware, tools, food-processing equipment), and miscellaneous (conveyor parts, packaging, flame-retardant laminates).

7.2 Poly(chlorotrifluoroethylene)

Poly(chlorotrifluoroethylene (PCTFE) is less crystalline and exhibits higher rigidity and strength than PTFE.⁵⁷ Poly(chlorotrifluoroethylene has excellent chemical resistance and heat resistance up to 200°C. Unlike PTFE, PCTFE can be molded and extruded by conventional processing techniques.

Uses PCTFE applications include electrical/electronic (insulation, cable jacketing, coilforms), industrial (pipe and pump parts, gaskets, seals, diaphragms, coatings for corrosive process equipment and in cryogenic systems), and pharmaceutical packaging.

7.3 Fluorinated Ethylene–Propylene

Copolymerization of tetrafluoroethylene with some hexafluoropropylene produces fluorinated ethylene–propylene polymer (FEP), which has less crystallinity, lower melting point, and improved impact strength than PTFE. FEP can be molded by normal thermo-plastic techniques.⁵⁷

Uses FEP applications include wire insulation and jacketing, high-frequency connectors, coils, gaskets, and tube sockets.

7.4 Polyvinylidene Fluoride

Polyvinylidene fluoride (PVDF) is made by emulsion and suspension polymerization and has better ability to be processed but less thermal and chemical resistance than FEP, CTFE, and PTFE.⁵⁷ PVDF has excellent mechanical properties and resistance to severe environmental stresses and good chemical resistance.

Uses Polyvinylidene fluoride applications include electronic/electrical (wire and cable insulation, films) fluid handling (solid and lined pipes, fittings, valves, seals and gaskets, diaphragms, pumps, microporous membranes), and coatings (metal finishes, exterior wall panels, roof shingles).

7.5 Poly(ethylene chlorotrifluoroethylene)

The copolymer of ethylene and chlorotrifluoroethylene (ECTFE) has high strength and chemical and impact resistance. ECTFE can be processed by conventional techniques.

Uses Poly(ethylene chlorotrifluoroethylene) applications include wire and cable coatings, chemical-resistant coatings and linings, molded laboratory ware, and medical packing.

7.6 Poly(vinyl fluoride)

Poly(vinyl fluoride) (PVF) is the least chemical resistant fluoropolymer.⁵⁷ PVF offers weathering and UV resistance, antisoiling, durability, and chemical resistance.

Uses Poly(vinyl fluoride) uses include protective coatings (aircraft interior, architectural fabrics, pressurized exterior building panels, wall coverings, glazing, lighting).

8 THERMOSETS

Thermosetting resins are used in molded and laminated plastics.⁵⁸ They are first polymerized into a low-molecular-weight linear or slightly branched polymer or oligomers, which are still soluble, fusible, and highly reactive during final processing. Thermoset resins are generally highly filled with mineral fillers and glass fibers. Thermosets are generally catalyzed and/or heated to finish the polymerization reaction, crosslinking them to almost infinite molecular weight. This step is often referred to as curing. Such cured polymers cannot be reprocessed or reshaped.

The high filler loading and the high crosslink density of thermoset resins result in high densities and low ductility but high rigidity and good chemical resistance.

8.1 Phenolic Resins

Phenolic resins combine the high reactivity of phenol and formaldehyde to form prepolymers and oligomers called resoles and novolacs. These materials can be used as adhesives and coatings or combined with fibrous filler to give phenolic resins, which when heated undergo a rapid, complete crosslinking to give a highly cured structure. The curing typically requires heat and pressure. Fillers include cellulosic materials and glass and mineral fibers/fillers. The high-crosslinked aromatic structure has high hardness, dimensional stability, rigidity, strength, heat resistance, chemical resistance, and good electrical properties.

Phenolic resins have good chemical resistance to hydrocarbons, phenols, and ethers. However, they can undergo chemical reaction with acids and bases.

Uses Phenolic applications include appliance parts (handles, knobs, bases, end panels), automotive uses (parts in electric motors, brake linings, fuse blocks, coil towers, solenoid covers and housings, ignition parts), electrical/electronic (high-performance connectors and coil bobbins, circuit breakers, terminal switches and blocks, light sockets, receptacles), and miscellaneous (adhesives in laminated materials such as plywood, coatings).

8.2 Epoxy Resins

Epoxy resins are materials whose molecular structure contains an epoxide or oxirane ring. The most common epoxy resins are prepared from the reaction of bisphenol A and epichlorohydrin to yield low-molecular-weight resins that are liquid either at room temperature or on warming. Other epoxy resins are available—these include novolac and cycloaliphatic epoxy resins. Each polymer chain usually contains two or more epoxide groups. The high reactivity of the epoxide groups with aromatic and aliphatic amines, anhydrides, carboxylic acids, and other curing agents provides facile conversion into highly crosslinked materials. The large number of variations possible in epoxy structure and curing agent coupled with their ability to be formulated with a wide variety of filler and additives results in broad application potential. Cured epoxy resins exhibit hardness, strength, heat resistance, good electrical properties, and broad chemical resistance.

Most epoxies are resistant to numerous chemicals, including hydrocarbons, esters, and bases. However, epoxies can exhibit poor resistance to phenols, ketones, ethers, and concentrated acids.

Uses Epoxy resins are used in composites (glass-reinforced, high-strength composites in aerospace, pipes, tanks, pressure vessels), coatings (marine coatings, protective coatings on appliances, chemical scrubbers, pipes), electrical/electronic (encapsulation or casting of various electrical and electronic components, printed wiring boards, switches, coils, insulators,

bushings), and miscellaneous (adhesives, solder mask, industrial equipment, sealants).

8.3 Unsaturated Polyesters

Thermoset polyesters are prepared by the condensation polymerization of various diols and maleic anhydride to give a very viscous unsaturated polyester oligomer that is dissolved in styrene monomer. The addition of styrene lowers the viscosity to a level suitable for impregnation and lamination of glass fibers. The low-molecular-weight polyester has numerous maleate/fumarate ester units that provide facile reactivity with styrene monomer. Unsaturated polyesters can be prepared from a variety of different monomers.

Properly formulated glass-reinforced unsaturated polyesters are commonly referred to as sheet-molding compound (SMC) or reinforced plastics. The combination of glass fiber in the cured resins offers outstanding strength, high rigidity, impact resistance, high strength-to-weight ratio, and chemical resistance. SMC typically is formulated with 50% calcium carbonate filler, 25% long glass fiber, and 25% unsaturated polyester. The highly filled nature of SMC results in a high density and a brittle, easily pitted surface.

Bulk-molding compounds (BMCs) are formulated similar to SMCs except $\frac{1}{4}$ -in. chopped glass is typically used. The shorter glass length gives easier processing but lower strength and impact.

Thermoset polyesters have good chemical resistance, which includes exposure to alcohols, ethers, and organic acids. They exhibit poor resistance to hydrocarbons, ketones, esters, phenols, and oxidizing acids.

Uses The prime use of unsaturated polyesters is in combination with glass fibers in high-strength composites and in SMC and BMC materials. The applications include transportation markets (large body parts for automobiles, trucks, trailers, buses, and aircraft, automotive ignition components), marine markets (small- to medium-sized boat hulls and associated marine equipment), building and construction (building panels, housing and bathroom components—bathtub and shower stalls), and electrical/electronic (components, appliance housing, switch boxes, breaker components, encapsulation).

8.4 Vinyl Esters

Vinyl esters are part of the unsaturated polyester family. They are prepared by the reaction of an epoxy resin with methacrylic acid. Thus the epoxide group is converted into a methacrylate ester. Vinyl esters offer an enhancement in properties over unsaturated polyesters with greater toughness and better resistance to corrosion to a wide range of chemicals. This chemical resistance includes halogenated solvents, acids, and bases.

Uses Applications for vinyl esters are similar to those for unsaturated polyesters but where added

toughness and chemical resistance are required, that is, electrical equipment, flooring fans, adsorption towers, process vessels, and piping.

8.5 Alkyd Resins

Alkyd resins are unsaturated polyesters based on branched prepolymers from polyhydric alcohols (e.g., glycerol, pentaerythritol, ethylene glycol), polybasic acids (e.g., phthalic anhydride, maleic anhydride, fumaric acid), and fatty acids and oils (e.g., oleic, stearic, palmitic, linoleic, linolenic, lauric, and licanic acids). They are well suited for coating with their rapid drying, good adhesion, flexibility, mar resistance, and durability. Formulated alkyd molding resins have excellent heat resistance, are dimensionally stable at high temperatures and have excellent dielectric strength, high resistance to electrical leakage, and excellent arc resistance.

Alkyd resins can be hydrolyzed under alkaline conditions.

Uses Alkyd resin applications include coatings (drying oils in paints, enamels, and varnish) and molding compounds when formulated with reinforcing filler for electrical applications (circuit breaker insulation, encapsulation of capacitors and resistors, coil forms).

8.6 Diallyl Phthalate

Diallyl phthalate (DAP) is the most widely used compound in the allylic ester family. The neat resin is a medium-viscosity liquid. These low-molecular-weight prepolymers can be reinforced and compression molded into highly crosslinked, completely cured products.

The most outstanding properties of DAP are excellent dimensional stability and high insulation resistance. In addition, DAP has high dielectric strength and excellent arc resistance. DAP has excellent resistance to aliphatic hydrocarbons, oils, and alcohols but is not recommended for use with phenols and oxidizing acids.

Uses. DAP applications include electrical/electronic (parts, connectors, bases and housings, switches, transformer cases, insulators, potentiometers) and miscellaneous (tubing, ducting, radomes, junction bases, aircraft parts). DAP is also used as a coating and an impregnating resin.

8.7 Amino Resins

The two main members of the amino resin family of thermosets are the melamine-formaldehyde and urea-formaldehyde resins. They are prepared from the condensation reaction of melamine and urea with formaldehyde. In general, these materials exhibit extreme hardness, inherent flame resistance, heat resistance, scratch resistance, arc resistance, chemical resistance, and light fastness.

Table 38 Properties of General-Purpose Elastomers

Rubber	ASTM ^a Nomenclature	Outstanding Characteristic	Property Deficiency	Temperature Use Range (°C)
Butadiene rubber	BR	Very flexible; resistance to wear	Sensitive to oxidation; poor resistance to fuels and oil	-100-90
Natural rubber	NR	Similar to BR but less resilient	Similar to BR	-50-80
Isoprene rubber	IR	Similar to BR but less resilient	Similar to BR	-50-80
Isobutylene-isoprene rubber (butyl rubber)	IIR	High flexibility; low-permeability air		-45-150
Chloroprene	CR	Flame resistant; fair fuel and oil resistance; increased resistance to oxygen, ozone, heat, and light	Poor low-temperature flexibility	-40-115
Nitrile-butadiene	NBR	Good resistance to fuels, oils, and solvents; improved abrasion resistance	Lower resilience; higher hysteresis; poor electrical properties; poorer low-temperature flexibility	-45-80
Styrene-butadiene rubber	SBR	Relatively low cost	Less resilience; higher hysteresis; limited low-temperature flexibility	-45-80
Ethylene-propylene copolymer	EPDM	Resistance to ozone and weathering	Poor hydrocarbon and oil resistance	-50 to < 175
Polysulfide	T	Chemical resistance; resistance to ozone and weathering	Creep; low resilience	-45-120

^aAmerican Society for Testing and Materials.

Table 39 Properties of Specialty Elastomers

Elastomer	ASTM Nomenclature	Temperature Use Range (°C)	Outstanding Characteristic	Typical Applications
Silicones (polydimethylsiloxane)	MQ	-100-300	Wide temperature range; resistance to aging, ozone, and sunlight; very high gas permeability	Seals, molded and extruded goods; adhesive, sealants; biomedical; personal care products
Fluoroelastomers	CFM	-40-200	Resistance to heat, oils, and chemicals	Seals such as O-rings, corrosion-resistant coatings
Acrylic	AR	-40-200	Oil, oxygen, ozone, and sunlight resistance	Seals, hose
Epichlorohydrin	ECO	-18-150	Resistance to oil and fuels; some flame resistance; low gas permeability	Hose, tubing, coated fabrics, vibration isolators
Chlorosulfonated	CSM	-40-150	Resistance to oil, ozone weathering, and oxidizing chemicals	Automotive hose, wire and cable, linings for reservoirs
Chlorinated polyethylene	CM	-40-150	Resistance to oils, ozone, chemicals	Impact modifier, automotive applications
Ethylene-acrylic	-	-40-175	Resistance to ozone and weathering	Seals, insulation, vibration damping
Propylene oxide	-	-6-150	Low-temperature properties	Motor mounts

Uses Melamine–formaldehyde resins find use in colorful, rugged dinnerware, decorative laminates (countertops, tabletops, furniture surfacing), electrical applications (switchboard panels, circuit breaker parts, arc barriers, armature and slot wedges), and adhesives and coatings.

Urea–formaldehyde resins are used in particleboard binders, decorative housings, closures, electrical parts, coatings, and paper and textile treatment.

9 GENERAL-PURPOSE ELASTOMERS

Elastomers are polymers that can be stretched substantially beyond their original length and can retract rapidly and forcibly to essentially their original dimensions (on release of the force).^{59,60}

The optimum properties and/or economics of many rubbers are obtained through formulating with reinforcing agents, fillers extending oils, vulcanizing agents, antioxidants, pigments, and the like. End-use markets for formulated rubbers include automotive tire products (including tubes, retread applications, valve stems, and inner liners), adhesives, cements, caulks, sealants, latex foam products, hose (automotive, industrial, and consumer applications), belting (V-conveyor and trimming), footwear (heels, soles, slab stock, boots, and canvas), and molded, extruded, and calendered products (athletic goods, flooring, gaskets, household products, O-rings, blown sponge, thread, and rubber sundries). A summary of general-purpose elastomers and properties is provided in Table 38.

10 SPECIALTY ELASTOMERS

Specialty rubbers offer higher performance over general-purpose rubbers and find use in more demanding applications.⁶¹ They are more costly and hence are produced in smaller volume. Properties and uses are summarized in Table 39.

1 INTRODUCTION

Engineering ceramics possess unique combinations of physical, chemical, electrical, optical, and mechanical properties. Utilizing the gains in basic materials science understanding and advances in processing technology accrued over the past half century, it is now frequently possible to custom tailor the chemistry, phase content, and microstructure to optimize applications-specific combinations of properties in ceramics (which include glasses, single crystals, and coatings technologies, in addition to bulk polycrystalline materials). This capability in turn has led to many important, new applications of these materials over the past few decades. Indeed, in many of these applications the new ceramics and glasses are the key enabling technology.

Ceramics include materials that have the highest melting points, highest elastic moduli, highest hardness, highest particulate erosion resistance, highest thermal conductivity, highest optical transparency, lowest thermal expansion, and lowest chemical

reactivity known. Counterbalancing these beneficial factors are brittle behavior and vulnerability to thermal shock and impact. Over the past three decades major progress has been made in learning how to design to mitigate the brittleness and other undesirable behaviors associated with ceramics and glasses. Consequently, many exciting new applications for these materials have emerged over the past several decades.

Among the major commercial applications for these materials are:

- Passive electronics (capacitors and substrates)
- Optronics/photronics (optical fibers)
- Piezoceramics (transducers)
- Mechanical (bearings, cutting tools)
- Biomaterials (hard-tissue replacement)
- Refractories (furnace linings, space vehicle thermal protection)
- Electrochemical (sensors, fuel cells)
- Transparencies (visible, radar)

This chapter will provide a brief overview of how ceramics are processed and the ramification of processing on properties. Next a short discussion of the

Reprinted from *Handbook of Materials Selection*, Wiley, New York, 2002, with permission of the publisher.

special issues that one encounters in mechanical design with brittle materials is provided. Short reviews of several of the above engineering applications of ceramics and glasses, which discuss some of the specific combinations of properties that have led design engineers to the selected material(s), follow. A section on how to obtain information on materials sources is provided. Tables listing typical properties of candidate materials for each set of applications are included throughout. Finally, some areas of future potential will be discussed.

2 PROCESSING OF ADVANCED CERAMICS

The production of utilitarian ceramic artifacts via the particulate processing route outlined in Fig. 1 actually commenced about 10,000 years ago.¹ Similarly, glass melting technology goes back about 3500 years, and as early as 2000 years ago optical glass was being produced.¹ While many of the basic unit processes for making glasses and ceramics are still recognizable across the millennia, the level of sophistication in equipment, process control, and raw material control have advanced by "light years." In addition, the past 50 years has created a fundamental understanding of the materials science principles that underlie the processing–microstructure–property relationships. Additionally, new materials have been synthesized that possess extraordinary levels of performance for specific applications. These advances have led to the use of advanced ceramics and glasses in roles that were unimaginable 50 or 60 years ago. For example, early Egyptian glass ca. 2000 BC had an optical loss of $\sim 10^7$ dB/km, compared to an optical loss of $\sim 10^{-1}$ in mid-1980s glass optical fibers² a level of performance that has facilitated the fiber-optic revolution in telecommunications. Similarly, the invention of barium titanate and lead zirconate titanate ceramics, which

have much higher piezoelectric moduli and coupling coefficient than do naturally occurring materials, has enabled the existence of modern sonar and medical ultrasound imaging.³

The processing of modern ceramics via the particulate route, shown in Fig. 1, is the way that $\sim 99\%$ of all polycrystalline ceramics are manufactured. Other techniques for producing polycrystalline ceramics, such as chemical vapor deposition⁴ or reaction forming,⁵ are of growing importance but still represent a very small fraction of the ceramic industry. There are three basic sets of unit processes in the particulate route (and each of these three sets of processes may incorporate dozens of subprocesses). The first set of processes involves powder synthesis and treatment. The second set of processes involves the consolidation of the treated powders into a shaped preform, known as a "green" body. The green body typically contains about 50 vol % porosity and is extremely weak. The last set of unit processes utilizes heat, or heat and pressure combined, to bond the individual powder particles, remove the free space and porosity in the compact via diffusion, and create a fully dense, well-bonded ceramic with the desired microstructure. (See Ref. 4, chapters 9–11.) If only heat is used, this process is called sintering. If pressure is also applied, the process is then referred to as hot pressing (unidirectional pressure) or hot isostatic pressing [(HIP), which applies uniform omnidirectional pressure].

Each of the above steps can introduce processing flaws that can diminish the intrinsic properties of the material. For example, chemical impurities introduced during the powder synthesis and treatment steps may adversely affect the optical, magnetic, dielectric, or thermal properties of the material. Alternatively, the impurities may segregate in the grain boundary of

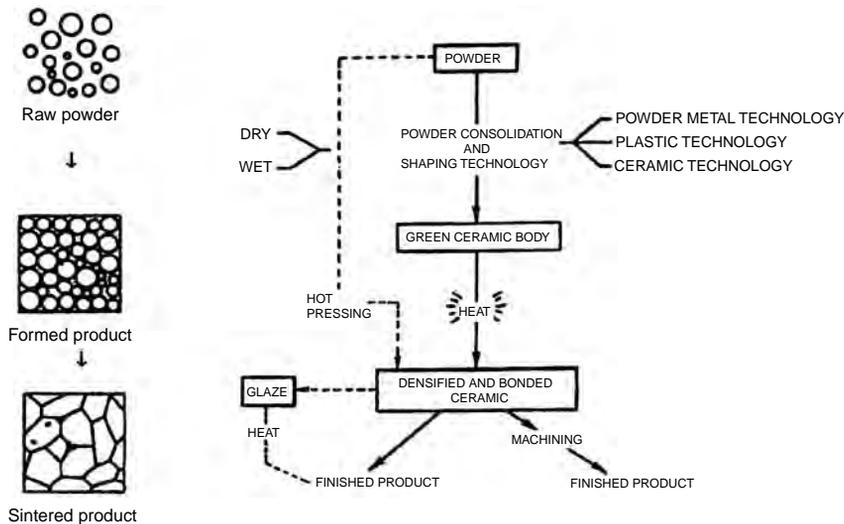

Fig. 1 Processing of polycrystalline ceramics via particular route.

the sintered ceramic and negatively affect its melting point, high-temperature strength, dielectric properties, or optical properties. In green-body formation, platey or high-aspect-ratio powders may align with a preferred orientation, leading to anisotropic properties. Similarly, hot pressing may impose anisotropic properties on a material. Since ceramics are not ductile materials, they can (usually) not be thermomechanically modified after primary fabrication. Thus, the specific path by which a ceramic component is fabricated can profoundly affect its properties. The properties encountered in a complex-shaped ceramic part are often quite different than those encountered in a simply shaped billet of material. This is an important point of which a design engineer specifying a ceramic component needs to be constantly mindful.

3 BRITTLENESS AND BRITTLE MATERIALS DESIGN

Even when ceramics are selected for other than mechanical applications, in most cases some levels of strength and structural integrity are required. It is therefore necessary to briefly discuss the issue of brittleness and how one designs with brittle materials before proceeding to discuss applications and the various ceramic and glass materials families and their properties.

The main issues in designing with a brittle material are that a very large scatter in strength (under tensile stress), a lack of capacity for mitigating stress concentrations via plastic flow and relatively low-energy absorption prior to failure dominate the mechanical behavior. Each of these issues is a result of the presence of one or more flaw distribution within or at the surface of the ceramic material and/or the general lack of plastic flow available in ceramics. As a consequence, ceramic and glass components that are subjected to tensile stresses are not designed using a single valued strength (*deterministic design*) as commonly done with metals. Rather, ceramic components are designed to a specific probability of failure (*probabilistic design*) that is set at acceptably low values. The statistics of failure of brittle materials whose strength is determined by a population of varying sized flaw are similar to modeling the statistics of a chain failing via its weakest link. The statistics utilized are known as Weibull statistics. A Weibull probability of failure distribution is characterized by two parameters, the characteristic stress and the Weibull modulus.⁶ Computer programs for incorporating Weibull statistical distributions into finite-element design codes have been developed that facilitate the design of ceramic components optimized for low probabilities of failure.⁷ The effectiveness of such probabilistic design methodology has been demonstrated by the reliable performance of ceramics in many highly stressed structural applications, such as bearings, cutting tools, turbocharger rotors, missile guidance domes, and hip prosthesis.

Flaws (strength-limiting features) can be intrinsic or extrinsic to the material and processing route by

which a test specimen or a component is made. Intrinsic strength-limiting flaws are generally a consequence of the processing route and may include features such as pores, aggregations of pores, large grains, agglomerates, and shrinkage cracks. While best processing practices will eliminate or reduce the size and frequency of many of these flaws, it is inevitable that some will still persist. Extrinsic flaws can arise from unintended foreign material entering the process stream, that is, small pieces of debris from the grinding media or damage (cracks) introduced in machining a part to final dimensions. Exposure to a service environment may bring new flaw populations into existence, that is, oxidation pits on the surface of nonoxide ceramics exposed to high temperatures, or may cause existing flaws to grow larger as in the case of static fatigue of glass. In general, one can have several flaw populations present in a component at any time, and the characteristics of each population may change with time. As a consequence of these constantly changing flaw populations, at the present time the state of the art in life prediction of ceramic components for use in extreme environments significantly lags the state of the art in component design. As in most field of engineering, there are some rules of thumb that one can apply to ceramic design.⁸ While these are not substitutes for a carefully executed probabilistic finite-element design analysis, they are very useful in spotting pitfalls and problems when a full-fledged design cannot be executed due to financial or time constraints.

Rules of Thumb for Design with Brittle Materials

1. Point loads should be avoided to minimize stress where loads are transferred. It is best to use areal loading (spherical surfaces are particularly good); line loading is next best.
2. Structural compliance should be maintained by using compliant layers or springs or radiusing of mating parts (to avoid lockup).
3. Stress concentrators—sharp corners, rapid changes in section size, undercuts and holes—should be avoided or minimized. Generous radii and chamfers should be used.
4. The impact of thermal stresses should be minimized by using the smallest section size consistent with other design constraints. The higher the symmetry, the better (a cylinder will resist thermal shock better than a prism), and breaking up complex components into subcomponents with higher symmetry may help.
5. Components should be kept as small as possible—the strength and probability of failure at a given stress level are dependent on size; thus minimizing component size increases reliability.
6. The severity of impact should be minimized. Where impact (i.e., particulate erosion) cannot be avoided, low-angle impacts (20° – 30°) should be designed for. Note this is very different than

the case of metals, where minimum erosion is at 90°.

- Avoid surface and subsurface damage. Grinding should be done so that any residual grinding marks are parallel, not perpendicular, to the direction of principal tensile stress during use. Machining-induced flaws are often identified to be the strength-limiting defect.

4 APPLICATIONS

The combinations of properties available in many advanced ceramics and glasses provide the designers of mechanical, electronic, optical, and magnetic systems a variety of options for significantly increasing systems performance. Indeed, in some cases the increase in systems performance is so great that the use of ceramic materials is considered an enabling technology. In the applications examples provided below the key properties and combinations of properties required will be discussed, as well as the resultant systems benefits

4.1 Ceramics in Wear Applications

In the largest number of applications where modern ceramics are used in highly stressed mechanical applications, they perform a wear resistance function. This is true of silicon nitride used as balls in rolling element bearings, silicon carbide journal bearings or water pump seals, alumina washers in faucets and beverage dispensing equipment, silicon nitride and alumina-based metal-cutting tools, zirconia fuel injector components, or boron carbide sand blast nozzles, to cite some typical applications and materials.

Wear is a systems property rather than a simple materials property. As a systems property, wear depends upon what material is rubbing, sliding, or rolling over what material, upon whether the system is lubricated or not, upon what the lubricant is, and so forth. To the extent that the wear performance of a material can be predicted, the wear resistance is usually found to be a complex function of several parameters. Wear of ceramic materials is often modeled using an abrasive wear model where the material removed per length of contact with the abrasive is calculated. A wide variety of such models exist, most of which are of the form

$$V \propto P^{0.8} K_{Ic}^{-0.75} H^{-0.5} N \quad (1)$$

where V is the volume of material worn away, P is the applied load, K_{Ic} is the fracture toughness, H is the indentation hardness, and N is the number of abrasive particles contacting the wear surface per unit length. Even if there are no external abrasives particles present, the wear debris of the ceramics themselves act as abrasive particles. Therefore, the functional relationships that predict that wear resistance should increase as fracture toughness and hardness increase are, in fact, frequently observed in practice.

Even though the point contacts that occur in abrasive wear produce primarily hertzian compressive stresses, in regions away from the hertzian stress field tensile stresses will be present and strength is, thus, a secondary design property. In cases where inertial loading or weight is a design consideration, density may also be a design consideration. Accordingly, Table 1 lists typical values of the fracture toughness, hardness, Young's modulus, four-point modulus of rupture (MOR) in tension, and the density for a variety of advanced ceramic wear materials. Several successful applications of ceramics to challenging wear applications are described below.

Bearings Rolling element bearings, for use at very high speeds or in extreme environments, are limited in performance by the density, compressive strength, corrosion resistance, and wear resistance of traditional high-performance bearing steels. The key screening test to assess a material's potential as a bearing element is rolling contact fatigue (RCF). RCF tests on a variety of alumina, SiC, Si₃N₄, and zirconia materials, at loads representative of high-performance bearings demonstrated that only fully dense silicon nitride (Si₃N₄) could outperform bearing steels.⁹ This behavior has been linked to the high fracture toughness of silicon nitride, which results from a unique "self-reinforced" microstructure combined with a high hardness. Additionally, the low density of silicon nitride creates a reduced centrifugal stress on the outer races at high speeds. Fully dense Si₃N₄ bearing materials have demonstrated RCF lives 10 times that of high-performance bearing steel. This improved RCF behavior translates into DN (DN = bearing bore diameter in millimeters × shaft rpm) ratings for hybrid ceramic bearings (Si₃N₄ balls running in steel races, the most common ceramic bearing configuration about 50% higher than the DN rating of

Table 1 Key Properties for Wear-Resistant Ceramics

Material	K_{Ic} (MPa · m ^{1/2})	H (kg/mm ²)	E (GPa)	MOR (MPa)	ρ (g/cm ³)
Al ₂ O ₃ 99%	3.9–4.5	1900	360–395	350–560	3.9
B ₄ C	–	3000	445	300–480	2.5
Diamond	6–10	8000	800–925	800–1400	3.5
SiC	2.6–4.6	2800	380–445	390–550	3.2
Si ₃ N ₄	4.2–7	1600	260–320	450–1200	3.3
TiB ₂	5–6.5	2600	550	240–400	4.6
ZrO ₂ (Y-TZP)	7–12	1000	200–210	800–1400	5.9

steel bearings. Other benefit of silicon nitride hybrid bearings include an order-of-magnitude less wear of the inner race, excellent performance under marginal lubrication, survival under lubrication starvation conditions, lower heat generation than comparable steel bearings, and reduced noise and vibration.

Another important plus for Si_3N_4 is its failure mechanism. When Si_3N_4 rolling elements fail, they do not fail catastrophically; instead they spall—just like bearing steel elements (though by a different microstructural mechanism). Thus, the design community only had to adapt their existing practices, instead of developing entirely new practices to accommodate new failure modes. The main commercial applications of silicon nitride bearing elements are listed in Table 2.

Cutting Tool Inserts While ceramic cutting tools have been in use for over 60 years, it is only within the past two decades that they have found major application, principally in turning and milling cast iron and nickel-based superalloys and finishing of hardened steels. In these areas ceramics based on aluminum oxide and silicon nitride significantly outperform cemented carbides and coated carbides. High-speed cutting tool tips can encounter temperatures of 1000°C or higher. Thus, a key property for an efficient cutting tool is hot hardness. Both the alumina and Si_3N_4 families of materials retain a higher hardness at temperatures between 600 and 1000°C than either tool steels or cobalt-bonded WC cermets. The ceramics are also more chemically inert.

The combination of hot hardness and chemical inertness means that the ceramics can run hotter and longer with less wear than the competing materials. Historic concerns with ceramic cutting tools have focused on low toughness, susceptibility to thermal shock, and unpredictable failure times. Improvements in processing together with microstructural modifications to increase fracture toughness have greatly increased the reliability of the ceramics in recent years.

Alumina-based inserts are reinforced (toughened) with zirconia, TiC, or TiN particles or SiC whiskers. The thermal shock resistance of alumina–SiC^w is sufficiently high, so that cooling fluids can be used when cutting Ni-based alloys. Silicon-nitride-based inserts include fully dense Si_3N_4 and SiAlON's, which are solid solutions of alumina in Si_3N_4 . Fully dense Si_3N_4

can have a fracture toughness of $6\text{--}7 \text{ MPa} \cdot \text{m}^{1/2}$, almost as high as cemented carbides ($\sim 9 \text{ MPa} \cdot \text{m}^{1/2}$), a high strength (greater than symbol 1000 MPa), and a low thermal expansion that yields excellent thermal shock behavior. Silicon nitride is the most efficient insert for the turning of gray cast iron and is also used for milling and other interrupted cut operations on gray iron. Because of its thermal shock resistance, coolant may be used with silicon nitride for turning applications. SiAlON's are typically more chemically stable than the Si_3N_4 's but not quite as tough or thermal shock resistant. They are mainly used in rough turning of Ni-based superalloys.

Ceramic inserts are generally more costly than carbides (1.5–2 times more), but their metal removal rates are $\sim 3\text{--}4$ times greater. However, that is not the entire story. Ceramic inserts also demonstrate reduced wear rates. The combination of lower wear and faster metal removal means many more parts can be produced before tools have to be indexed or replaced. In some cases this enhanced productivity is truly astonishing. In the interrupted single-point turning of the outer diameter counterweights on a gray cast-iron crankshaft, a SiAlON tool was substituted for a coated carbide tool. This change resulted in the metal removal rate increasing 150% and the tool life increasing by a factor of 10. Each tool now produced 10 times as many parts and in much less time. A gas turbine manufacturer performing a machining operation on a Ni-based alloy using a SiAlON tool for roughing and a tungsten carbide tool for finishing required a total of 5 hr. Changing to SiC-whisker-reinforced alumina inserts for both operations reduced the total machining time to only 20 min. This yielded a direct savings of \$250,000 per year, freed up 3000 hr of machine time per year, and avoided the need to purchase a second machine tool.

Ceramic Wear Components in Automotive and Light-Truck Engines Several engineering ceramics have combinations of properties that make them attractive materials for a variety of specialized wear applications in automotive engines.

The use of structural ceramics as wear components in commercial engines began in Japan in the early 1980s. Table 3 lists many of the components that have been manufactured, the engine company that first

Table 2 Commercial Applications of Si_3N_4 Hybrid Bearings

Machine tool spindles	The first and largest application, its main benefits are higher speed and stiffness, hence greater throughput and tighter tolerances
Turbomolecular pump shaft	Presently the industry standard, the main benefits are improved pump reliability and marginal lubrication capability, which provide increased flexibility in pump-mounting orientation
Dental drill shaft	The main benefit is sterilization by autoclaving
Aircraft wing flap actuators	Wear and corrosion resistance are the main benefits
In-line skates/mountain bikes	Wear and corrosion resistance are the main benefits
Space Shuttle main-engine oxygen fuel pump	Here, the bearing is lubricated by liquid oxygen. Steel bearings are rated for one flight; Si_3N_4 hybrid bearings are rated for five.

Table 3 Ceramic Wear Components in Automotive and Light-Truck Engines

Component	Engine Manufacturer	Engine Type	Ceramic	Year of Introduction
Rocker arm insert	Mitsubishi	Spark Ignited	Si ₃ N ₄	1984
Tappet	Nissan	Diesel	Si ₃ N ₄	1993
Fuel injector link	Cummins	Diesel	Si ₃ N ₄	1989
Injector shim	Yanmar	Diesel	Si ₃ N ₄	1991
Cam roller	Detroit Diesel	Diesel	Si ₃ N ₄	1992
Fuel injector timing plunger	Cummins	Diesel	ZrO ₂	1995
Fuel pump roller	Cummins	Diesel	Si ₃ N ₄	1996

introduced the component, the material, and the year of introduction. In some of these applications several companies have introduced a version of the component into one or more of their engines.

Many of these applications are driven by the need to control the emissions of heavy-duty diesels. Meeting current emissions requirements creates conditions within the engine fuel delivery system that increase wear of lubricated steel against steel. One of these conditions is increased injection pressure, another is an increase in the soot content of engine lubricating oils. Strategic utilization of ceramic components within the fuel delivery systems of many heavy-duty truck engines has enabled the engines to maintain required performance for warranties of 500,000 miles and more. The fuel injector link introduced by Cummins in 1989 is still in production. Well over a million of these components have been manufactured. And many of these have accumulated more than a million miles of service with so little wear that they can be reused in engine rebuilds. In a newer model electronic fuel injector, Cummins introduced a zirconia timing plunger. The part has proved so successful that a second zirconia component was added to the timing plunger assembly several years later. Increasingly stringent emissions requirements for heavy diesels have increased the market for ceramic components in fuel injectors and valve train components. Many of these heavy-duty engine parts are manufactured at rates of 20,000 up to 200,000 per month.

Perhaps the largest remaining problem for this set of applications is cost. Ceramic parts are still more expensive than generally acceptable for the automotive industry. Reluctance of designers to try ceramic solutions still exists, but it is greatly diminishing thanks to the growing list of reliable and successful applications of structural ceramic engine components.

4.2 Thermostructural Applications

Due to the nature of their chemical bond, many ceramics maintain their strength and hardness to higher temperatures than metals. For example, at temperatures above 1200°C, silicon carbide and silicon nitride ceramics are considerably stronger than any superalloy. As a consequence, structural ceramics have been considered and utilized in a number of demanding applications where both mechanically imposed tensile stresses and thermally imposed tensile stresses are

present. One dramatic example is the ceramic (silicon nitride) turbocharger that has been in commercial production for automobiles in Japan since 1985. Over one million of these have been manufactured and driven with no recorded failure. This is a very demanding application, as the service temperature can reach 900°C, stresses at ~700°C can reach 325 MPa, and the rotor must also endure oxidative and corrosive exhaust gases that may contain erosion-inducing rust and soot particles. Silicon nitride gas turbine nozzle vanes have been flying for several years in aircraft auxiliary power units. Other applications include heat exchangers and hot-gas valving. Recently, ceramic matrix composites have been introduced as disks for disk breaks in production sports cars by two European manufacturers. A major future market for structural ceramics may be high-performance automotive valves. Such valves are currently undergoing extensive, multiyear fleet tests in Germany.

This class of applications requires a focus on the strength, Weibull modulus, m (the higher the m , the narrower the distribution of observed strength values), thermal shock resistance, and often the stress rupture (strength decrease over time at temperature) and/or creep (deformation with time at temperature) behavior of the materials. Indeed, as shown in Fig. 2, the stress rupture performance of current structural ceramics represents a significant jump in materials performance over superalloys.

The thermal shock resistance of a ceramic is a systems property rather than a fundamental materials property. Thermal shock resistance is given by the maximum temperature change a component can sustain, ΔT :

$$\Delta T = \frac{\sigma(1 - \mu)}{\alpha E} \frac{k}{r_m h} S \quad (2)$$

where σ is strength, μ is Poisson's ratio, α is the coefficient of thermal expansion (CTE), E is Young's modulus, k is thermal conductivity, r_m is the half-thickness for heat flow h is the heat transfer coefficient and S is a shape factor totally dependent on component geometry.¹⁰ Thus it can be seen that thermal shock resistance, ΔT , is made up of terms wholly dependent on materials properties and dependent on heat transfer conditions and geometry. It is the role of the

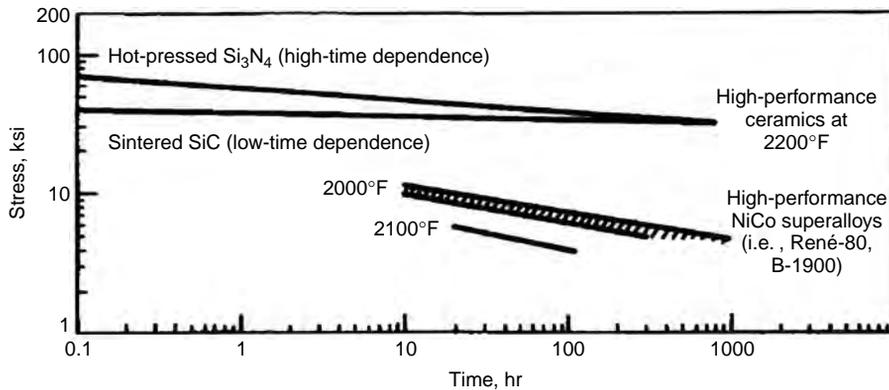

Fig. 2 Stress rupture performance of nonoxide structural ceramics compared to superalloys (oxidizing atmosphere).

Table 4 Calculated Thermal Shock Resistance of Various Ceramics

Material	σ (MPa)	μ	CTE (cm/cm · K)	E (GPa)	R (K)
Al ₂ O ₃ (99 %)	345	0.22	7.4×10^{-6}	375	97

LAS (glass CERAMIC)	96	0.27	0.5×10^{-6}	68	2061
Al titanate	41	0.24	1.0×10^{-6}	11	2819

ceramic engineer to maximize the former and of the design engineer to maximize the latter two terms. It has become usual practice to report the materials-related thermal shock resistance as the instantaneous thermal shock parameter R , which is equal to

$$R = \frac{\sigma(1 - \mu)}{\alpha E} \quad (3)$$

The value of R for selected ceramics is presented in Table 4. Another frequently used parameter is R' , the thermal shock resistance where some heat flow occurs: R' is simply R multiplied by the thermal conductivity, k . For cases where heat transfer environments are complex, Ref. 11 lists 22 figure of merit for selecting ceramics to resist thermal stress.

4.3 Corrosion Resistance

Many advanced structural ceramics such as alumina, silicon nitride, or SiC have strong atomic bonding that yields materials that are highly resistant to corrosion by acidic or basic solutions at room temperature (the notable exception being glass or glass-bonded ceramics attacked by HF). This corrosion resistance has led to many applications. Carbonated soft drinks are acidic, and alumina valves are used to meter and dispense these beverages at refreshment stands. The chemical

industry utilizes a wide variety of ceramic components in pumps and valves for handling corrosive materials. For example, the outstanding corrosion resistance of fully dense SiC immersed in a variety of hostile environments is given in Table 5. There are many cases where corrosion and particulate wear are superimposed, as in the handling of pulp in papermaking or transporting slurries in mineral processing operations, and ceramics find frequent application in such uses.

Table 5 Weight Loss of Fully Dense SiC in Acids and Bases^a

Reagent (wt %)	Test Temperature (°C)	Weight Loss (mg/cm ² · yr)
98% H ₂ SO ₄	100	1.5
50% NaOH	100	2.5
53% HF	100	<0.2
85% H ₃ PO ₄	100	<0.2
45% KOH	100	<0.2
25% HCl	100	<0.2
10% HF + 57% HNO ₃	25	<0.2

Table 6 Key Properties for Electronic Substrates and Packages

Material	CTE ($10^{-6}/K$)	Thermal Conductivity (W/mK)	Resistivity	Dielectric Constant
Al ₂ O ₃ (96%)	6.8	26	$>10^{14}$	9.5
Al ₂ O ₃ (99%)	6.7	35	$>10^{14}$	10
AlN	4.5	140–240	$>10^{14}$	9
BeO	6.4	250	$>10^{14}$	6.5
Diamond	2	2000	$>10^{14}$	5.5
Silicon	2.8	150		

Note: CTE and thermal conductivity are at room temperature, and the dielectric constant is at 1 MHz.

4.4 Passive Electronics

The role of passive electronics is to provide insulation (prevent the flow of electrons) either on a continuous basis (as in the case of substrates or packages for microelectronics) or on an intermittent basis, as is the case for ceramic capacitors (which store electric charge and hence need a high polarizability). These applications constitute two of the largest current markets for advanced ceramics. For electronic substrates and packages key issues include the minimization of thermal mismatch stresses between the Si (or GaAS) chip and the package material (so the CTE will be important) and dissipation of the heat generated as electrons flow through the millions of transistors and resistors that comprise modern microelectronic chips; hence the thermal conductivity is a key property. All other things being equal, the delay time for electrons to flow in the circuit is proportional to the square root of the dielectric constant of the substrate (or package) material. Additionally, the chip or package must maintain its insulating function, so resistivities of $>10^{14}$ are required. Most high-performance packages for computer chips are alumina. With the advent of microwave integrated circuits (e.g., cell phones) aluminum nitride substrates are beginning to be utilized for high thermal conductivity. The environmental drawbacks to machining BeO have tended to favor the use of AlN to replace or avoid the use of BeO. Synthetic diamond is an emerging substrate material for special applications. Isotopically “pure” synthetic, single-crystal diamond has values of thermal conductivity approaching 10,000 W/mK. Typical values of the above properties for each of these materials are given in Table 6, along with selected properties of silicon for comparison. For design purposes exact values for specific formulations of the materials should be obtained from the manufacturers.

Over a billion ceramic capacitors or multilayer ceramic capacitors (MLCCs) are made every day.¹² Since electrons do not flow through capacitors, they are considered passive electronic components. However, the insulators from which ceramic capacitors are made polarize, thereby separating electric charge. This separated charge can be released and flow as electrons, but the electrons do not flow through the dielectric

Table 7 Dielectric Constants for Various Ceramic Capacitor Materials

Material	Dielectric Constant at RT
Tantalum oxide (Ta ₂ O ₅)	~25
Barium titanate	~5,000
Barium–zirconium titanate	~20,000
Lead–zirconium titanate (PZT)	~2,000
PZT with W or Mg additives	~9,000
Lead magnesium niobate (PMN)	~20,000
Lead zinc niobate (PZN)	~20,000

material of which the capacitor is composed. Thus, the materials parameter, which determines the amount of charge that can be stored, the dielectric constant k , is the key parameter for design and application. Table 7 lists the approximate dielectric constant at room temperature (RT) for several families of ceramics used in capacitor technology. The dielectric constant varies with both temperature and frequency. Thus, for actual design precise curves of materials performance over a relevant range of temperatures and frequencies are often utilized. Many ceramics utilized as capacitors are ferroelectrics, and the dielectric constant of these materials is usually a maximum at or near the Curie temperature.

4.5 Piezoceramics

Piezoceramics are a multi-billion-dollar market.¹³ Piezoceramics are an enabling material for sonar systems, medical ultrasonic imaging, micromotors and micropositioning devices, the timing crystals in our electronic watches, and numerous other applications. A piezoelectric material will produce a charge (or a current) if subjected to pressure (the *direct* piezoelectric effect) or, if a voltage is applied, the material will produce a strain (the *converse* piezoelectric effect). Upon the application of a stress, a polarization charge, P , per unit area is created that equals $d\sigma$, where σ is the applied stress and d is the piezoelectric modulus. This modulus, which determines piezoelectric behavior, is a third-rank tensor¹⁴ that is thus highly dependent on directions along which the crystal is stressed. For example, a quartz crystal stressed in the [100] direction will produce a voltage, but one stressed in the

[001] direction will not. In a polycrystalline ceramic the random orientation of the grains in an as-fired piezoceramic will tend to minimize or zero out any net piezoelectric effects. Thus, polycrystalline piezoceramics have to undergo a postsintering process to align the electrically charged dipoles within the polycrystalline component. This process is known as poling and it requires the application of a very high electric field. If the piezoceramic is taken above a temperature, known as the Curie temperature, a phase transformation occurs and piezoelectricity will disappear. The piezoelectric modulus and the Curie temperature are thus two key materials selection parameters for piezoceramics.

The ability of piezoceramics to almost instantaneously convert electrical current to mechanical displacement, and vice versa, makes them highly useful as transducers. The efficiency of conversion between mechanical and electrical energy (or the converse) is measured by a parameter known as the coupling coefficient. This is a third key parameter that guides the selection of piezoelectric materials.

Although piezoelectricity was discovered by Pierre and Jacques Curie in 1880, piezoceramics were not widely utilized until the development of polycrystalline barium titanate in the 1940s and PZTs in the 1950s. Both of these materials have high values of d and thus develop a high voltage for a given applied stress. PZT has become widely used because, in addition to a high d value, it also has a very high coupling coefficient. Sonar, in which ultrasonic pulses are emitted and reflected "echoes" are received, is used to locate ships and fish and map the ocean floor by navies, fishermen and scientists all over the globe. Medical ultrasound utilizes phased arrays of piezoceramic transducers to image organs and fetuses noninvasively and without exposure to radiation. A relatively new application that has found significant use in the microelectronics industry is the use of piezoceramics to drive micropositioning devices and micromotors. Some of these devices can control positioning to a nanometer or less. Piezoceramic transducers are combined with sophisticated signal detection and generation electronics to create "active" noise and vibration damping devices. In such devices the electronics detect and quantify a noise spectrum and then drive the transducers to provide a spectrum 180° out of phase with the noise, thereby effectively canceling it.

Many of the current high-performance applications of piezoceramics are based on proprietary modifications of PZT, which contain additions of various dopants or are solid solutions with perovskite compounds of Pb with Mg, Mn, Nb, Sn, Mo, or Ni. Table 8 lists the range of several key piezoceramic selection parameters for proprietary PZT compositions from one manufacturer.

4.6 Transparencies

Transparent ceramics (which include glasses and single-crystal and polycrystalline ceramics) have been

Table 8 Key Properties for PZT-Based Piezoceramics

Material	Piezoelectric Modulus, d_{33} (m/V)	Curie Temperature (°C)	Coupling Coefficient, k_{33}
A	226×10^{-12}	320	0.67
B	635×10^{-12}	145	0.68
C	417×10^{-12}	330	0.73

used as optical transparencies or lenses for millennia. Glass windows were in commercial production in first-century Rome, but it was not until the 1800s, with the need for precision optics for microscopes, telescopes, and ophthalmic lenses, that glasses and other optical materials became the object of serious scientific study. As noted in the introduction, progress in glass science and technology, coupled with lasers, has led to the current broadband digital data transmission revolution via optical fibers. Various ceramic crystals are used as laser hosts and specialty optical lenses and windows. A significant fraction of supermarket scanner windows combine the scratch resistance of sapphire (single-crystal alumina) with its ability to transmit the red laser light that we see at the checkout counter. While such windows are significantly more costly than glass, their replacement rate is so low that they have increased profitability for several supermarket chains. For the same reason the crystal in many high-end watches are scratch-resistant man-made sapphire. Polycrystalline translucent (as opposed to fully transparent) alumina is used as containers (envelopes) for the sodium vapor lamps that light our highways and industrial sites.

Not all windows have to pass visible light. Radar or mid- to far-infrared transparencies look opaque to the human eye but are perfectly functional windows at their design wavelengths. The most demanding applications for such transparencies is for the guidance domes of missiles. Materials that can be used for missile radomes include slip-cast fused silica, various grades of pyroceram (glass ceramics), and silicon-nitride-based materials. Infrared (IR) windows and missile domes include MgF_2 and $ZnSe$. Requirements exist for having missile guidance domes that can transmit in the visible, IR, and radar frequencies (multimode domes). Ceramic materials that can provide such functionality include sapphire and aluminum oxynitride spinel (AlON). In addition to optical properties, missile domes must be able to take high aerothermal loading (have sufficient strength) and be thermal shock resistant (a high-speed missile encountering a rain cloud can have an instant ΔT of minus several hundred degrees kelvin).

Key properties for visible and IR optical materials include the index of refraction, n (which will be a function of wavelength), and absorption or loss. For radar transparencies key parameters are dielectric constant (which can be thought of as analogous to the index of refraction) and dielectric loss.

5 INFORMATION SOURCES

5.1 Manufacturers and Suppliers

There are hundreds of manufacturers of advanced ceramics and glasses. Locating ones that already have the material that is needed and can produce it in the configuration required can be a daunting task. There are two resources published annually that make this task much easier. The American Ceramic Society publishes a directory of suppliers of materials, supplies, and services that can help locate such information quickly. It is called *Ceramic Source*. This directory can also be accessed on the web at www.ceramics.org. A similar *Buyers Guide* is published by *Ceramic Industry Magazine*, and this can also be viewed online at www.ceramicindustry.com. Once a likely source for your need has been identified a visit to the supplier's website can often provide a great deal of background information and specific data, which can make further contacts with the supplier much more meaningful and informative.

5.2 Data

Manufacturer's literature, both hard copy and posted on the web, is an invaluable source of data. The handbooks, textbooks, and encyclopedias listed below are also excellent sources of data. However, before committing to a finalized design or to production, it is advisable to develop your own test data in conformance with your organization's design practice. Such data should be acquired from actual components made by the material, processing route, and manufacturer that have been selected for the production item.

ASM, *Ceramics and Glasses*, Vol. 4: *Engineered Materials Handbook*, ASM International, Materials Park, OH, 1991.

Brook, R. J. (Ed.), *Concise Encyclopedia of Advanced Ceramic Materials*, Pergamon, Oxford, 1991.

Campbell, C. X., and El-Rahaiby, S. K. (Eds.), *Databook on Mechanical and Thermophysical Properties of Whisker-Reinforced Ceramic Matrix Composites*, Ceramics Information Analysis Center, Purdue University, W. Lafayette, IN, and The American Ceramic Society, Westerville, OH, 1995.

Shackelford, J. F., Alexander, W., and Park, J. (Eds.), *Materials Science and Engineering Handbook*, 2nd ed., CRC Press, Boca Raton, FL, 1994.

5.3 Standards and Test Methods

To reliably design, procure materials, and assure reliability, it is necessary to have common, agreed-upon, and authoritative test standards, methods, and practices. Institutions such as the American Society for Testing and Materials (ASTM), the Japanese Institute for Standards (JIS), the German Standards Organization (DIN), and the International Standards Organization (ISO) all provide standards for their various constituencies. The following are a sampling of standards available from the ASTM and JIS for advanced ceramics and ceramic matrix composites. One can reach these organizations at the following addresses.

American Society for Testing and Materials, 100 Barr Harbor Drive, Conshohocken, PA 19428-2959:

- C-177-85(1993), Test Method for Steady State Heat Flux and Thermal Transmission by Means of the Gradient-Hot-Plate Apparatus
- C-1161-90, Test Method for Flexural Strength of Advanced Ceramics at Ambient Temperature
- C-1211-92, Test Method for Flexural Strength of Advanced Ceramics at Elevated Temperature
- C-1259-94, Test Method for Dynamic Young's Modulus, Shear Modulus and Poisson's Ratio for Advanced Ceramics by Impulse Excitation of Vibration
- C-1286-94, Classification for Advanced Ceramics
- C-1292-95A, Test Method for Shear Strength of Continuous Fiber-Reinforced Ceramic Composites (CFCCs) at Ambient Temperatures
- C-1337-96, Test Method for Creep and Creep-Rupture of CFFFs under Tensile Loading at Elevated Temperature
- C-1421-99, Standard Test Method for Determination of Fracture Toughness of Advanced Ceramics at Ambient Temperature
- C-1425-99, Test Method for Interlaminar Shear Strength of 1-D and 2D CFCCs at Elevated Temperature
- E-228-85(1989), Test Method for Linear Thermal Expansion of Solid Materials with a Vitreous Silica Dilatometer
- E-1269-94, Test Method for Determining Specific Heat Capacity by Differential Scanning Calorimetry
- E-1461-92, Test Method for Thermal Diffusion of Solids by the Flash Method

The Japanese Standards Association, 1-24, Akasaka 4, Minato-ku, Tokyo 107 Japan:

- Testing Methods for Elastic Modulus of High Performance Ceramics at Elevated Temperatures; JIS R 1605-(1989)
- Testing Methods for Tensile Strength of High Performance Ceramics at Room and Elevated Temperatures; JIS R 1606-(1990)
- Testing Methods for Fracture Toughness of High Performance Ceramics; JIS R 1607-(1990)
- Testing Methods for Compressive Strength of High Performance Ceramics; JIS R 1608-(1990)
- Testing Methods for Oxidation Resistance of Non-Oxide of High Performance Ceramics; JIS R 1609-(1990)
- Testing Methods for Vickers Hardness of High Performance Ceramics; JIS R 1610-(1991)
- Testing Methods of Thermal Diffusivity, Specific Heat Capacity, and Thermal Conductivity for High Performance Ceramics by Laser Flash Method; JIS R 1611-(1991)

In addition to testing standards, it is possible to obtain standard materials with certified properties to calibrate several of these new standards against your own tests. Such standard materials can be obtained from the National Institute of Science and Technology (NIST). For example, a standard material to calibrate ASTM C-1421-99 is available. Materials standards are not available for all of the above tests.

5.4 Design Handbooks

It has been widely recognized that procedural handbooks that provide methodology on how to design with advanced ceramics and that can provide high-quality evaluated design data are sorely needed for ceramic materials. The ceramics matrix composites (CMCs) community has taken the initiative to begin the process of creating such a handbook for its constituency. The activity is sponsored by various U.S. governmental agencies, including the Department of Defense, the Department of Energy, the Federal Aviation Administration, and the National Aeronautics and Space Administration, and is entitled MIL-Handbook-17. This activity brings together materials suppliers, materials testers, designers, and end users who are engaged in developing a handbook that will provide design tools and guidance; provide guidelines on data generation, documentation, and use; and provide an authoritative source of design quality data. This is a work in progress and its completion is many years off, if ever. Nevertheless, much guidance in design and testing of advanced CMCs has already resulted from this activity. Progress can be followed by periodically accessing the handbook websites at <http://mil-17.udel.edu> or <http://www.materials-sciences.com/MIL17/>. Unfortunately, no similar activity exists for monolithic ceramics.

6 FUTURE TRENDS

It has been estimated that in the United States advanced ceramics of the type discussed above are an over \$8-billion-a-year industry with a growth rate of ~8% per year.¹⁵

The largest segment of this growth will come from the electronics area. Not only will there be significant growth in the "traditional" roles of ceramics as insulators, packages, substrates, and capacitors, but structural ceramics will play a major role in the equipment used in semiconductor manufacturing. This trend will be especially driven by the resistance of ceramics such as SiC, AlN, silicon nitride, and alumina to the erosive and corrosive environments within high-energy plasma chambers used in single-wafer processing operations.

The intertwined global issues of energy sufficiency and environmental protection will see commercial use of advanced ceramics in energy systems as diverse as solid oxide fuel cells and pebble-bed modular reactors (nuclear). As more and more industries move toward "green" (pollution-free) manufacturing, there will be

growth in wear- and corrosion-resistant ceramics for industrial machinery. There will also be substantial growth potential for ceramic filters and membranes. One major environmentally driven opportunity will be particulate traps for diesel trucks and industrial power sources. This technology is just beginning to be commercialized, and it is certain to see rapid growth as emissions requirements for diesel engines grow more stringent. Not all progress in these areas will create increased markets for ceramics; some will reduce them. For example, the rapid growth of energy-efficient light-emitting diode technology for illumination will create a significant growth opportunity for producers of single-crystal SiC substrates and GaN materials. However, this will come at a cost to the ceramics industry of a significant decrease in glass envelopes for incandescent bulbs and fluorescent tubes. Another area of growth will be filter and membranes for filtration of hot or corrosive, or both, gases and liquids.

The explosive growth of fiber-optic- and microwave-based digital communications technology has produced significant opportunities and markets for advanced ceramics and glasses and will continue to do so into the foreseeable future.

Medical applications are sure to grow, in the areas both of diagnostics and prosthetics.

At the entrance to the Pohang Steel complex in Pohang, Republic of Korea, is a wonderful sign. It proclaims, "Resources are Limited—Creativity is Unlimited." This thought certainly applies to the global future of advanced ceramics. Creatively utilized advanced ceramics will effectively expand our resources, protect our environment, and create new technological opportunities. The potential opportunities go far beyond the few discussed in this chapter.

1 INTRODUCTION TO STRESS AND STRAIN

1.1 Definitions of Stress and Strain

Stress at a Point Stress is the description of the intensity of force. For a general state of loading, such as represented in Fig. 1, the stress vector \mathbf{S} acting on

the section D at point Q is given by

$$\mathbf{S} = \lim_{\Delta A \rightarrow 0} \frac{\Delta \mathbf{P}}{\Delta A}$$

where $\Delta \mathbf{P}$ is the force acting on the area ΔA . The stress vector \mathbf{S} can be further divided into a component

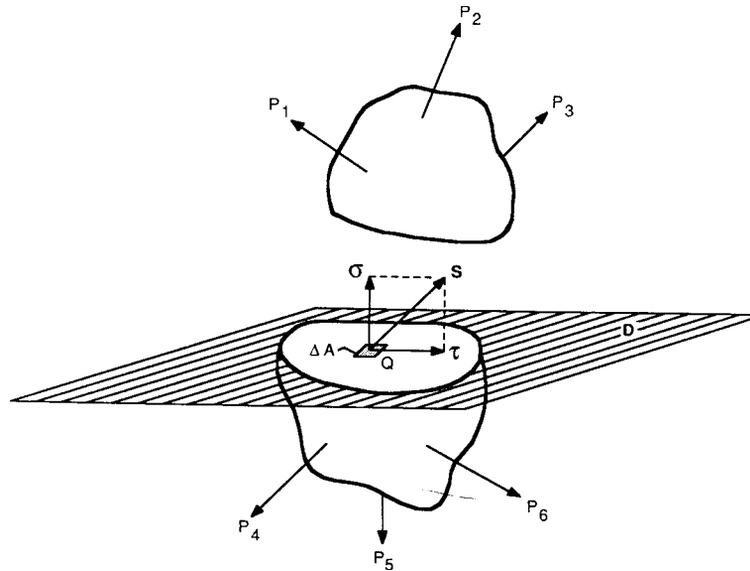

Fig. 1 Normal and shear components of stress.

normal to the section and a component tangential to the section. The normal component is referred to as the normal stress and is usually denoted by σ . The tangential component is referred to as the shear (or shearing) stress and is commonly denoted by τ . It is often useful to further divide τ into two orthogonal components, thus giving an orthogonal triad of stress components. Tensile stresses are normal stresses that tend to increase the length of a member. Compressive stresses are normal stresses that tend to decrease the length of a member. In the U.S. customary system of units, stress is expressed in pounds per square inch (psi). Stress is also commonly expressed in kilopounds per square inch (ksi).

In general, if different sections are considered through the same point in a body under load, different stress vectors will be obtained. In order to completely specify the state of stress at a point, it is sufficient to

consider the stresses acting on three mutually orthogonal sections at that point. The common procedure is to envision an infinitesimally small cube at the point of interest (see Fig. 2). In the figure σ_{ij} is the stress acting on the i face in the j direction, where i and j can be any of $x, y,$ or z . The state of stress at a point is often represented in matrix form as

$$[\sigma_{ij}] = \begin{bmatrix} \sigma_{xx} & \sigma_{xy} & \sigma_{xz} \\ \sigma_{yx} & \sigma_{yy} & \sigma_{yz} \\ \sigma_{zx} & \sigma_{zy} & \sigma_{zz} \end{bmatrix} \quad (1)$$

The three diagonal terms ($\sigma_{xx}, \sigma_{yy}, \sigma_{zz}$) are the normal stress components in the $x, y,$ and z directions, respectively. The off-diagonal terms represent the shear stress components. The i face is considered positive if its outward normal acts in the same direction as the positive i axis; otherwise, it is considered negative. The stress

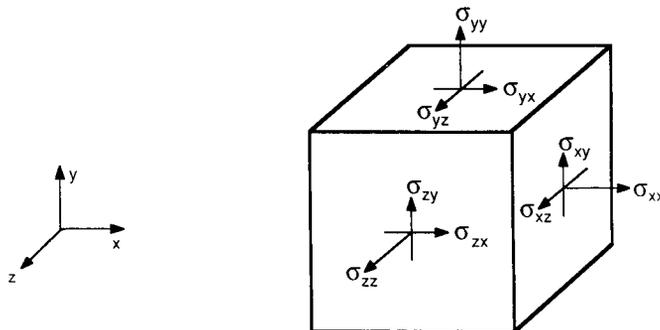

Fig. 2 General state of stress.

σ_{ij} is considered positive if it acts on the positive i face in the positive j direction or if it acts on the negative i face in the negative j direction. Thus, the three faces shown in Fig. 2 are positive as are the stress components acting on them. A positive normal stress is a tensile stress while a negative normal stress is a compressive stress.

If the point of interest is in a state of static equilibrium, it can be shown (by summing moments about a small element) that the cross-shearing stresses must be equal. That is, $\sigma_{xy} = \sigma_{yx}$, $\sigma_{xz} = \sigma_{zx}$, and $\sigma_{yz} = \sigma_{zy}$. The total number of stress components needed to completely define the state of stress at a point is thus reduced to six in this case. This so-called complementary property of shear is not valid for dynamic situations. It is also invalid in situations where surface or body couples are significant but this condition is rarely encountered in practice.

Strain at a Point Deformation is the movement of points in a body relative to each other. Strain is the description of the intensity of deformation. The normal strain at a point Q in the x direction, ϵ_{xx} , is given by

$$\epsilon_{xx} = \lim_{L \rightarrow 0} \frac{\Delta L}{L}$$

Here, L is the original length of a line segment in the x direction centered at Q , and ΔL is the

change in length due to the deformation (Fig. 3). Normal strains are considered positive if they cause an increase in the length of the line segment. The shear (or shearing) strain associated with the orthogonal x and y directions, γ_{xy} , is defined as the change in angle between infinitesimal line segments originally in the x and y directions before deformation (Fig. 4). Shear strains are considered positive if they bring about a reduction in angle. By this definition of shear strain, it is apparent that $\gamma_{xy} = \gamma_{yx}$, provided that no discontinuities (such as void formation) occur at the point of interest.

Tensorial shear strains ϵ_{ij} are defined to be equal to one-half the ordinary shear strains γ_{ij} . That is, $\epsilon_{ij} = \gamma_{ij}/2$ for $i \neq j$. Tensorial shear strains are often used in the theory of elasticity and continuum mechanics because they result in algebraically simpler equations than if ordinary shear strains are employed. Utilizing the tensorial shear strains, the state of strain at a point can be represented in matrix form as

$$[\epsilon_{ij}] = \begin{bmatrix} \epsilon_{xx} & \epsilon_{xy} & \epsilon_{xz} \\ \epsilon_{yx} & \epsilon_{yy} & \epsilon_{yz} \\ \epsilon_{zx} & \epsilon_{zy} & \epsilon_{zz} \end{bmatrix} \quad (2)$$

The three diagonal terms are the normal strain components while the off-diagonal terms are the tensorial shear strain components. Although strain is a dimensionless quantity, it is common to express it in terms of inches per inches or similar units.

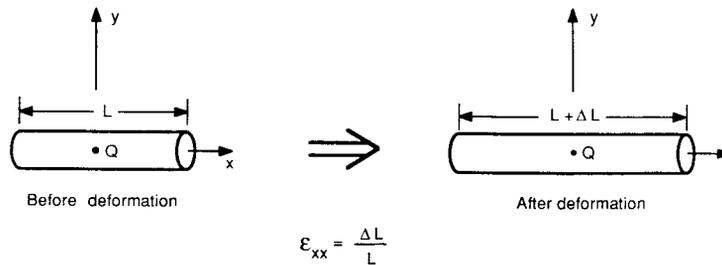

Fig. 3 Definition of normal strain.

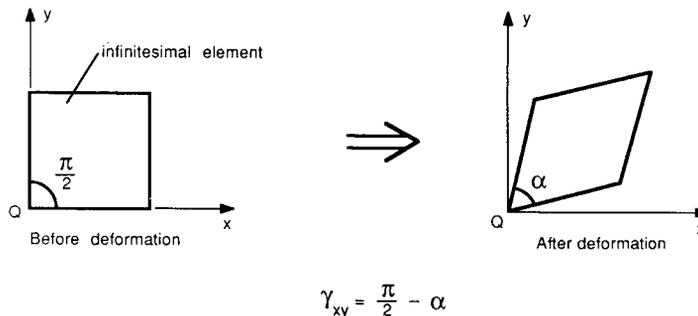

Fig. 4 Definition of shear strain.

Strain–Displacement Relations Mathematically, strains are defined in terms of derivatives of displacements. Assume a general point Q in a body undergoes a displacement to Q' when the body deforms under application of load. Let u , v , and w represent the displacement components of Q in the x , y , and z directions, respectively. Using the previously given definition of normal and shear strains, the strain components at the point Q can be shown to be¹

$$\begin{aligned}\varepsilon_{xx} &= \sqrt{1 + 2\frac{\partial u}{\partial x} + \left(\frac{\partial u}{\partial x}\right)^2 + \left(\frac{\partial v}{\partial x}\right)^2 + \left(\frac{\partial w}{\partial x}\right)^2} - 1 \\ \varepsilon_{yy} &= \sqrt{1 + 2\frac{\partial v}{\partial y} + \left(\frac{\partial u}{\partial y}\right)^2 + \left(\frac{\partial v}{\partial y}\right)^2 + \left(\frac{\partial w}{\partial y}\right)^2} - 1 \\ \varepsilon_{zz} &= \sqrt{1 + 2\frac{\partial w}{\partial z} + \left(\frac{\partial u}{\partial z}\right)^2 + \left(\frac{\partial v}{\partial z}\right)^2 + \left(\frac{\partial w}{\partial z}\right)^2} - 1 \quad (3) \\ \gamma_{xy} = \gamma_{yx} &= \sin^{-1} \left[\frac{\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} + \frac{\partial u}{\partial x} \frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} \frac{\partial v}{\partial y} + \frac{\partial w}{\partial x} \frac{\partial w}{\partial y}}{(1 + \varepsilon_{xx})(1 + \varepsilon_{yy})} \right] \\ \gamma_{xz} = \gamma_{zx} &= \sin^{-1} \left[\frac{\frac{\partial w}{\partial x} + \frac{\partial u}{\partial z} + \frac{\partial w}{\partial z} \frac{\partial w}{\partial x} + \frac{\partial u}{\partial z} \frac{\partial u}{\partial x} + \frac{\partial v}{\partial x} \frac{\partial v}{\partial z}}{(1 + \varepsilon_{xx})(1 + \varepsilon_{zz})} \right] \\ \gamma_{yz} = \gamma_{zy} &= \sin^{-1} \left[\frac{\frac{\partial v}{\partial z} + \frac{\partial w}{\partial y} + \frac{\partial v}{\partial y} \frac{\partial v}{\partial z} + \frac{\partial w}{\partial y} \frac{\partial w}{\partial z} + \frac{\partial u}{\partial y} \frac{\partial u}{\partial z}}{(1 + \varepsilon_{yy})(1 + \varepsilon_{zz})} \right]\end{aligned}$$

Equations (3) give the strain components for arbitrary displacements. They are known as the strain–displacement relations for large displacements. Slight variations of these equations, due to simplifying assumptions or slightly different definition of strain, are often found in the literature (see, e.g., Refs. 2, Chapter 33, and 3).

If the displacements and strains are sufficiently small, the higher-order terms in Eqs. (3) can be neglected. The equations then reduce to

$$\begin{aligned}\varepsilon_{xx} &= \frac{\partial u}{\partial x} & \gamma_{xy} = \gamma_{yx} &= \frac{\partial v}{\partial x} + \frac{\partial u}{\partial y} \\ \varepsilon_{yy} &= \frac{\partial v}{\partial y} & \gamma_{xz} = \gamma_{zx} &= \frac{\partial w}{\partial x} + \frac{\partial u}{\partial z} \\ \varepsilon_{zz} &= \frac{\partial w}{\partial z} & \gamma_{yz} = \gamma_{zy} &= \frac{\partial w}{\partial y} + \frac{\partial v}{\partial z}\end{aligned} \quad (4)$$

These equations are known as the strain–displacement relations for small displacements.

Equations of Compatibility Equations (4) allow for the determination of six strain components using only three displacement components. Physically, this implies that the strains must be compatible; that is, the infinitesimal elements of the deformed member must

fit together without any voids or overlap being present. Mathematically, this implies that the strains are not arbitrary functions of the coordinates. There must exist three equations relating the strains to one another. These equations of compatibility are as follows:

$$\begin{aligned}\frac{\partial^2 \gamma_{xy}}{\partial x \partial y} &= \frac{\partial^2 \varepsilon_{xx}}{\partial y^2} + \frac{\partial^2 \varepsilon_{yy}}{\partial x^2} \\ \frac{\partial^2 \gamma_{yz}}{\partial y \partial z} &= \frac{\partial^2 \varepsilon_{yy}}{\partial z^2} + \frac{\partial^2 \varepsilon_{zz}}{\partial y^2} \\ \frac{\partial^2 \gamma_{zx}}{\partial z \partial x} &= \frac{\partial^2 \varepsilon_{zz}}{\partial x^2} + \frac{\partial^2 \varepsilon_{xx}}{\partial z^2}\end{aligned} \quad (5a)$$

Three additional compatibility equations are often used,

$$\begin{aligned}2 \frac{\partial^2 \varepsilon_{xx}}{\partial y \partial z} &= \frac{\partial}{\partial x} \left(-\frac{\partial \gamma_{yz}}{\partial x} + \frac{\partial \gamma_{zx}}{\partial y} + \frac{\partial \gamma_{xy}}{\partial z} \right) \\ 2 \frac{\partial^2 \varepsilon_{yy}}{\partial z \partial x} &= \frac{\partial}{\partial y} \left(\frac{\partial \gamma_{yz}}{\partial x} - \frac{\partial \gamma_{zx}}{\partial y} + \frac{\partial \gamma_{xy}}{\partial z} \right) \\ 2 \frac{\partial^2 \varepsilon_{zz}}{\partial x \partial y} &= \frac{\partial}{\partial z} \left(\frac{\partial \gamma_{yz}}{\partial x} + \frac{\partial \gamma_{zx}}{\partial y} - \frac{\partial \gamma_{xy}}{\partial z} \right)\end{aligned} \quad (5b)$$

It can be shown that Eqs. (5b) are not independent of Eqs. (5a).² The equations of compatibility are used in the theory of elasticity. They are also useful in verifying the accuracy of experimentally determined strains such as in the Moiré method of strain analysis.

Stress Equations of Equilibrium By considering the static equilibrium of an infinitesimal element, it can be shown that the following equations must hold:

$$\begin{aligned}\frac{\partial \sigma_{xx}}{\partial x} + \frac{\partial \sigma_{yx}}{\partial y} + \frac{\partial \sigma_{zx}}{\partial z} + F_x &= 0 \\ \frac{\partial \sigma_{xy}}{\partial x} + \frac{\partial \sigma_{yy}}{\partial y} + \frac{\partial \sigma_{zy}}{\partial z} + F_y &= 0 \\ \frac{\partial \sigma_{xz}}{\partial x} + \frac{\partial \sigma_{yz}}{\partial y} + \frac{\partial \sigma_{zz}}{\partial z} + F_z &= 0\end{aligned} \quad (6)$$

where F_x , F_y , and F_z are the body forces per unit volume in the x , y , and z directions, respectively. Equations (6) are known as the stress equations of equilibrium.

1.2 Linear Elastic Stress–Strain Relationships

Stresses and strains in a solid body are generally not independent but rather can be related to each other. The exact form of these relationships depends on whether the body is behaving in an elastic, plastic, viscoelastic, or some other fashion. The relationships also depend

on whether the material is isotropic or anisotropic. An isotropic material displays the same properties in all directions. An anisotropic material displays different properties in different directions. Only isotropic response will be considered here. Anisotropic response is discussed in Section 7 on composite materials.

A member is said to experience elastic response if it returns to its original shape upon removal of loads. If, in addition, the relationship between stress and strain can be written in a linear form, the member is said to be experiencing linear elastic response.

Axial Loading For the case of uniaxial loading of a prismatic member, the stress-strain relationship is

$$\sigma_a = \frac{P}{A} = E\varepsilon_a \quad (7)$$

where P is the applied axial force, A is the cross-sectional area of the member, ε_a is the axial strain, and E is a material constant known as the modulus of elasticity or Young's modulus. Equation (7) is commonly referred to as Hooke's law. The transverse strain, ε_t , is given by

$$\varepsilon_t = -\nu\varepsilon_a = \frac{-\nu\sigma_a}{E} \quad (8)$$

where ν is a material constant known as Poisson's ratio. Its value is always between 0 and $\frac{1}{2}$ for linear elastic, isotropic response.

If the member has a length L , the axial elongation, δ , is given by $\delta = \varepsilon_a L$. In view of Eq. (7) this becomes $\delta = PL/AE$. If P , A , or E varies along the length of the member, the deflection must be found by integrating $\varepsilon_a dx$ over the length of the member:

$$\delta = \int_0^L \frac{P dx}{AE}$$

Multiaxial State of Stress For the general case of a three-dimensional state of stress, the stress-strain relationships are

$$\begin{aligned} \varepsilon_{xx} &= \frac{1}{E}[\sigma_{xx} - \nu(\sigma_{yy} + \sigma_{zz})] & \gamma_{xy} &= \frac{\sigma_{xy}}{G} \\ \varepsilon_{yy} &= \frac{1}{E}[\sigma_{yy} - \nu(\sigma_{xx} + \sigma_{zz})] & \gamma_{xz} &= \frac{\sigma_{xz}}{G} \\ \varepsilon_{zz} &= \frac{1}{E}[\sigma_{zz} - \nu(\sigma_{xx} + \sigma_{yy})] & \gamma_{yz} &= \frac{\sigma_{yz}}{G} \end{aligned} \quad (9)$$

where G is a material constant known as the shear modulus or modulus of rigidity. Equations (9) are often referred to as the generalized Hooke's law. These

equations can be inverted to give the stresses in terms of the strains:

$$\begin{aligned} \sigma_{xx} &= \frac{E}{(1+\nu)(1-2\nu)}[(1-\nu)\varepsilon_{xx} + \nu(\varepsilon_{yy} + \varepsilon_{zz})] \\ \sigma_{xy} &= G\gamma_{xy} \\ \sigma_{yy} &= \frac{E}{(1+\nu)(1-2\nu)}[(1-\nu)\varepsilon_{yy} + \nu(\varepsilon_{xx} + \varepsilon_{zz})] \\ \sigma_{xz} &= G\gamma_{xz} \\ \sigma_{zz} &= \frac{E}{(1+\nu)(1-2\nu)}[(1-\nu)\varepsilon_{zz} + \nu(\varepsilon_{xx} + \varepsilon_{yy})] \\ \sigma_{yz} &= G\gamma_{yz} \end{aligned} \quad (10)$$

The material constants G , E , and ν are not independent of one another. It is shown in the theory of elasticity that they are related by the equation $G = E/2(1+\nu)$.

The dilatation, e , represents the change in volume per unit volume. For small strains it is given by $e = \varepsilon_{xx} + \varepsilon_{yy} + \varepsilon_{zz}$. For the case of pure hydrostatic stress, $\sigma_{xx} = \sigma_{yy} = \sigma_{zz} = -p$ and $\sigma_{xy} = \sigma_{xz} = \sigma_{yz} = 0$, where p is the uniform pressure acting on the member. In this case the dilatation is linearly related to the pressure by $e = -p/k$, where k is a material constant known as the bulk modulus. The bulk modulus is related to E and ν by the equation $k = E/3(1-2\nu)$.

One other elastic constant that arises in the theory of elasticity is Lamé's constant, λ . Unlike the other constants (E , ν , G , and k), λ has no physical significance. That is, there is no mechanical test that can be used to directly measure λ . Since only two material constants are required to completely describe linear elastic isotropic response, the constants E , ν , G , k , and λ can be interrelated (see Ref. 1, p. 44, for details).

Plane Stress Plane stress, or the two-dimensional state of stress, exists at a point if an orientation can be found such that the stress in one of the three coordinate directions is zero. If this direction of zero stress is arbitrarily taken to be the z direction (i.e., $\sigma_{zz} = \sigma_{xz} = \sigma_{yz} = 0$), then Eqs. 9 reduce to

$$\begin{aligned} \varepsilon_{xx} &= \frac{1}{E}(\sigma_{xx} - \nu\sigma_{yy}) & \gamma_{xy} &= \frac{\sigma_{xy}}{G} \\ \varepsilon_{yy} &= \frac{1}{E}(\sigma_{yy} - \nu\sigma_{xx}) & \gamma_{xz} &= 0 \\ \varepsilon_{zz} &= \frac{-\nu}{E}(\sigma_{xx} + \sigma_{yy}) & \gamma_{yz} &= 0 \end{aligned} \quad (11)$$

In addition, ε_{zz} can be written as

$$\varepsilon_{zz} = \frac{-\nu}{1-\nu}(\varepsilon_{xx} + \varepsilon_{yy})$$

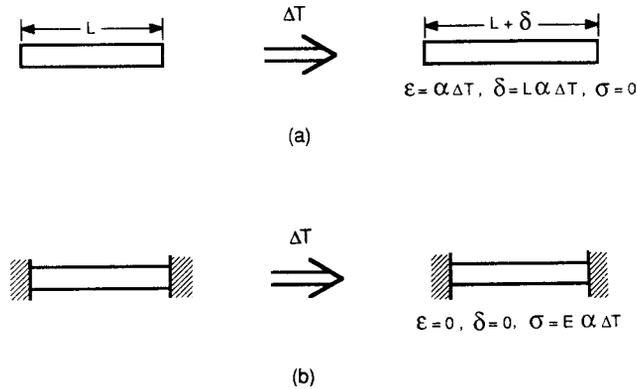

Fig. 5 Thermally induced stresses and strains: (a) member free to expand; (b) member fixed at both ends.

Equations (10) reduce to

$$\begin{aligned} \sigma_{xx} &= \frac{E}{1-\nu^2}(\varepsilon_{xx} + \nu\varepsilon_{yy}) & \sigma_{xy} &= G\gamma_{xy} \\ \sigma_{yy} &= \frac{E}{1-\nu^2}(\varepsilon_{yy} + \nu\varepsilon_{xx}) & \sigma_{xz} &= 0 \\ \sigma_{zz} &= 0 & \sigma_{yz} &= 0 \end{aligned} \quad (12)$$

Plane Strain Plane strain occurs at a point if an orientation can be found such that the strain in one of the three coordinate directions is zero. If this direction is arbitrarily taken to be the z direction, then $\varepsilon_{zz} = \gamma_{xz} = \gamma_{yz} = 0$. Equations (9) reduce to

$$\begin{aligned} \varepsilon_{xx} &= \frac{1+\nu}{E}[(1-\nu)\sigma_{xx} - \nu\sigma_{yy}] & \gamma_{xy} &= \frac{\sigma_{xy}}{G} \\ \varepsilon_{yy} &= \frac{1+\nu}{E}[(1-\nu)\sigma_{yy} - \nu\sigma_{xx}] & \gamma_{xz} &= 0 \\ \varepsilon_{zz} &= 0 & \gamma_{yz} &= 0 \end{aligned} \quad (13)$$

Equations (10) reduce to

$$\begin{aligned} \sigma_{xx} &= \frac{E}{(1+\nu)(1-2\nu)}[(1-\nu)\varepsilon_{xx} + \nu\varepsilon_{yy}] \\ \sigma_{xy} &= G\gamma_{xy} \\ \sigma_{yy} &= \frac{E}{(1+\nu)(1-2\nu)}[(1-\nu)\varepsilon_{yy} + \nu\varepsilon_{xx}] \\ \sigma_{xz} &= 0 \\ \sigma_{zz} &= \frac{\nu E}{(1+\nu)(1-2\nu)}[\varepsilon_{xx} + \varepsilon_{yy}] \\ \gamma_{yz} &= 0 \end{aligned} \quad (14)$$

In addition, σ_{zz} can be written as $\sigma_{zz} = \nu(\sigma_{xx} + \sigma_{yy})$.

Thermal Stresses and Strains Thermal stresses and strains can occur when a member is subjected to a temperature change. For the case of a uniform, unrestrained slender rod of length L , the total increase in length, δ , due to a temperature change ΔT is given by (Fig. 5a)

$$\delta = L \int_T^{T+\Delta T} \alpha(T) dT$$

where α is the material's coefficient of thermal expansion. For many materials, α can be considered to be constant over a wide temperature range. In this case δ is given by $\delta = \alpha L \Delta T$, and the thermal strain is given by $\varepsilon = \delta/L = \alpha \Delta T$. If the slender rod is fixed at both ends so that no deformation can occur in the axial direction as the temperature is changed, an internal axial stress will develop (Fig. 5b). If the magnitude of this stress remains within the linear elastic range, its value is given by

$$|\sigma| = E \int_T^{T+\Delta T} \alpha(T) dT$$

If the temperature change is small enough so that α can be considered a constant, then $\sigma = E\alpha \Delta T$. Thus, the thermal stress is equal to E times the thermal strain that would develop if the member were free to expand. The determination of thermal stresses and strains for members of more complex geometries can be a formidable task. In such cases, assuming the stresses remain within the elastic range, it is necessary to apply the theory of thermal elasticity (see, e.g., Ref. 4).

1.3 Transformations of Stress and Strain

General Equations of Transformation Given the complete state of stress or strain in a given orientation, it is often desirable to obtain the state of stress or strain in some new orientation. Using the notation that

$\cos(i', j)$ represents the direction cosine between the original j coordinate axis and the new i' coordinate axis, the matrix equation for stress transformation from the $Oxyz$ coordinate system to the $Ox'y'z'$ coordinate system is given by

$$[\sigma'] = [\alpha]^T [\sigma] [\alpha] \quad (15)$$

In this equation, $[\sigma]$ is the stress matrix for the original xyz coordinate system [see Eq. (11)], $[\sigma']$ is the stress matrix for the new $x'y'z'$ coordinate system, and $[\alpha]$ is the matrix of direction cosines given by

$$[\alpha] = \begin{bmatrix} \cos(x', x) & \cos(y', x) & \cos(z', x) \\ \cos(x', y) & \cos(y', y) & \cos(z', y) \\ \cos(x', z) & \cos(y', z) & \cos(z', z) \end{bmatrix} \quad (16)$$

Finally, $[\alpha]^T$ is the matrix transpose of $[\alpha]$.

The equation for strain transformation is similarly given by

$$[\varepsilon'] = [\alpha]^T [\varepsilon] [\alpha] \quad (17)$$

Here, $[\varepsilon]$ is the strain matrix for the original xyz coordinate system [see Eq. (2)], $[\varepsilon']$ is the strain matrix

for the new $x'y'z'$ coordinate system, and $[\alpha]$ is again given by Eq. (16).

Transformation about a Fixed Axis If the new orientation is obtained by rotating through an angle θ about the z axis (i.e., $z' = z$), Eqs. (15) and (16) can be greatly simplified. Using the notation of Fig. 6b, where θ is measured positive counterclockwise, it follows that

$$\cos(x', x) = \cos(y', y) = \cos \theta$$

$$\cos(y', x) = \cos(90^\circ + \theta)$$

$$\cos(x', y) = \cos(90^\circ - \theta)$$

$$\cos(z', x) = \cos(x', z) = \cos(z', y) = \cos(y', z) = 0$$

$$\cos(z', z) = 1$$

Equation (15) reduces to

$$\begin{aligned} \sigma'_{xx} &= \frac{1}{2}(\sigma_{xx} + \sigma_{yy}) + \frac{1}{2}(\sigma_{xx} - \sigma_{yy}) \cos 2\theta \\ &\quad + \sigma_{xy} \sin 2\theta \\ \sigma'_{yy} &= \frac{1}{2}(\sigma_{xx} + \sigma_{yy}) - \frac{1}{2}(\sigma_{xx} - \sigma_{yy}) \cos 2\theta \\ &\quad - \sigma_{xy} \sin 2\theta \end{aligned} \quad (18)$$

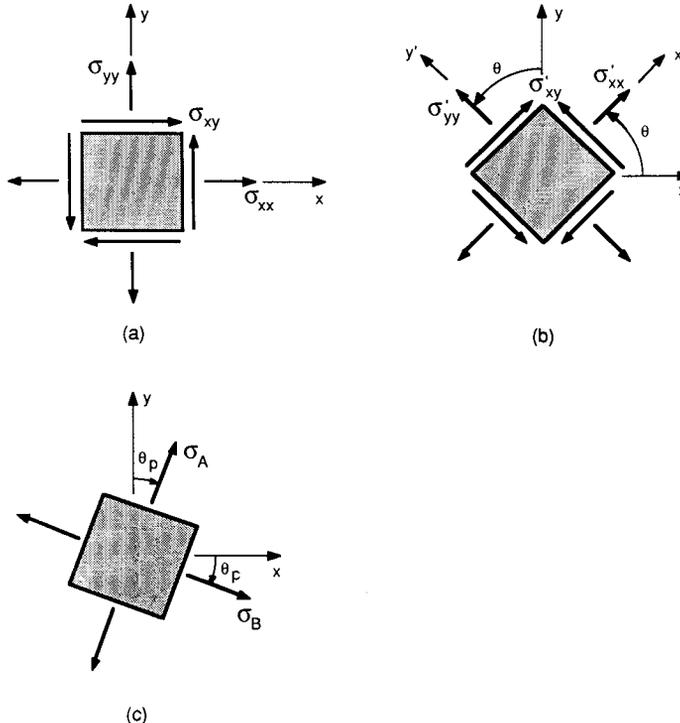

Fig. 6 Two-dimensional coordinate rotation: (a) original configuration; (b) arbitrary rotation; (c) rotation to principal coordinates.

$$\begin{aligned} \sigma'_{xy} &= -\frac{1}{2}(\sigma_{xx} - \sigma_{yy}) \sin 2\theta - \sigma_{xy} \cos 2\theta \\ \sigma'_{zz} &= \sigma_{zz} \quad \sigma'_{xz} = \sigma_{xz} \quad \sigma'_{yz} = \sigma_{yz} \end{aligned}$$

where

$$\begin{aligned} \sigma_{\text{avg}} &= \frac{\sigma_{xx} + \sigma_{yy}}{2} \quad \text{and} \\ R &= \left[\left(\frac{\sigma_{xx} - \sigma_{yy}}{2} \right)^2 + \sigma_{xy}^2 \right]^{1/2} \end{aligned}$$

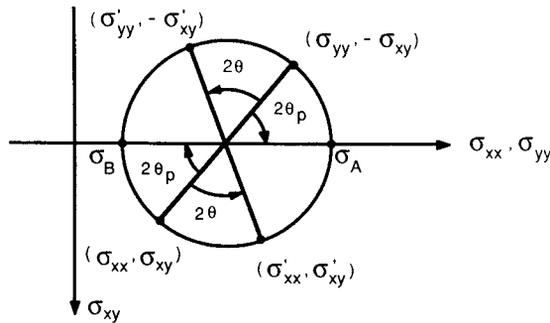

Similarly, Eq. (17) reduces to

$$\begin{aligned} \varepsilon'_{xx} &= \frac{1}{2}(\varepsilon_{xx} + \varepsilon_{yy}) + \frac{1}{2}(\varepsilon_{xx} - \varepsilon_{yy}) \cos 2\theta \\ &\quad + \varepsilon_{xy} \sin 2\theta \\ \varepsilon'_{yy} &= \frac{1}{2}(\varepsilon_{xx} + \varepsilon_{yy}) - \frac{1}{2}(\varepsilon_{xx} - \varepsilon_{yy}) \cos 2\theta \\ &\quad - \varepsilon_{xy} \sin 2\theta \\ \varepsilon'_{xy} &= -\frac{1}{2}(\varepsilon_{xx} - \varepsilon_{yy}) \sin 2\theta + \varepsilon_{xy} \cos 2\theta \\ \varepsilon'_{zz} &= \varepsilon_{zz} \quad \varepsilon'_{xz} = \varepsilon_{xz} \quad \varepsilon'_{yz} = \varepsilon_{yz} \end{aligned} \tag{19}$$

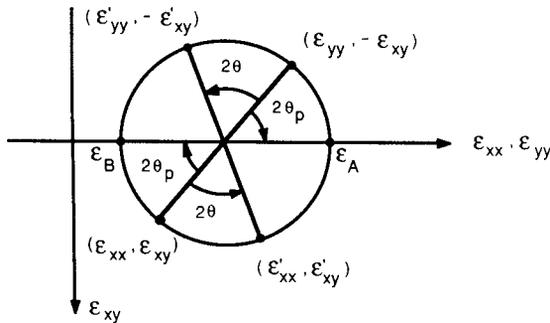

Mohr's Circle for Stress and Strain Through further mathematical manipulation, Eqs. (18) can be written as

$$(\sigma'_{xx} - \sigma_{\text{avg}})^2 + (\sigma'_{xy})^2 = R^2$$

This is the equation of a circle in the $(\sigma_{xx}, \sigma_{xy})$ plane known as Mohr's circle for stress. The horizontal and vertical axes are chosen to represent the applied normal and shear stresses, respectively (Fig. 7a). Normal stresses are plotted positive to the right. Shear stresses are plotted positive downward. With this convention, the points $(\sigma_{xx}, \sigma_{xy})$ and $(\sigma_{yy}, -\sigma_{xy})$ should be plotted on the Mohr's circle in order that the positive direction of θ is the same in Figs. 6b and 7a. Mohr's circle for stress thus consists of the points $(\sigma_{xx}, \sigma_{xy})$ and $(\sigma_{yy}, -\sigma_{xy})$ as 2θ ranges from 0° to 360° . Note that exactly the same Mohr's circle would be obtained if shear stresses were plotted positive upward and the points $(\sigma_{xx}, -\sigma_{xy})$ and $(\sigma_{yy}, \sigma_{xy})$ were plotted. A variety of sign conventions for the shear stress can be found in the literature, but all

(a)

(b)

Fig. 7 Mohr's circles for stress and strain: (a) Mohr's circle for stress; (b) Mohr's circle for strain.

of them will lead to the same Mohr's circle when used consistently in each system.

It is important to keep in mind that a rotation of the element in Fig. 6a through an angle θ to bring about the orientation of Fig. 6b corresponds to a rotation of 2θ on the Mohr's circle in Fig. 7a. It is also important to realize that the application of Mohr's circle relies only on the fact that the old and new coordinate systems have a common axis of rotation (e.g., the z axis). It is not required that the element also be in a state of plane stress as is often stated in elementary strength of materials texts.

Mohr's circle for strain can be constructed in a manner analogous to Mohr's circle for stress. The appropriate equation is

$$(\epsilon'_{xx} - \epsilon_{\text{avg}})^2 + (\epsilon'_{xy})^2 = R^2$$

where

$$\epsilon_{\text{avg}} = \frac{\epsilon_{xx} + \epsilon_{yy}}{2} \quad \text{and}$$

$$R = \left[\left(\frac{\epsilon_{xx} - \epsilon_{yy}}{2} \right)^2 + \epsilon_{xy}^2 \right]^{1/2}$$

Normal strains are plotted horizontally with positive values to the right. Tensorial shear strains are plotted vertically with positive values downward. Mohr's circle for strain thus consists of the points $(\epsilon_{xx}, \epsilon_{xy})$ and $(\epsilon_{yy}, -\epsilon_{xy})$ as 2θ ranges from 0° to 360° (Fig. 7b).

Principal Stresses and Strains For any state of stress at a point there exists an orientation such that the shear stresses vanish. In this orientation the stress matrix is given by

$$[\sigma] = \begin{bmatrix} \sigma_1 & 0 & 0 \\ 0 & \sigma_2 & 0 \\ 0 & 0 & \sigma_3 \end{bmatrix}$$

where $\sigma_1, \sigma_2,$ and σ_3 are known as the principal stresses. It is common to assume that the orientation has been taken so that σ_1 is the largest algebraic stress and σ_3 is the smallest algebraic stress. The principal stresses represent the solutions to the cubic equation

$$\sigma_n^3 - I_1\sigma_n^2 + I_2\sigma_n - I_3 = 0 \quad (20)$$

where $I_1 = \sigma_{xx} + \sigma_{yy} + \sigma_{zz}$

$$I_2 = \sigma_{xx}\sigma_{yy} + \sigma_{xx}\sigma_{zz} + \sigma_{yy}\sigma_{zz} - \sigma_{xy}^2 - \sigma_{xz}^2 - \sigma_{yz}^2$$

$$I_3 = \sigma_{xx}\sigma_{yy}\sigma_{zz} - \sigma_{xx}\sigma_{yz}^2 - \sigma_{yy}\sigma_{xz}^2 - \sigma_{zz}\sigma_{xy}^2 + 2\sigma_{xy}\sigma_{xz}\sigma_{yz}$$

$I_1, I_2,$ and I_3 are known as the first, second, and third invariants of stress, respectively. These quantities are independent of the orientation being considered.

Once the principal stresses have been found, their orientations can be determined by substituting each principal stress, σ_n , individually into the following set of equations and solving for the direction cosines associated with that principal stress:

$$(\sigma_{xx} - \sigma_n) \cos(n, x) + \sigma_{yx} \cos(n, y) + \sigma_{zx} \cos(n, z) = 0$$

$$\sigma_{xy} \cos(n, x) + (\sigma_{yy} - \sigma_n) \cos(n, y) + \sigma_{zy} \cos(n, z) = 0$$

$$\sigma_{xz} \cos(n, x) + \sigma_{yz} \cos(n, y) + (\sigma_{zz} - \sigma_n) \cos(n, z) = 0$$

$$\cos^2(n, x) + \cos^2(n, y) + \cos^2(n, z) = 1$$

The last equation is based on the fact that a direction cosine vector has unit magnitude. It is required since the first three equations are not linearly independent and hence are insufficient to explicitly solve for the direction cosines.

Just as for stresses, an orientation can be found such that the shear strains vanish. The principal strains ($\epsilon_1, \epsilon_2,$ and ϵ_3) represent the solutions to the cubic equation

$$\epsilon_n^3 - J_1\epsilon_n^2 + J_2\epsilon_n - J_3 = 0 \quad (21)$$

where $J_1 = \epsilon_{xx} + \epsilon_{yy} + \epsilon_{zz}$

$$J_2 = \epsilon_{xx}\epsilon_{yy} + \epsilon_{xx}\epsilon_{zz} + \epsilon_{yy}\epsilon_{zz} - \epsilon_{xy}^2 - \epsilon_{xz}^2 - \epsilon_{yz}^2$$

$$J_3 = \epsilon_{xx}\epsilon_{yy}\epsilon_{zz} - \epsilon_{xx}\epsilon_{yz}^2 - \epsilon_{yy}\epsilon_{xz}^2 - \epsilon_{zz}\epsilon_{xy}^2 + 2\epsilon_{xy}\epsilon_{xz}\epsilon_{yz}$$

$J_1, J_2,$ and J_3 are known as the first, second, and third invariants of strain, respectively. These quantities remain the same regardless of the orientation under consideration.

Once the principal strains have been found, their orientations can be determined by substituting each principal strain, ϵ_n , individually into the following set of equations and solving for the direction cosines associated with that principal strain:

$$(\epsilon_{xx} - \epsilon_n) \cos(n, x) + \epsilon_{yx} \cos(n, y) + \epsilon_{zx} \cos(n, z) = 0$$

$$\epsilon_{xy} \cos(n, x) + (\epsilon_{yy} - \epsilon_n) \cos(n, y) + \epsilon_{zy} \cos(n, z) = 0$$

$$\epsilon_{xz} \cos(n, x) + \epsilon_{yz} \cos(n, y) + (\epsilon_{zz} - \epsilon_n) \cos(n, z) = 0$$

$$\cos^2(n, x) + \cos^2(n, y) + \cos^2(n, z) = 1$$

Again, the last equation is required since the first three equations are not linearly independent.

For linear elastic isotropic response, $\sigma_{ij} = G\gamma_{ij} = 2G\epsilon_{ij}$ for $i \neq j$. It thus follows in this case that $\epsilon_{ij} = 0$ when $\sigma_{ij} = 0$. That is, the principal directions of stress and strain coincide. If the principal stresses are known, the principal strains can be found using Eqs. (9) rather

than solving Eq. (21). Similarly, if the principal strains are known, the principal stresses can be found using Eqs. (10) rather than solving Eq. (20).

For anisotropic response, such as often occurs in composite materials, the principal strains may have a different orientation than the principal stresses. It is worth noting, however, that Eqs. (20) and (21) are still valid for anisotropic response, as are Mohr's circles for stress and strain.

For the case of plane stress ($\sigma_{zz} = \sigma_{xz} = \sigma_{yz} = 0$) in a material exhibiting linear elastic isotropic response, it is clear that the z direction is a principal direction. The other two principal directions lie in the xy plane. Since the horizontal axis of Mohr's circle represents a state of zero shear stress, the principal stresses σ_A and σ_B and their directions relative to the x axis (θ_p and $\theta_p + 90^\circ$, respectively) can be found easily from Mohr's circle (Fig. 7a). The corresponding rotated element is shown in Fig. 6c. The principal strains ε_A and ε_B in this case can also be found easily from the corresponding Mohr's circle for strain (Fig. 7b). The principal strain in the z direction can be found from $\varepsilon_{zz} = (-\nu/E)(\sigma_{xx} + \sigma_{yy})$.

Similarly, for the case of plane strain ($\varepsilon_{zz} = \varepsilon_{xz} = \varepsilon_{yz} = 0$), the z direction is again a principal direction. The determination of the principal stresses and strains lying within the xy plane can once more be accomplished using Mohr's circles. The principal stress in the z direction can be found from

$$\sigma_{zz} = \frac{\nu E}{(1 + \nu)(1 - 2\nu)}(\varepsilon_{xx} + \varepsilon_{yy})$$

Maximum Shear Stress The maximum shear stress at a point is given by $\tau_{\max} = (\sigma_1 - \sigma_3)/2$, where σ_1 and σ_3 are the maximum and minimum principal stresses, respectively. The maximum shear stress acts in the 1–3 plane at an angle of $\pm 45^\circ$ to the 1 axis.

1.4 Tension Test

The tension test is one of the most fundamental and important of mechanical tests. A wide and diverse set of material properties can be determined from it. Specimens used for tension tests commonly consist of round or rectangular cross sections with a gage region, a gripping region, and an intermediate fillet region. It is important that the gage region has a reduced cross-sectional area; otherwise, the specimen will often fail in or near the region of gripping. The *Annual Book of ASTM Standards*⁵ is a multiple-volume reference containing adopted standards for a wide variety of tests. Included within this book are standards for tension tests on a number of different types of materials. These standards describe the required specimen dimensions, gripping arrangement, and testing procedure. In particular, see Volume 3.01, standard E8 for tension testing of metallic materials.

In general, to perform a tension test, the following procedure is used. First, the specimen is appropriately

gripped in the testing system. This is usually a screw-driven tension testing machine or the more sophisticated closed-loop, servo-hydraulic mechanical testing system (see Section 9.1 for further discussion of these testing systems). Next, a displacement measuring device must be attached to the specimen. When specimen size and rigidity are sufficient the attachment of an extensometer within the gage region of the specimen is desirable. Finally, the specimen is pulled apart at a constant displacement rate until failure occurs. While the test is proceeding, the load on the specimen and the displacement of the specimen are continuously recorded. The resulting load–displacement plot must be converted to an engineering stress–strain plot or a true stress–strain plot so that mechanical properties can be determined.

Engineering Stress and Strain Engineering stress S is defined as the instantaneous value of the load P on the specimen divided by the specimen's original cross-sectional area, A_0 . That is, $S = P/A_0$. Engineering strain e is defined by $e = (L - L_0)/L_0$, where L is the instantaneous gage length and L_0 the initial gage length. Engineering stress–strain diagrams for some common materials are shown in Fig. 8. For some materials, the engineering stress does not monotonically increase to failure. This is due to the fact that the specimen necks down within the gage area. When necking down occurs, one small region of the specimen begins to deform at a much more rapid rate than the rest of the specimen. This region of the specimen thus has a much smaller cross-sectional area and hence a larger stress. The strain rate within this region is much higher than in the rest of the specimen; as a result, the load applied to the specimen must be lowered in order to maintain a constant displacement rate in the necked-down region. The state of stress within this region is no longer uniaxial, which further complicates matters. When engineering stress and strain are used, this necking-down phenomenon disguises the true nature of the material's mechanical response. In order to obtain a more realistic material response up to the point of failure, the true stress–strain diagram should be determined.

True Stress and Strain True stress σ is defined as $\sigma = P/A_i$, where A_i is the instantaneous minimal cross-sectional area and P is again the instantaneous value of the load acting on the specimen. Before necking down occurs, A_i will be approximately the same along the entire gage region. Once necking down begins, however, A_i must be measured at the point where the necking down is taking place.

True strain ε is defined by $\varepsilon = \log(L_i/L_0)$, where \log represents the natural logarithm. For this equation to hold, the strain must be uniform within the region where L_i is being measured. This assumption is obviously invalid when necking down occurs within the gage region. To overcome this problem, it is often assumed that plastic deformation occurs with

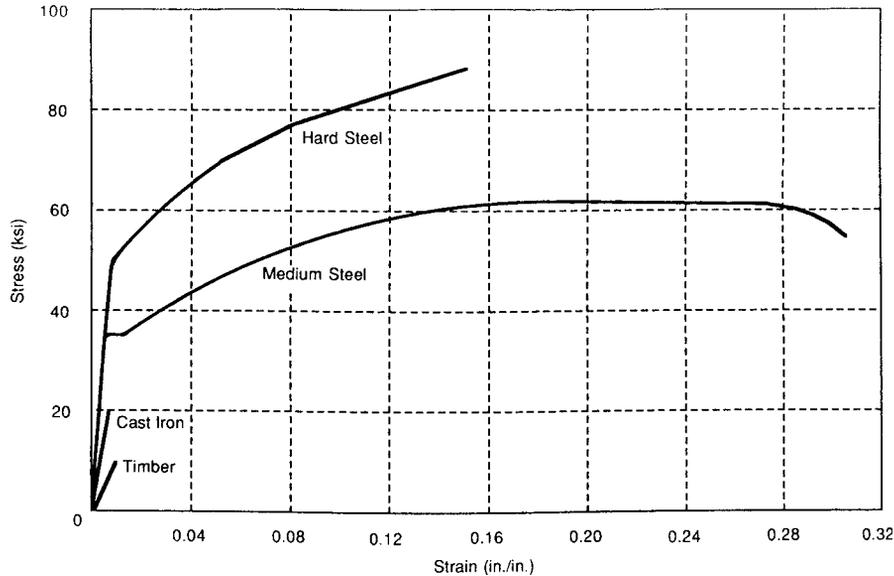

Fig. 8 Monotonic engineering stress-strain diagrams for some common materials.

no change in volume: $A_0 L_0 = A_i L_i$. This assumption is fairly reasonable for many ductile metals. By using this assumption, the true strain can be written as $\epsilon = \log(A_0/A_i)$.

If the instantaneous minimal cross-sectional area can be measured during a test along with P and L_i , and if the constant-volume deformation assumption is valid while plastic deformation is occurring, then a true stress-strain diagram can be constructed. The construction should consist of using the equation $\epsilon = \log(L_i/L_0)$ for true strain in the elastic and initial plastic regions and the equation $\epsilon = \log(A_0/A_i)$ once significant plastic deformation has begun. In practice, however, the equation $\epsilon = \log(A_0/A_i)$ is used for the entire strain range since the amount of error introduced is usually negligible. The equation $\sigma = P/A_i$ for true stress is valid throughout the entire test. Accurate construction of a true stress-strain diagram becomes exceedingly difficult if the plastic deformation cannot be assumed to occur at a constant volume. Finally, it should be mentioned that neither the true stress-strain diagram nor the engineering stress-strain diagram accounts for the fact that the state of stress within the necked-down region is multiaxial. There is no simple way to account for the effect of this multiaxial state of stress on the material's response, so it is customarily ignored. A schematic representation of an engineering stress-strain diagram and the corresponding true stress-strain diagram can be found in Fig. 9.

Relationships between Engineering and True Stress and Strain There are two useful equations for constructing a true stress-strain diagram if the

engineering stress-strain diagram is known. The first equation is given by $\epsilon = \log(1 + e)$. It is based on the assumption of homogeneous strains and is thus valid only up to the point in the tension test when necking down begins. The second equation, $\sigma = S(1 + e)$, assumes a constant-volume process as well as homogeneous strains and is thus valid between the onset of plastic deformation (assuming constant-volume plastic deformation) and the beginning of the necking-down process. In fact, this equation will be slightly inaccurate because of the fact that the elastic deformation that took place prior to the beginning of plastic flow was not a constant-volume process. However, because of the small size of the elastic strains, the error introduced can usually be ignored.

For small strains (such as those that occur within the elastic range of most metals), there is no significant difference between engineering stress-strain and true stress-strain, but for large strains the difference can be considerable. It becomes apparent that the true stress-strain diagram is considerably more difficult to obtain than the engineering stress-strain diagram. As a result, material properties based on the engineering stress-strain diagram are usually reported. However, the importance of the true stress-strain diagram in giving a more representative picture of a material's response should not be overlooked.

Mechanical Properties Determined from the Tension Test A variety of mechanical properties can be determined from a tension test. Of course, some properties such as the yield strength and the strain-hardening exponent only apply to ductile materials.

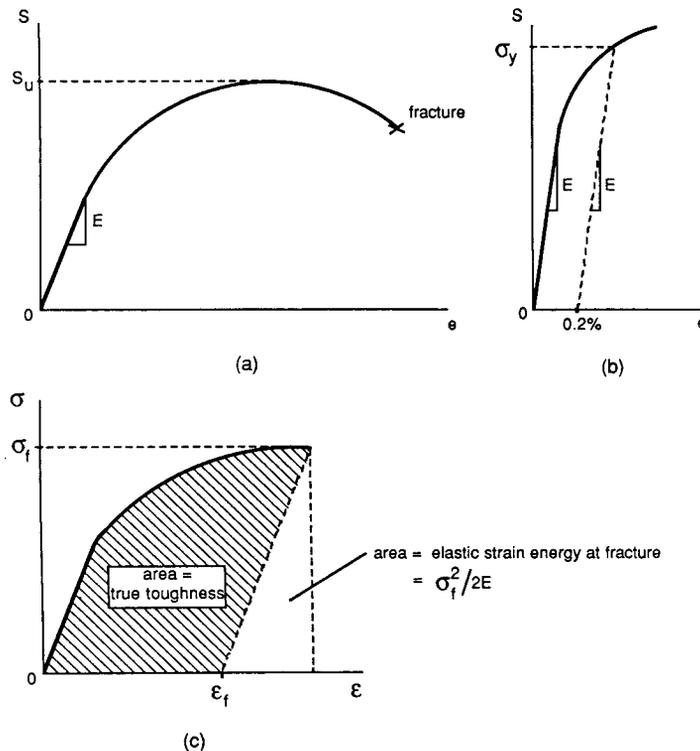

Fig. 9 Material properties determined from stress–strain diagrams: (a) engineering stress–strain diagram; (b) determination of σ_y by offset method; (c) true stress–strain diagram.

Table 1 lists mechanical properties for a wide variety of materials. Many of the mechanical properties that will be discussed are displayed graphically in Fig. 9.

The *modulus of elasticity* E is given by the slope of the initial straight-line portion of the stress–strain diagram.

The *proportional limit* is the largest stress for which the stress–strain relationship is linear. It is the largest stress for which Hooke's law can be applied for the material. This property depends on the judgment of the observer and is thus of limited value.

The *elastic limit* is the largest stress to which a material can be subjected and still return to its original form upon removal of the load. It can be determined by application and release of a series of increasing loads to the specimen until a permanent deformation is observed upon release of the load. With the advent of equipment that can measure extremely small strains, it has been found that most materials will experience a small amount of permanent deformation at stresses far below what was once thought to be the elastic limit. The determination of this property is thus dependent on the sensitivity of the testing equipment. Its use in design is strongly discouraged.

The *yield strength* σ_y is roughly defined as the stress at which the material begins to experience significant plasticity. In order to make this material property of use to the designer, the yield strength is now usually taken to be the stress that will cause a specific amount of permanent set (also called offset). The amount of permanent set specific is arbitrary, and hence the value used should be reported along with the yield strength. The most commonly used offset is 0.2%. The yield strength is determined by drawing a line of slope E on the engineering stress–strain diagram through the point on the strain axis representing the desired amount of offset. The stress corresponding to the intersection of this line with the stress–strain curve represents the yield strength (Fig. 9b).

The *ultimate strength* S_u is the maximum tensile load a specimen can resist, P_{\max} , divided by the specimen's original cross-sectional area. Thus, $S_u = P_{\max}/A_0$.

The *percent elongation* equals $100(L_f - L_0)/L_0$, where L_f is the final gage length at fracture. The percent elongation varies depending on the initial gage length and is of somewhat limited value.

The *percent reduction of area* is given by $\%RA = 100(A_0 - A_f)/A_0$, where A_f is the cross-sectional

area of the specimen at the point of fracture. The %RA is not as strongly dependent on specimen geometry as the percent elongation. It is a good measure of a material's ductility.

The *fracture strength* σ_f represents the true stress just prior to fracture. It should not be confused with the ultimate strength.

The *fracture ductility* ε_f is the true plastic strain at fracture. If the plastic deformation occurs without volume change, ε_f is related to %RA by

$$\varepsilon_f = \log \left(\frac{A_0}{A_f} \right) = \log \frac{100}{100 - \%RA}$$

Toughness has several common definitions. In its simplest form, the toughness is the area under the engineering stress-strain diagram.

True toughness represents the irrecoverable work done on a material during plastic deformation. It is given by the area under a plot of true stress versus true plastic strain, ε_p . The true plastic strain is related to σ and ε by $\varepsilon_p = \varepsilon - \sigma/E$. The true toughness is equivalently given by the total area under the true stress-strain diagram minus the elastic strain energy at fracture, $\sigma_f^2/2E$ (Fig. 9c).

For ductile materials it is often found that a simple power law relationship exists between the true stress and the true plastic strain. This relationship takes the form

$$\sigma = K \varepsilon_p^n \quad (22)$$

where K is known as the *strength coefficient*, and n is the *strain-hardening exponent*. These two quantities are easily determined by plotting $\log \sigma$ versus $\log \varepsilon_p$. The slope of such a plot gives n , while K is given by the value of σ corresponding to $\varepsilon_p = 1$.

2 BEAMS AND BENDING

2.1 Shear and Bending Moment in Beams

Classification of Beams A *beam* is a structural member whose length is large compared to its transverse dimensions and is subjected to forces acting transverse to its longitudinal axis. The following categories of beams are simple abstractions that approximate actual beams used in practice.

A *simple beam*, or simply supported beam (Fig. 10a), has a roller support at one end and a pin support at the other. The ends of a simple beam cannot support a bending moment but can support upward and downward vertical loads. Stated differently, the ends are free to rotate but cannot translate in the vertical direction. The end with the roller support is free to translate in the axial direction.

A *cantilever beam* (Fig. 10b) has one end rigidly fixed and the other end free. The fixed end can neither translate nor rotate while the free end can do both.

A *continuously supported beam* (Fig. 10c) is a beam resting on more than two supports.

A *fixed beam* (Fig. 10d) is rigidly fixed at both ends.

A *restrained beam* (Fig. 10e) is rigidly fixed at one end and simply supported at the other.

An *overhanging beam* (Fig. 10f) projects beyond one or both ends of its supports.

Loads on a beam commonly include concentrated loads (Fig. 10a), distributed loads (Fig. 10b), concentrated moments (Fig. 10c), and combinations of these.

Relations among Load, Shear, and Bending Moment

At any point along a beam, the shear force and bending moment acting on the beam cross section must be such as to balance the external loads on either side of the cross section. The commonly used sign convention for internal shear force and bending moment is shown in Fig. 11. It is important to determine the points along a beam where the shear force and bending moment are maximum since it is at these points that the shear stresses and bending stresses, respectively, reach their maximum values. These points are commonly referred to as critical points.

Consider an infinitesimal section of a beam that is under a general state of loading (Fig. 12). Equilibrium in the vertical direction requires that

$$\frac{dV}{dx} = -q(x) \quad (23a)$$

or

$$V_B - V_A = \Delta V_{A-B} = - \int_{x_A}^{x_B} q(x) dx \quad (23b)$$

where $q(x)$ is the applied distributed load, A and B are arbitrary points along the beam, V is the internal shear force, and ΔV_{A-B} is the change in shear force between points A and B . There is equilibrium of moments if

$$\frac{dM}{dx} = V(x) \quad (24a)$$

or

$$M_B - M_A = \Delta M_{A-B} = \int_{x_A}^{x_B} V(x) dx \quad (24b)$$

where ΔM_{A-B} is the change in bending moment between points A and B . Equation (23b) is valid only if no concentrated loads act between points A and B since discontinuities in the shear occur at points of application of concentrated loads. Similarly, Eq. (23b) is valid only if no concentrated moments act between points A and B .

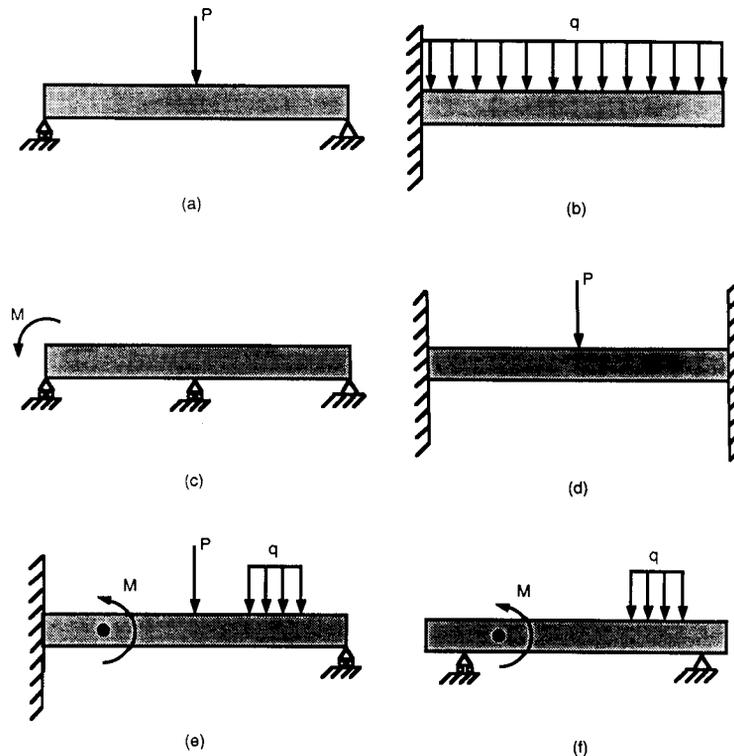

Fig. 10 Classification of beams and bending: (a) simple beam, concentrated load; (b) cantilever beam, distributed load; (c) continuous beam, concentrated moment; (d) fixed beam, concentrated load; (e) restrained beam, combined loading; (f) overhanging beam, combined loading.

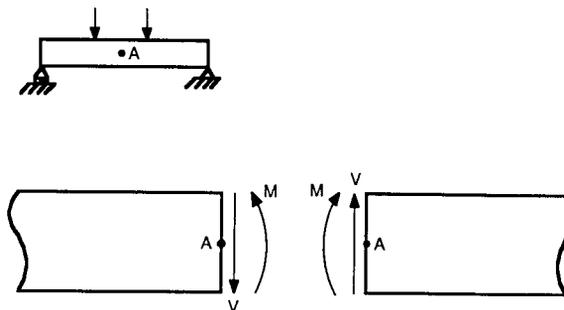

Fig. 11 Positive-sign convention for internal shear and bending moment.

Shear and Bending Moment Diagrams

Equations (23b) and (24b) provide a simple means for determining the shear and bending moment as a function of distance along the beam. In particular, if no distributed or concentrated loads act between two points on a beam, Eq. (23b) shows that the shear force is constant in this region. Equation (24b) shows that

the moment varies linearly in this region, provided that no concentrated moments exist.

A shear diagram is a graphical representation of the vertical shear at every point along a beam. A bending moment diagram is a graphical representation of the bending moment at every point along a beam. It is clear from Eq. (24b) that the bending moment at any

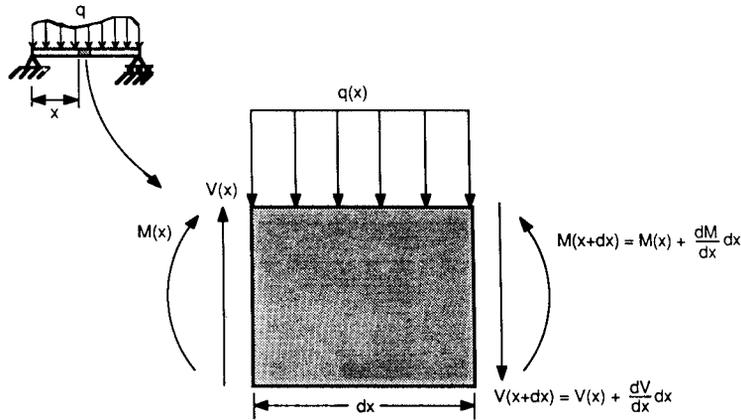

Fig. 12 Infinitesimal element of a beam.

point along a beam is equal to the area under the shear diagram up to that point, provided that no concentrated moments are present. If concentrated moments do exist, they will cause abrupt changes in the bending moment diagram, but this situation can be accounted for easily.

The general procedure for constructing shear and bending moment diagrams is described with the aid of Fig. 13:

1. Using the equations of static equilibrium ($\Sigma F_y = 0$ and $\Sigma M_z = 0$), determine the reactions at the supports (Fig. 13*b*). If the beam is statically indeterminate, the reactions can often be found by considering the deformations of the beam (see Section 2.4).
2. Determine the equations for shear and bending moment within each region of the beam in which the loading is continuous (Fig. 13*c*). Every discontinuity in loading, such as the application of a concentrated force, requires that another set of equations for shear and bending moment be determined.
3. Using the equations derived in step 2, draw the shear and bending moment diagrams (Fig. 13*d*).

Shear and bending moment diagrams are useful because they provide a rapid means for determining the critical points in a beam. These are the points at which failure is most likely to occur. With practice, it becomes possible to draw the diagrams directly without the need for first deriving the equations for shear and bending moment (at least for relatively simple loadings).

2.2 Theory of Flexure

For a straight beam possessing a plane of symmetry and subjected to moments acting in that plane of symmetry, it is assumed that cross sections perpendicular

to the longitudinal axis remain plane. This assumption is very accurate except for short beams subjected to shear forces. It follows from this assumption that the beam deforms into a circular arc subtending an angle θ (Fig. 14*a*). The only stress acting in the beam will be a normal stress component in the longitudinal direction, σ_{xx} . On the concave side, the strain ϵ_{xx} and stress σ_{xx} are negative (compressive), while on the convex side they are positive (tensile); consequently, there exists a surface in the beam where ϵ_{xx} and σ_{xx} are zero. The neutral surface is the surface within which the normal stress and strain are zero. The neutral axis is the intersection of the neutral surface with any cross section perpendicular to the longitudinal axis (Fig. 14*b*).

Since the normal strain within the neutral surface is zero, it follows that $L = \rho\theta$. Here, L is the original beam length and ρ is the radius of the arc AB of the neutral surface (Fig. 14*a*). At a radial distance y from the neutral surface (where y is shown as positive on the concave side of the beam), the length of the beam is given by $L' = (\rho - y)\theta$. The strain along this arc is given by $\epsilon_{xx} = (L' - L)/L$, or equivalently by $\epsilon_{xx} = -y/\rho$. Thus, the longitudinal strain varies linearly with distance from the neutral axis.

Assuming linearly elastic isotropic response, the longitudinal stress distribution is given by $\sigma_{xx} = E\epsilon_{xx}$, or

$$\sigma_{xx} = \frac{-Ey}{\rho} \tag{25}$$

From statics, the integral of σ_{xx} over the cross-sectional area of the beam must equal zero since there is no applied longitudinal force. Placing the origin of the coordinate axes at the center of the neutral surface and integrating over the cross-sectional area gives

$$-\frac{E}{\rho} \int y dA = 0$$

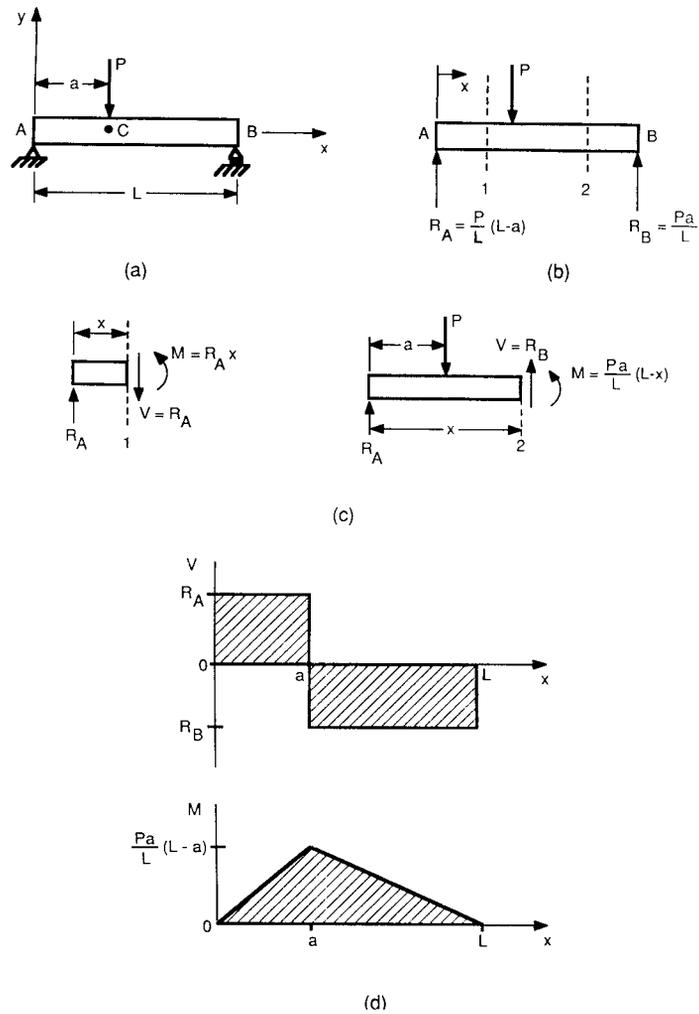

Fig. 13 Construction of shear and bending moment diagrams: (a) beam configuration; (b) static equilibrium of forces; (c) shear and bending moment in sections AC and CB ; (d) shear and bending moment diagrams.

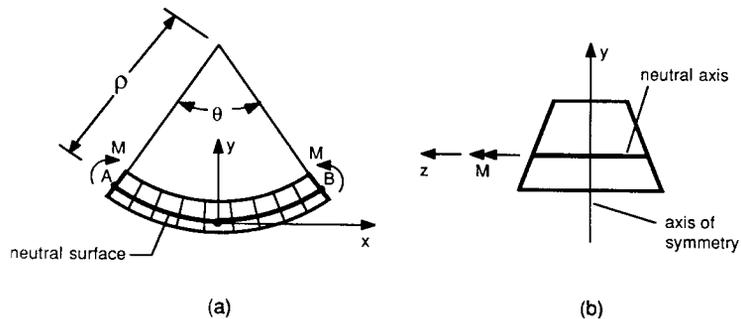

Fig. 14 Symmetric beam in pure bending: (a) side view; (b) enlarged cross-sectional view.

For finite ρ and nonzero E it follows that

$$\int y dA = 0$$

Stated in words, the first moment of the cross-sectional area with respect to the neutral axis must equal zero. The neutral axis therefore passes through the centroid of the cross section.

The applied moment M must be equal to the integral of $-y\sigma_{xx}$ over the cross-sectional area:

$$M = - \int y\sigma_{xx} dA$$

Substituting Eq. (25) into this expression gives

$$M = \frac{E}{\rho} \int y^2 dA$$

This can be rewritten as

$$\frac{1}{\rho} = \frac{M}{EI_{zz}} \quad (26)$$

where I_{zz} is the moment of inertia of the cross section with respect to the neutral axis (the z axis in Fig. 14b). Thus, $I_{zz} = \int y^2 dA$. Substituting for ρ from Eq. (25) into (26) leads to

$$\sigma_{xx} = \frac{-My}{I_{zz}} \quad (27)$$

This is known as the elastic flexure formula. The longitudinal stress is seen to have a maximum value at the farthest distance from the neutral axis. Denoting this distance by c , it follows that $|\sigma_{\max}| = Mc/I_{zz}$.

The section modulus, S , is equal to I_{zz}/c . The maximum longitudinal stress in the beam can be written as $|\sigma_{\max}| = M/S$. The section modulus represents the ability of a beam section to resist an applied bending moment. When designing beams, S should be made as large as is practical while minimizing the amount and cost of the material used. Table 2 gives values for the moment of inertia and section modulus of some common beam cross sections.

In summary, the following conditions must be satisfied if the elastic flexure formula is to be valid:

1. The beam must be straight or nearly straight.
2. The beam must possess a plane of symmetry and be subjected to moments acting in that plane of symmetry.
3. The material must be homogeneous and exhibit linear elastic, isotropic response.

4. The beam should be long enough so that shear forces do not cause warping of the cross section. A length-to-height ratio of 10 or better is normally sufficient to make shearing effects negligible.
5. The beam must have sufficient lateral stiffness so that it does not buckle under the applied loads (see Section 5.4 for details).

2.3 Shear Stresses in Beams

Symmetric beams that are subjected to a state of pure bending acting in the plane of symmetry experience only a flexural normal stress as given by Eq. 27. Thus, $\sigma_{xx} = -My/I_{zz}$, and $\sigma_{yz} = \sigma_{xz} = \sigma_{xy} = \sigma_{yy} = \sigma_{zz} = 0$ (using the coordinate axes given in Fig. 14). Beams that are subjected to transverse loads experience shear stresses σ_{xy} in addition to the flexural stress σ_{xx} . The average vertical shear stress throughout a cross section is given by $(\sigma_{xy})_{\text{avg}} = V/A$, where V is the resisting vertical shear force on the cross section, and A is the cross-sectional area.

In general, the shear stress is not uniformly distributed over the cross section. To determine the shear stress distribution, it must first be noted that the presence of a shear stress σ_{xy} implies the presence of a shear stress σ_{yx} of equal magnitude. This follows from the complementary property of shearing stresses (see Section 1.1).

Consider the beam shown in Fig. 15. For simplicity of demonstration, a rectangular cross section has been drawn, but Eq. (29), to be derived, is valid for an arbitrary cross-sectional shape provided there is at least one axis of symmetry, and the beam is loaded in that plane of symmetry. A portion CD of the beam is shown enlarged in Fig. 15c. Static equilibrium in the horizontal direction leads to

$$(\sigma_{yx})_{\text{avg}} Lt = \int_{y=y_0}^{y=h} (\sigma_D - \sigma_C) dA \quad (28)$$

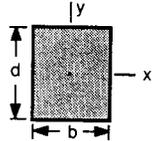

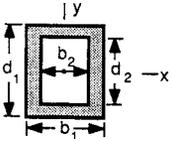

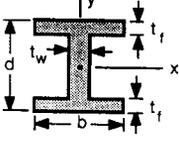

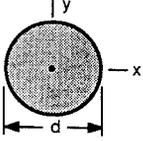

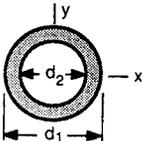

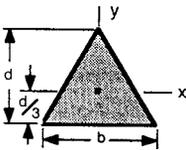

where L is the length of the beam element CD , t is the thickness of CD , and $(\sigma_{yx})_{\text{avg}}$ is the average horizontal shear stress acting on the bottom face of CD . From Eq. (24a), $M_D - M_C = VL$, since V is constant between C and D . Note that V is the shear force acting on the cross-sectional area of the whole beam at C , whereas V' , shown in Fig. 15c, is only that portion of V that acts on the cross-sectional area of element CD . Also, recalling Eq. 27, $\sigma = -My/I$, and substituting $M_D - M_C = VL$ gives

$$\sigma_D - \sigma_C = -\frac{(M_D - M_C)y}{I} = -\frac{VLy}{I}$$

Finally, substituting this result into Eq. (28) and considering the limit as L goes to zero leads to

$$(\sigma_{yx})_{\text{avg}} = -\frac{VQ}{It} \quad (29)$$

Table 2 Properties for Common Beam Cross Sections

Beam Section	Moment of Inertia, I_{xx}	Section Modulus, $\frac{I_{xx}}{c}$
	$\frac{bd^3}{12}$	$\frac{bd^2}{6}$
	$\frac{b_1 d_1^3 - b_2 d_2^3}{12}$	$\frac{b_1 d_1^3 - b_2 d_2^3}{6d_1}$
	$\frac{bt_f^3}{6} + \frac{bt_f}{2}(d - t_f)^2 + \frac{t_w}{12}(d - 2t_f)^3$	$\frac{2I_{xx}}{d}$
	$\frac{\pi d^4}{64}$	$\frac{\pi d^3}{32}$
	$\frac{\pi(d_1^4 - d_2^4)}{64}$	$\frac{\pi(d_1^4 - d_2^4)}{32d_1}$
	$\frac{bd^3}{36}$	$\frac{bd^2}{24}$

where

$$Q = \int_{y=y_0}^{y=h} y \, dA$$

The quantity Q represents the first moment of the shaded area in Fig. 15b with respect to the neutral axis. The minus sign in Eq. (29) implies that σ_{yx} is negative when V is positive (see Sections 1.1 and 2.1 for discussions of the sign conventions for σ_{yx} and V , respectively).

From the complementary property of shear (Section 1.1), it follows that $\sigma_{xy} = \sigma_{yx}$, provided that

static equilibrium exists. In particular, along the top and bottom of the beam, $Q = 0$. Thus, $\sigma_{xy} = \sigma_{yx} = 0$ on these surfaces; consequently, the shear stress goes from zero at the top and bottom surfaces of the beam to some maximum value in the interior.

Shear Stresses in Rectangular Beams For the case of a beam having a rectangular cross section, Eq. (29) can be greatly simplified. Denoting the height of the beam by $2h$, it can be shown that the shear stress is given by

$$\sigma_{xy} = \sigma_{yx} = \frac{3V}{2A} \left(1 - \frac{y^2}{h^2} \right)$$

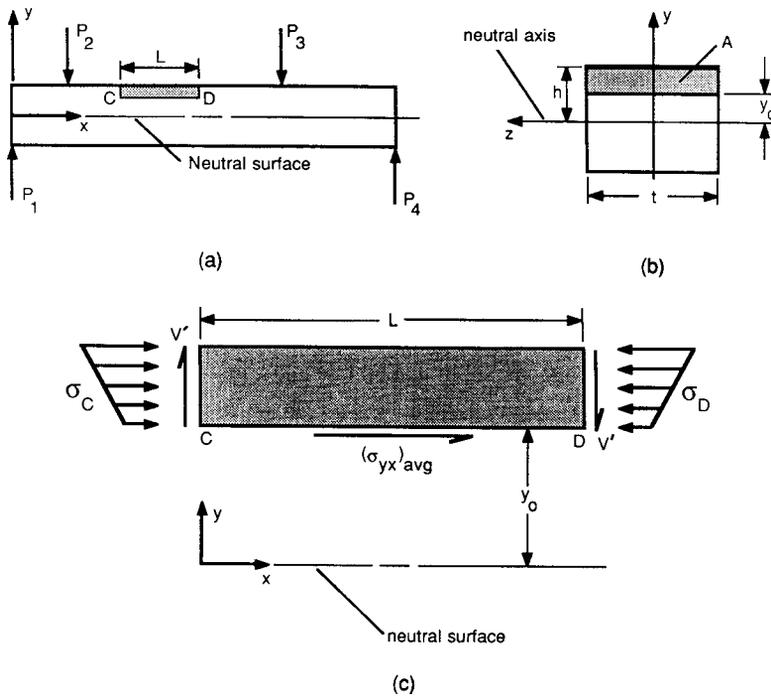

Fig. 15 Shear stresses in a beam: (a) side view; (b) cross-sectional view; (c) enlarged view of segment CD.

Clearly, the maximum shear stress is given by $(\sigma_{xy})_{max} = 1.5(V/A)$. This maximum shear stress occurs at $y = 0$ (at the neutral axis, where the normal stress σ_{xx} is zero). The shear stress distribution for a beam of rectangular cross section is shown in Fig. 16.

Shear Stresses in Thin-Walled Beams It can be shown that Eq. (29) can be used to describe the shear stress on an arbitrary longitudinal cut. For example, consider a section of a T beam as shown in Fig. 17a. The shear stress σ_{xy} must equal zero on the top and bottom of the flange since these are free surfaces.

Provided the flange thickness is small, σ_{xy} will not become significant through the thickness of the flange. Note that on the bottom of the flange Q is nonzero. Equation (29) thus predicts that a shear stress $\sigma_{xy} = \sigma_{yx}$ would exist on the free surface. In reality, this is physically impossible. This demonstrates one of the limitations of Eq. (29). This equation also gives incorrect results along the free surface of beams of circular cross section, except along the neutral axis (see Ref. 6 for further details). For a proper analysis that leads to an answer of zero shear stress on the bottom of the flange, the theory of elasticity must be employed. Equation (29) should thus be used with care.

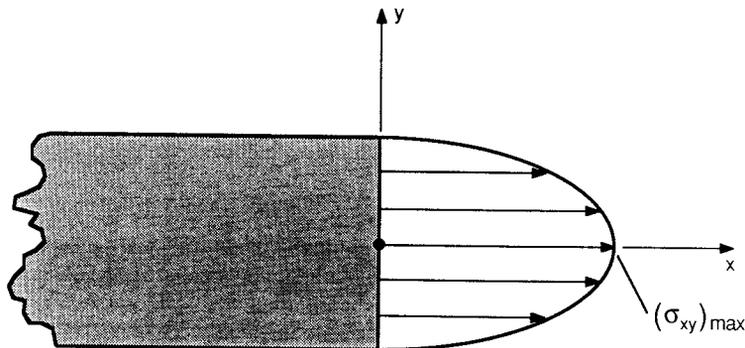

Fig. 16 Shear stress distribution in a rectangular beam subjected to transverse loads.

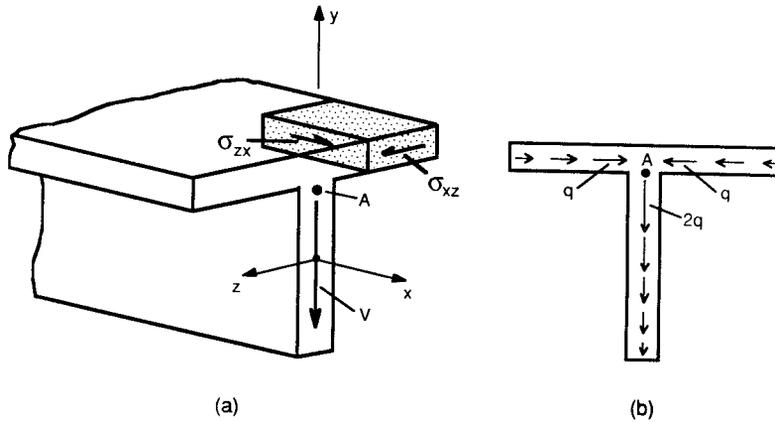

Fig. 17 Shear flow in a thin-walled beam: (a) isometric view of a beam; (b) sketch of shear flow.

The shear stresses $\sigma_{xz} = \sigma_{zx}$ in the flange can become large. Their value is again given by Eq. (29). As the web is reached (point A in Fig. 17a), the horizontal shear stress, σ_{xz} , becomes a vertical shear stress, σ_{xy} . The shear flow q , is defined as

$$q = \frac{VQ}{I_{zz}} = \tau_{\text{avg}} t$$

where V is again the internal resisting shear force, Q is the first moment of area with respect to the neutral axis, I_{zz} is the moment of inertia of the beam cross section, and τ_{avg} is the average horizontal shear stress acting in the web. Shear flow in a thin-walled beam is analogous to the flow of water through a channel. If the beam thickness decreases, τ_{avg} will increase so as to keep q constant. This is analogous to conservation of mass in fluid flow through a channel of variable diameter. Similarly, as the point A is approached in Fig. 17b, the shear flow from each flange q , combine to give a shear flow of $2q$ in the web. This is analogous to water flow through a T section.

The total shear flow acting over the area of the cross section must be such as to equal the resisting shearing force, V . For example, if no external horizontal forces are present, horizontal forces due to shear flow must cancel each other out. This is obvious for the T section of Fig. 17b since the horizontal shear flow in one flange exactly cancels the horizontal shear flow in the other flange.

Shear Center for Beams In general, a beam will undergo both bending and twisting when it is subjected to transverse loads. There does exist a point, however, at which transverse loads can be applied without any twisting occurring. This point is referred to as the shear center of the beam. For thick-walled or solid cross sections, the shear center will usually

be located close to the centroid of the cross section. Knowledge of the precise location of the shear center in beams with thick or solid cross sections is generally unimportant since such beams will exhibit considerable resistance to torsional loads. If such a beam is loaded through a point slightly away from the shear center, no significant amount of twisting occurs.

For thin-walled open-section beams, the situation is quite different. Such beams exhibit very little torsional resistance; therefore, it is important that the application of transverse loads occurs at the shear center. The shear center is found by balancing out the moments due to the shear flow q in the beam and the resisting shear force V . Details of the procedure can be found in Refs. 7 and 8. Table 3 gives the location of the shear center for some common thin-walled cross sections. More extensive tables can be found in Refs. 8 and 9.

2.4 Deflection of Beams

A variety of techniques exist for determining the elastic deflection of beams. The techniques to be discussed here are only valid for small deflections. In addition, the assumptions used in deriving the elastic flexure formula must also be satisfied (see Section 2.2).

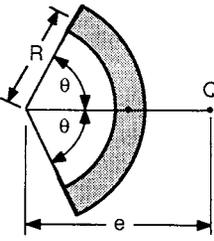

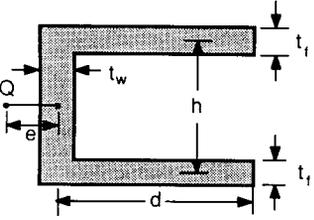

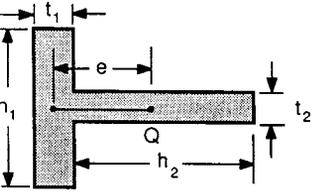

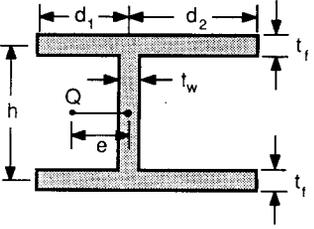

Method of Integration For small deflection the radius of curvature, ρ , can be written as

$$\frac{1}{\rho} = \frac{d^2 y(x)}{dx^2}$$

where $y(x)$ represents the deflection of the beam at a longitudinal distance, x , from the origin of the coordinates. Substituting this result into Eq. (26) leads to

$$\frac{d^2 y(x)}{dx^2} = \frac{M(x)}{EI_{zz}} \quad (30)$$

Table 3 Shear Centers for Common Sections

Beam Cross Section	Location of Q
	$e = \frac{4R(\sin \theta - \theta \cos \theta)}{2\theta - \sin 2\theta}$
	$e = \frac{3t_f d^2}{6t_f d + t_w h}$
	$e = \frac{(t_1 + h_1^2)(t_2^3 h_2)}{2(t_2^3 h_2 + h_1^3 t_1)}$
	$e = \frac{3t_f(d_2^2 - d_1^2)}{6t_f(d_1 + d_2) + t_w h}$ <p>provided $d_1 < d_2$</p>

Equation (30) is a second-order linear differential equation for y . Its solution requires a knowledge of the bending moment at every point along the beam as well as two boundary conditions. The equation is only valid provided that no sudden changes in M , E , or I_{zz} occur. When there is a sudden change, such as the application of a concentrated force, it is necessary to divide the beam into several portions and solve Eq. (30) within each portion. The following example illustrates the method of integration.

Example 1. For the beam shown in Fig. 13a, derive the deflection equation by the method of integration. Consider the case where $a = L/2$.

Solution. Since the beam contains a concentrated load at $x = L/2$, it is necessary to write two separate

differential equations for the two halves of the beam. Using the moment equations derived in Fig. 13c and substituting them into Eq. (30), with $a = L/2$, leads to

$$\frac{d^2 y_1}{dx^2} = \frac{P}{2EI} x \quad 0 \leq x \leq \frac{L}{2}$$

and

$$\frac{d^2 y_2}{dx^2} = \frac{-P}{2EI} x + \frac{PL}{2EI} \quad \frac{L}{2} \leq x \leq L$$

Integrating these equations gives

$$\frac{dy_1}{dx} = \frac{Px^2}{4EI} + C_1$$

$$\begin{aligned} \frac{dy_2}{dx} &= \frac{-Px^2}{4EI} + \frac{PL}{2EI}x + C_3 \\ y_1 &= \frac{Px^3}{12EI} + C_1x + C_2 \\ y_2 &= \frac{-Px^3}{12EI} + \frac{PLx^2}{4EI} + C_3x + C_4 \end{aligned}$$

Finally, the boundary conditions must be applied. Clearly, four boundary conditions are needed to solve for the four constants of integration, C_1 through C_4 . These boundary conditions are as follows:

$$\begin{aligned} \text{At } x = 0: \quad y_1 &= 0 \Rightarrow C_2 = 0 \\ \text{At } x = L: \quad y_2 &= 0 \Rightarrow C_4 = \frac{-PL^3}{6EI} - C_3L \\ \text{At } x = \frac{L}{2}: \quad \frac{dy_1}{dx} &= \frac{dy_2}{dx} \Rightarrow \frac{PL^2}{16EI} + C_1 \\ &= \frac{3PL^2}{16EI} + C_3 \\ \text{At } x = \frac{L}{2}: \quad y_1 &= y_2 \Rightarrow \frac{PL^3}{96EI} + C_1 \frac{L}{2} \\ &= \frac{5PL^3}{96EI} + C_3 \frac{L}{2} + C_4 \end{aligned}$$

The last two conditions are due to the fact that the slope and deflection must be continuous at $x = L/2$. Solving these equations for the constants gives

$$\begin{aligned} C_1 &= \frac{-PL^2}{16EI} & C_2 &= 0 \\ C_3 &= \frac{-3PL^2}{16EI} & C_4 &= \frac{PL^3}{48EI} \end{aligned}$$

The deflection equations for the two halves of the beam are thus given by

$$\begin{aligned} y_1 &= \frac{P}{48EI}(4x^3 - 3L^2x) & 0 \leq x \leq \frac{L}{2} \\ y_2 &= \frac{P}{48EI}(-4x^3 + 12Lx^2 - 9L^2x + L^3) \\ & & \frac{L}{2} \leq x \leq L \end{aligned}$$

In general, if n discontinuities in the loading occur between the end points of the beam, it will be necessary to write and solve $n + 1$ differential equations in order to describe the displacement along the entire length of the beam. It is possible to write a single differential equation for even the most general state of loading by using singularity functions.¹⁰ Table 4 contains deflection equations for a variety of loading conditions.

Method of Superposition Since Eq. (30), the governing differential equation for beam deflection is linear, it is possible to solve a beam deflection problem involving many loads by considering the effect of each load as if it acted alone. The total deflection is obtained by adding together the deflection caused by each individual load. The procedure (known as the method of superposition) is illustrated in Example 2.

Example 2. Consider the case of a simple beam of length L carrying a uniformly distributed load q , and a concentrated load P at its center. Find the center deflection of the beam using the method of superposition.

Solution. From Table 4, the center deflection for a simple beam carrying a concentrated load at its center is equal to $-PL^3/48EI$. Similarly, for a simple beam having a uniformly distributed load, the center deflection is equal to $-5qL^4/384EI$. Thus, applying the method of superposition, it follows that the center deflection for a simple beam having both a uniformly distributed load along its length and a concentrated load at its center is given by

$$Y_{x=L/2} = \frac{-PL^3}{48EI} - \frac{5qL^4}{384EI} = \frac{-L^3}{384EI}(8P + 5qL)$$

Since the center deflection were the maximum deflections for the individual loadings, it follows that the center deflection is the maximum deflection for the combined state of loading as well.

2.5 Unsymmetric Bending

Moments of Inertia of a Plane Area In order to determine the flexure stress in a beam undergoing unsymmetric bending, it is necessary to compute the moments of inertia of the cross-sectional area of the beam. Assuming the beam cross section lies in the xy plane, the required terms are as follows:

$$I_{xx} = \int y^2 dA \quad I_{yy} = \int x^2 dA \quad I_{xy} = \int xy dA \quad (31)$$

The terms I_{xx} and I_{yy} are known as the moments of inertia of the cross section, while the term I_{xy} is called the product of inertia of the cross section. Whereas I_{xx} and I_{yy} are always positive, I_{xy} can be positive, negative, or zero. For the cross sections shown in Table 2, the products of inertia are zero. This is because each of these cross sections has one or more axes of symmetry, and at least one of the two coordinate axes lies along an axis of symmetry. In fact, every cross section has some orientation for which $I_{xy} = 0$. A Mohr's circle for inertias can even be drawn. Details can be found in most statics and mechanics texts.

Parallel Axis Theorem The determination of the moments of inertia for a complex cross section using the definition in Eq. (31) is often quite difficult. Instead, it is usually more expeditious to consider the cross section to be made up of several smaller sections of simple shapes and to determine the moments of inertia of these smaller sections separately. After this, the moments of inertia of the smaller sections must somehow be assembled to give the moment of inertia of the whole cross section. This assemblage is accomplished using the parallel axis theorem. This theorem states that the moments of inertia of a cross section with respect to an arbitrary xy coordinate system are related to the moments of inertia of that cross section with respect to a parallel, centroidal $x'y'$ coordinate system by the following:

$$I_{xx} = I'_{xx} + A\bar{y}^2 \quad I_{yy} = I'_{yy} + A\bar{x}^2 \quad I_{xy} = I'_{xy} + A\bar{x}\bar{y}$$

where A is the area of the cross section, and \bar{x} and \bar{y} are the distances from the origin of the xy coordinate system to the origin of the $x'y'$ coordinate system.

Example 3. For the angle section shown in Fig. 18, determine the moments of inertia of the cross section with respect to its centroid.

Solution. First determine the coordinates of the centroid C with respect to the given x^*y^* reference frame. The cross section is considered to be made up of two small rectangles as shown in Fig. 18. The centroid of the cross section is given by the coordinates x_C^* and y_C^* :

$$x_C^* = \frac{\sum(\bar{x}A)}{\sum A} = \frac{1(2)(4) + 3(2)(6)}{(2)(4) + (2)(6)} = 2.2 \text{ in.}$$

$$y_C^* = \frac{\sum(\bar{y}A)}{\sum A} = \frac{2(2)(4) + 5(2)(6)}{(2)(4) + (2)(6)} = 3.8 \text{ in.}$$

These equations are based on the definition of the centroid of a cross section. Next, place the xy coordinate system at the centroid C . Using the values for the moments of inertia of a rectangle with respect to its centroid (from Table 2) and applying the parallel axis theorem leads to

$$I_{xx} = \frac{6(2)^3}{12} + 6(2)(1.2)^2 + \frac{2(4)^3}{12} + 2(4)(-1.8)^2$$

$$= 57.87 \text{ in.}^4$$

$$I_{yy} = \frac{2(6)^3}{12} + 6(2)(0.8)^2 + \frac{4(2)^3}{12} + 2(4)(-1.2)^2$$

$$= 57.87 \text{ in.}^4$$

$$I_{xy} = 0 + 6(2)(1.2)(0.8) + 0 + 2(4)(-1.8)(-1.2)$$

$$= 28.80 \text{ in.}^4$$

Equation for Flexural Stress When a beam cross section does not have a plane of symmetry, or if it has a plane of symmetry but the applied moments do not act in this plane, Eq. (27) is no longer valid. Provided that the origin of the xy coordinate axes is at the centroid of the cross section, the flexural stress at a point $P(x, y)$ is given by

$$\sigma_{zz} = \frac{(M_x I_{yy} + M_y I_{xy})y - (M_x I_{xy} + M_y I_{xx})x}{I_{xx} I_{yy} - I_{xy}^2} \quad (32)$$

where M_x and M_y are the components of the moment acting along the x and y axes, respectively.

The neutral axis can be found by setting $\sigma_{xx} = 0$ in Eq. (32). Since $x = y = 0$ satisfies $\sigma_{xx} = 0$, it is clear that the neutral axis passes through the centroid of the cross section. Let α be the angle of the neutral

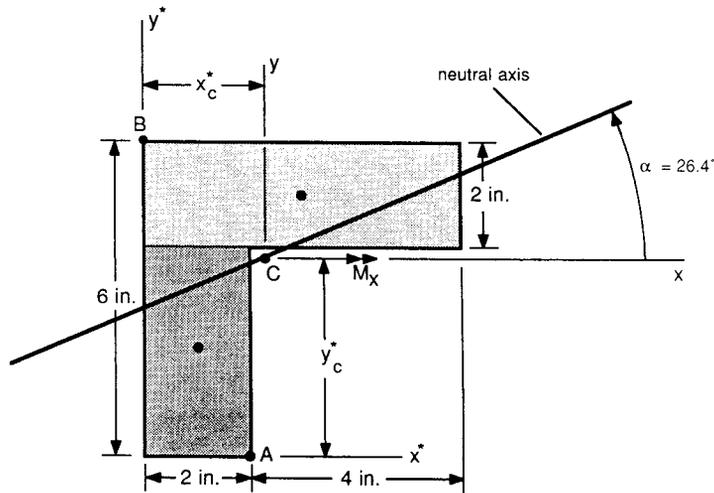

Fig. 18 Beam cross section for use with Examples 3 and 4.

axis with respect to the x axis. Then α satisfies the following:

$$\tan \alpha = \frac{y}{x} = \frac{M_x I_{xy} + M_y I_{xx}}{M_x I_{yy} + M_y I_{xy}} \quad (33)$$

By eliminating M_y between Eqs. (32) and (33), a simpler expression for the flexural stress is obtained:

$$\sigma_{zz} = \frac{y - x \tan \alpha}{I_{xx} - I_{xy} \tan \alpha} M_x \quad (34)$$

This equation is invalid if $\alpha = \pm 90^\circ$. In such cases, Eq. (32) should be used.

Example 4. Suppose a beam has the cross-sectional dimensions given in Fig. 18. Assume the beam is acted upon by a 90,000-lb-in. moment that acts along the positive x axis. Determine the maximum flexural stress in the beam.

Solution. The moments of inertia for this cross section were previously found in Example 3. The values are $I_{xx} = 57.9 \text{ in.}^4$, $I_{yy} = 57.9 \text{ in.}^4$, and $I_{xy} = 28.8 \text{ in.}^4$. The orientation of the neutral axis is found using Eq. (33) with $M_y = 0$:

$$\tan \alpha = \frac{28.8}{57.9} \Rightarrow \alpha = 26.4^\circ$$

The neutral axis has been shown in Fig. 18. From this figure it is logical to expect that the maximum stress will occur at A or B since these points are furthest

from the neutral axis. Using Eq. (34), the stresses at these points are given by

$$\begin{aligned} (\sigma_{zz})_A &= \frac{(-3.8) - (-0.2) \tan 26.4^\circ}{57.9 - 28.8 \tan 26.4^\circ} (90,000) \\ &= -7640 \text{ psi} \end{aligned}$$

$$\begin{aligned} (\sigma_{zz})_B &= \frac{(2.2) - (-2.2) \tan 26.4^\circ}{57.9 - 28.8 \tan 26.4^\circ} (90,000) \\ &= 6800 \text{ psi} \end{aligned}$$

Thus, the maximum tensile stress in the beam is 6800 psi and the maximum compressive stress is 7640 psi.

2.6 Curved Beams

Circumferential Stress The formula presented in Section 2.2 for flexural stress, $\sigma = -My/I$, is applicable for long, initially straight beams. It can still be used with reasonable accuracy for beams with some initial curvature provided the beam depth is small compared to the radius of curvature. When the beam's depth is of the same order of magnitude as its curvature, however, a new equation must be used. The derivation of this equation is too involved to be presented here. The details can be found in almost any modern text on strength of materials; in particular, see Refs. 7 and 8.

The equation for the circumferential stress distribution of a curved member with a plane of symmetry and subjected to moments acting in this plane of symmetry is given by (see Fig. 19):

$$\sigma = \frac{-My}{A(R - r_n)r} \quad (35)$$

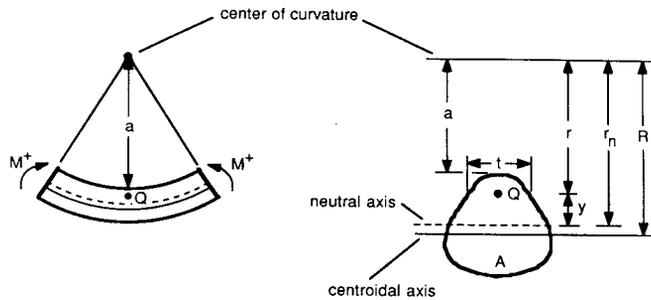

Fig. 19 Notation for theory of curved beams.

where r = distance from center of curvature to point under consideration

r_n = distance from center of curvature to neutral axis of cross section

y = distance from neutral axis to point Q under consideration

R = distance from center of curvature to centroidal axis of cross section

A = area of cross section

M = applied moment

The moment is considered positive if it tends to create compressive stresses on the concave side of the beam cross section. The coordinate y is taken to be positive on the concave side of the neutral axis.

It can be shown that r_n is given by

$$r_n = \frac{A}{\int \frac{dA}{r}}$$

Also, R is given by

$$R = \frac{1}{A} \int r dA$$

Thus, the centroidal axis and the neutral axis do not coincide. In general their difference is small; consequently, it is important to determine these distances accurately since their difference occurs in the denominator of Eq. (35). Table 5 gives required cross-sectional properties for application to curved beams. More complete tables can be found in Refs. 7-9.

Radial Stress For an initially straight beam, only circumferential stresses develop upon application of a bending moment. For initially curved beams, however, significant radial stresses can develop. An approximate solution for the radial stress is given by⁷

$$\sigma_r = \frac{-M}{A(r - r_n)} t r \left(r_n \int_a^r \frac{dA}{r} - \int_a^r dA \right) \quad (36)$$

where a is the distance from the center of curvature to the edge of the cross section, and t is the thickness

of the cross section at the point under consideration. All other terms were previously defined in conjunction with Eq. (35). See Fig. 19 for details.

It should be noted that Eq. (36) neglects the effect of normal and shear forces on the radial stress. In general, these forces do not have a major effect on the radial stress and can be ignored for most applications.⁷

3 TORSION AND SHAFTS

3.1 Circular Shafts

Shear Stress Distribution Circular shafts have the unique property that, when subjected to torsion, every cross section of the shaft remains plane and undistorted. This fact allows for the easy determination of the shear strain distribution. When subjected to torsion, a small square element, A , deforms into a rhombus, A' , as shown in Fig. 20a. The angle γ shown in Fig. 20a is identical to the shear strain that the square element has gone through, Fig. 20b.

For small values of γ it is reasonable to assume that $\gamma = r\phi/L$, where L is the shaft length, r is the radius of the shaft at the point under consideration, and ϕ is the angle of twist of the shaft (see Fig. 20). Denoting the outer radius of the shaft by c , it follows that

$$\gamma_{\max} = \frac{c\phi}{L} \quad (37)$$

and hence,

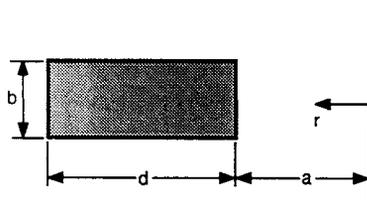

$$\gamma(r) = \frac{r}{c} \gamma_{\max} \quad (38)$$

The only assumption made in deriving Eq. (38) was to assume that the shear strains are small. For linear elastic response, $\tau = G\gamma$. Substituting this relationship into Eq. (38) leads to

$$\tau(r) = \frac{r}{c} \tau_{\max} \quad (39)$$

It follows that, for torsion of an isotropic linear solid elastic circular shaft, the shear stress distribution is linear with respect to radius. This is illustrated in

Table 5 Cross-Sectional Properties for Curved Beams

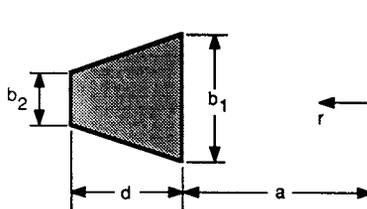

$$A = bd$$

$$R = a + \frac{d}{2}$$

$$\int \frac{dA}{r} = b \log \left(1 + \frac{d}{a} \right)$$

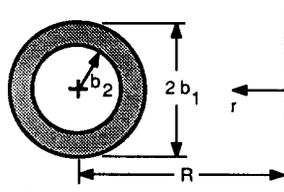

“log” denotes the natural logarithm

$$A = \frac{d}{2}(b_1 + b_2)$$

$$R = a + \frac{d(b_1 + 2b_2)}{3(b_1 + b_2)}$$

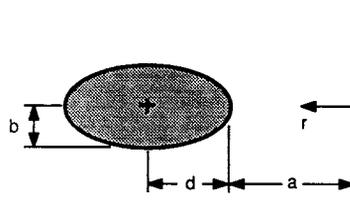

$$\int \frac{dA}{r} = b_1 - b_2 + \frac{a(b_1 - b_2) + db_1}{d} \log \left(1 + \frac{d}{a} \right)$$

$$A = \pi(b_1^2 - b_2^2)$$

$$\int \frac{dA}{r} = 2\pi \left(\sqrt{R^2 - b_2^2} - \sqrt{R^2 - b_1^2} \right)$$

Use $b_2 = 0$ for solid circular cross section

$$A = \pi bd$$

$$R = a + d$$

$$\int \frac{dA}{r} = \frac{2\pi b}{d} \left(R - \sqrt{a^2 + 2ad} \right)$$

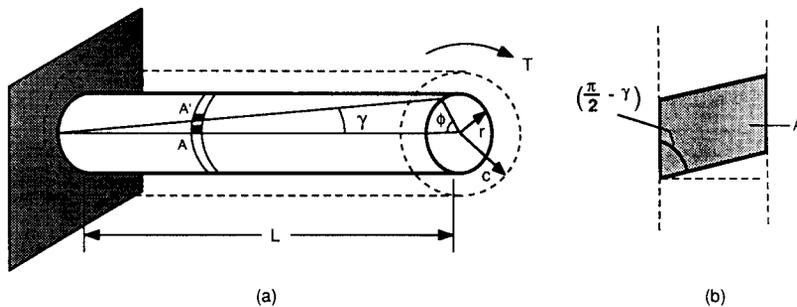

Fig. 20 Torsion of a circular shaft.

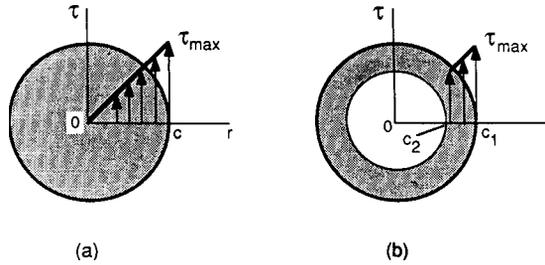

Fig. 21 Shear stress distribution in a circular shaft: (a) solid shaft; (b) hollow shaft.

Fig. 21a. The shear stress distribution of a hollow circular shaft (Fig. 21b) is also given by Eq. (39).

From statics, the net resisting torque generated by the internal shear stresses must equal the applied external torque, T :

$$T = \int r \tau dA \quad (40)$$

Substituting for τ from Eq. (39) into (40) leads to

$$\tau_{\max} = \frac{Tc}{J} \quad (41)$$

where $J = \int r^2 dA$. The term J is known as the polar moment of inertia of the cross section with respect to its centroid. For a solid circular cross section, $J = \pi c^4/2$. For a hollow circular tube, $J = \pi(c_1^4 - c_2^4)/2$, where c_1 and c_2 are the outer radius and inner radius of the tube, respectively. Since the shear stress distribution is linear with respect to radius, it follows that the shear stress at a distance r from the centroid of a circular shaft is given by $\tau(r) = Tr/J$.

Angle of Twist Using Hooke's law, Eq. (41) can be rewritten as

$$\gamma_{\max} = \frac{\tau_{\max}}{G} = \frac{Tc}{JG}$$

Equating this expression with Eq. (37) leads to

$$\phi = \frac{TL}{JG} \quad (42)$$

Equation (42) applies to a uniform shaft subjected to a single torque at its end. If the shaft dimensions vary continuously with axial distance, ϕ must be found by integration:

$$\phi = \int_0^L \frac{T dx}{JG}$$

where x is the axial distance coordinate.

If several concentrated torques are applied to the shaft, or if the shaft has sudden changes in cross

section, the relative angle of twist must be found within each uniform shaft region. The total angle of twist is found by summing these relative angles of twist:

$$\phi_{\text{total}} = \sum_k \phi_k = \sum_k \frac{T_k L_k}{J_k G_k}$$

Design of Transmission Shafts Circular shafts are often used for power transmission. The relation between the power transmitted, P , the angular speed of the shaft, ω , and the applied torque, T , is given by $P = T\omega$. If ω is expressed in revolutions per minute and P is expressed in horsepower,

$$T = \frac{63,030P}{\omega} \quad (43)$$

where T has units of pound-inches. For a given power transmission and a given speed of rotation, it is important that the shaft dimensions are large enough so that the torque, as given by Eq. (43), does not cause the maximum shear stress in the shaft to exceed allowable limits. Since $\tau_{\max} = Tc/J$, it is clear that the quantity c/J should be kept as small as possible.

3.2 Thin-Walled Closed Hollow Tubes

A tube is considered thin if the shear stress due to an applied torque does not vary significantly across the wall thickness. Put another way, the wall thickness must be small compared to the overall dimensions of the cross section.

Single Cells Consider the single-celled, thin-walled, closed hollow tube shown in Fig. 22a. By considering equilibrium of horizontal forces for the small element A , as shown in Fig. 22b, it becomes apparent that

$$q = \tau_1 t_1 = \tau_2 t_2 = \text{const}$$

where q is known as the shear flow and t is the tube thickness. The following equation is obtained when equilibrium of the torsional forces is considered:

$$T = \oint q r ds \quad (44)$$

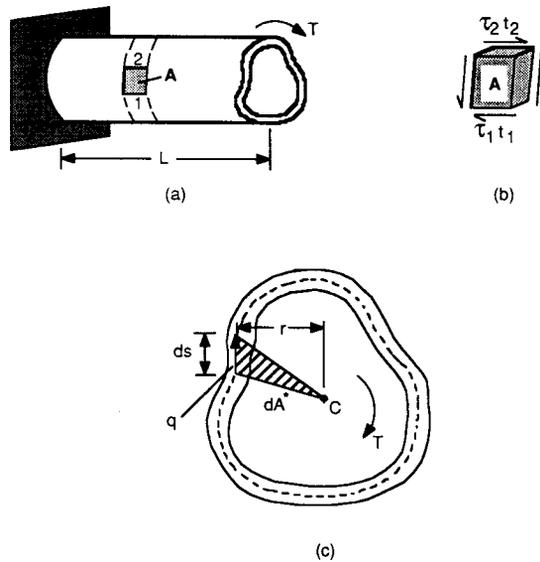

Fig. 22 Torsion of a single-celled, thin-walled, closed hollow tube.

where T is the applied torque, and r is the perpendicular distance from the centroid of the cross section to the shear flow q acting on the small section ds (Fig. 22c). The area of the shaded triangle in Fig. 22c is given by

$$dA^* = \frac{1}{2} r ds \tag{45}$$

Substituting for $r ds$ from Eq. (45) into (44) leads to

$$T = 2qA^*$$

where A^* is the area bounded by the centerline of the wall. Recall that $q = \tau t$ gives

$$\tau = \frac{T}{2tA^*} \tag{46}$$

Clearly, the maximum shear stress occurs at the thinnest section of the wall.

Using energy methods, it can be shown that the angle of twist is given by (see Ref. 7 for details):

$$\phi = \frac{TL}{4G(A^*)^2} \oint \frac{ds}{t} \tag{47}$$

where L is the length of the tube, and G is the shear modulus of the material.

Multicells For a multicell section, the shear flow is no longer constant throughout the cross section.

Instead, the shear flow is analogous to the flow of water through pipes or the flow of current in an electric circuit. Consider the rectangular multicell section shown in Fig. 23. If the two sections are labeled 1 and 2 as shown, the shear flow around the outer walls of these sections are q_1 and q_2 , respectively. The shear flow in the intermediate wall is $q_1 - q_2$.

The torque can be expressed in terms of the shear flow using a procedure similar to that used for single-celled tubes. In fact, it can be shown that for an n -celled tube:

$$T = \sum_{i=1}^n A_i^* q_i \tag{48}$$

where A_i^* is the area contained within the centerline bounding the i th cell.

For an n -celled section there are $n + 1$ unknowns ($q_1, q_2, \dots, q_n, \phi$); consequently, $n + 1$ equations are

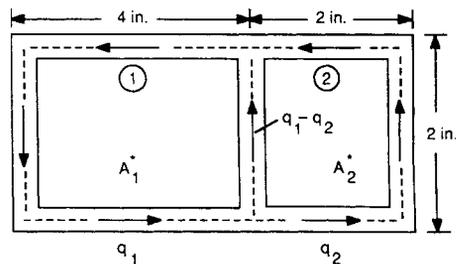

Fig. 23 Two-celled rectangular cross section for use with Example 5.

required in order to solve for these unknowns. Equation (48) provides one equation. The other n equations come about by noting that, according to Saint-Venant's torsion theory, cross sections do not warp within their own plane when a torque is applied. In other words, the angle of twist ϕ is the same for each cell. It follows that

$$\phi = \frac{L}{2G(A_i^*)} \left(\oint \frac{q ds}{t} \right)_i \quad i = 1, 2, \dots, n \quad (49)$$

Equation (49) provides the other n equations needed to solve for all the unknowns.

Example 5. For the cross section shown in Fig. 23, assume the wall thickness is uniform at 0.25 in. If the tube length is 12 in. and a torque of 50,000 lb-in. is applied, find the maximum shear stress in the tube. Assume $G = 11.5 \times 10^6$ psi.

Solution. Writing Eq. (49) for the two cells,

$$\begin{aligned} 2G \frac{\phi}{L} &= \frac{1}{4(2)} \left[\frac{4+2+4}{0.25} q_1 + \frac{2}{0.25} (q_1 - q_2) \right] \\ &= \frac{1}{2(2)} \left[\frac{2+2+2}{0.25} q_2 + \frac{2}{0.25} (q_2 - q_1) \right] \end{aligned}$$

Using Eq. (48),

$$T = 50,000 = 4(2)q_1 + 2(2)q_2$$

Solving these equations for q_1 , q_2 , and ϕ gives $\phi = 0.0115$ rad, $q_1 = 4310$ lb/in., and $q_2 = 3830$ lb/in. Thus, $\tau_{\max} = \tau_1 = 4310/0.25 = 17,250$ psi.

3.3 Torsion of Noncircular Cross Sections

Theories for analyzing the torsional response of circular shafts and thin-walled, closed hollow tubes were developed in Sections 3.1 and 3.2. For solid or thick-walled noncircular cross sections, it is usually necessary to use the theory of elasticity in order to determine torsion formulas. Because of the complexities involved, the most practical means for determining the torsion formula for a noncircular cross section is to find the appropriate formula in a handbook or other source. Table 6 gives formulas for several common cross sections. A much more thorough listing is provided in Ref. 9.

Although quantitative determination of the stress distribution for the torsion of a noncircular cross section is usually quite difficult, an analogy does exist that provides for a qualitative understanding. This is the Prandtl elastic-membrane analogy. In essence, this analogy states that the shear stress at a given point (x, y) in a cross section is proportional to the slope at the point (x, y) of a membrane (such as a soap film) made of the same cross-sectional dimensions, where the membrane is pressurized from one side. Thus, by

visualizing the shape of a membrane of the same cross-sectional dimensions, it is possible to obtain an idea of the distribution of shear stresses in the cross section of a shaft undergoing torsional loading. In particular, it becomes obvious that the shear stress is zero at the corners of a shaft made of a rectangular cross section since a membrane of the same geometry and pressurized from one side will have zero slope at its corners. See Refs. 7, 8, and 11 for further details.

4 PLATES, SHELLS, AND CONTACT STRESSES

4.1 Classical Theory of Elastic, Isotropic Plates

Flat plates are most often used to carry transverse pressure loads. Just as with beams, these pressure loads are carried by out-of-plane shear stresses, which in turn induce a bending moment distribution in the plate. Unlike beams, however, the bending moment distribution in a plate is two dimensional, and a torsional moment distribution is also usually present.

Assumptions Used In deriving the equations of equilibrium, it is conventional to take the origin of coordinates at the middle surface of the plate, as shown in Fig. 24a. The commonly used sign convention for moments and shear forces is shown in Fig. 24b. A number of assumptions are used in deriving the classical theory of elastic isotropic plates. These assumptions are listed below:

1. The plate is initially flat
2. The material is linear elastic, isotropic, and homogeneous.
3. The plate thickness, h , is small compared to its in-plane dimensions, a and b (see Fig. 24a). Generally, a and b should be at least 10 times greater than h .
4. Deflections are small and slopes of the deflected middle surface are small compared to unity.
5. The middle surface of the plate is a neutral surface; that is, it remains unstrained during bending.
6. Distortions due to transverse shear are negligible. Thus, initially straight lines normal to the middle surface remain straight and normal after deformation.
7. Stresses normal to the middle surface are negligible compared to other stresses.

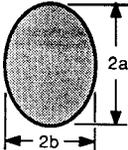

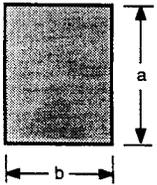

Stresses and Moments in Terms of Curvature

The displacements in the x and y directions, u and v , respectively, depend on the z coordinate and the slope components:

$$u = -z \frac{\partial w}{\partial x} \quad v = -z \frac{\partial w}{\partial y}$$

where w is the displacement component in the z direction. Using the strain-displacement relations,

Table 6 Torsion Formulas for Solid Sections

 Regular Hexagon	$\tau_{\max} = \frac{1.09T}{a^3}$	$\theta = \frac{0.967TL}{a^4 G}$																											

Note: T = applied torque, L = length of shaft, G = shear modulus.

Eqs. (4), the strains can be expressed in terms of the curvatures as follows:

$$\epsilon_{xx} = -z \frac{\partial^2 w}{\partial x^2} \quad \epsilon_{yy} = -z \frac{\partial^2 w}{\partial y^2} \quad \gamma_{xy} = -2z \frac{\partial^2 w}{\partial x \partial y} \tag{50}$$

For thin plates, plane stress conditions prevail ($\sigma_{zz} = \sigma_{xz} = \sigma_{yz} = 0$). Substituting from Eqs. (50) into (11) leads to

$$\begin{aligned} \sigma_{xx} &= \frac{-Ez}{1 - \mu^2} \left(\frac{\partial^2 w}{\partial x^2} + \nu \frac{\partial^2 w}{\partial y^2} \right) \\ \sigma_{yy} &= \frac{-Ez}{1 - \nu^2} \left(\frac{\partial^2 w}{\partial y^2} + \nu \frac{\partial^2 w}{\partial x^2} \right) \end{aligned} \tag{51}$$

$$\sigma_{xy} = \frac{-Ez}{1 + \nu} \frac{\partial^2 w}{\partial x \partial y}$$

The moments per unit length are given by

$$\begin{aligned} M_x &= \int_{-h/2}^{h/2} \sigma_{xx} z \, dz \\ M_y &= \int_{-h/2}^{h/2} \sigma_{yy} z \, dz \\ M_{yx} &= M_{xy} = \int_{-h/2}^{h/2} \sigma_{xy} z \, dz \end{aligned} \tag{52}$$

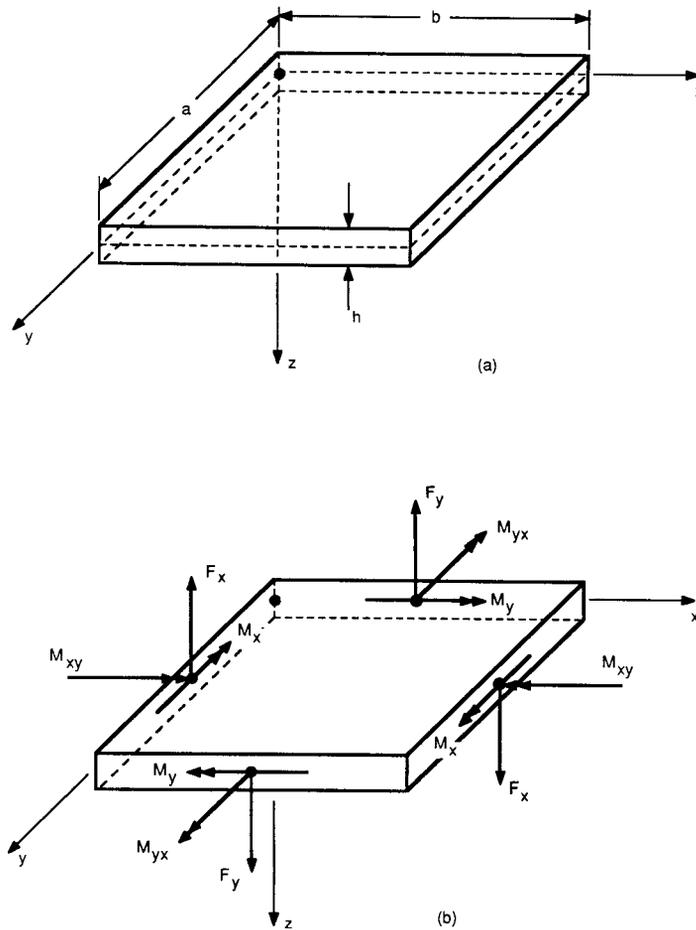

Fig. 24 Positive-sign convention for plate deformation: (a) plate dimensions; (b) positive-sign convention for forces and moments.

Substitution of Eqs. (51) into (52) gives

$$\begin{aligned} M_x &= -D \left(\frac{\partial^2 w}{\partial x^2} + \nu \frac{\partial^2 w}{\partial y^2} \right) \\ M_y &= -D \left(\frac{\partial^2 w}{\partial y^2} + \nu \frac{\partial^2 w}{\partial x^2} \right) \\ M_{xy} &= -D(1 - \nu) \frac{\partial^2 w}{\partial x \partial y} \end{aligned} \quad (53)$$

where

$$D = \frac{Eh^3}{12(1 - \nu^2)}$$

The parameter D is known as the bending stiffness, or flexura rigidity, of the plate.

Equations of Equilibrium If an infinitesimal section of the plate is considered, equilibrium of moments about the x and y axes leads to

$$\frac{\partial M_x}{\partial x} + \frac{M_{xy}}{\partial y} - F_x = 0 \quad \frac{\partial M_y}{\partial y} + \frac{M_{xy}}{\partial x} - F_y = 0 \quad (54)$$

where F_x and F_y are the shear forces per unit length on the x and y faces, respectively (see Fig. 24b). These equations, when combined with Eqs. (53), lead to

$$F_x = -D \frac{\partial}{\partial x} \nabla^2 w \quad F_y = -D \frac{\partial}{\partial y} \nabla^2 w \quad (55)$$

where

$$\nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2}$$

Consideration of equilibrium in the z direction gives

$$\frac{\partial F_x}{\partial x} + \frac{\partial F_y}{\partial x} + p = 0 \quad (56)$$

where p is the load per unit area in the z direction acting on the infinitesimal section. Finally, substituting Eqs. (55) into (56) gives the governing differential equation for equilibrium of a plate:

$$\nabla^2 \nabla^2 w = \nabla^4 w = \frac{p}{D} \quad (57)$$

where

$$\nabla^4 = \frac{\partial^4}{\partial x^4} + 2 \frac{\partial^4}{\partial x^2 \partial y^2} + \frac{\partial^4}{\partial y^4}$$

Boundary Conditions When attempting to solve Eq. (57) for a given pressure distribution $p(x, y)$, the boundary conditions of the plate edges must be known. The mathematical forms of the three commonly encountered boundary conditions follow for a plate edge parallel to the y axis and at a distance $x = a$.

1. Simply-supported-edge conditions

$$w = 0 \quad \text{at } x = a$$

$$\frac{\partial^2 w}{\partial x^2} + \nu \frac{\partial^2 w}{\partial y^2} = 0 \quad \text{at } x = a$$

2. Fixed-edge conditions

$$w = 0 \quad \text{at } x = a$$

$$\frac{\partial w}{\partial y} = 0 \quad \text{at } x = a$$

3. Free-edge conditions

$$\frac{\partial^2 w}{\partial x^2} + \nu \frac{\partial^2 w}{\partial y^2} = 0 \quad \text{at } x = a$$

$$\frac{\partial^3 w}{\partial x^2} + (2 - \nu) \frac{\partial^3 w}{\partial x \partial y^2} = 0 \quad \text{at } x = a$$

Strain Energy When the elastic energy of a component is written in terms of displacements, it is referred to as the strain energy. For thin plates undergoing small deflections only the strain energy due to bending is significant. This quantity is given by

$$U = \frac{1}{2} \int_A D \left\{ \left(\frac{\partial^2 w}{\partial x^2} \right)^2 + \left(\frac{\partial^2 w}{\partial y^2} \right)^2 + 2\nu \frac{\partial^2 w}{\partial x^2} \frac{\partial^2 w}{\partial y^2} + 2(1 - \nu) \left(\frac{\partial^2 w}{\partial x \partial y} \right)^2 \right\} dx dy$$

This expression can be useful for obtaining approximate solutions to plate problems.

Solutions to Plate Problems For relatively simple loadings and edge conditions, solutions for the lateral deflection w , can be found using classical techniques, such as Fourier series analysis.^{12,13} Approximate solutions can be obtained by means of Galerkin's method and energy methods such as the Rayleigh–Ritz method (Ref. 14, Chapter 5). In more recent years, the trend has been to apply numerical methods, most notably the finite-difference and finite-element methods.^{15,16}

The most important quantities in plate design are usually the maximum stress and maximum deflection. Figure 25b and 26a contain this information in graphical form for a variety of loading and edge conditions. More extensive data bases can be found in Refs. 9 (Chapter 10) and 17.

4.2 Orthotropic Plates

The discussion of Section 4.1 assumed an isotropic plate. That is, the material properties are independent of direction. With the current widespread usage of composite materials, the problem of determining stresses and deflection in anisotropic plates has become quite prevalent. A good treatment of the general theory of anisotropic plates can be found in Ref. 18. Typical examples of anisotropic plates include asymmetrically laminated plates made from multiple plies of fiber-reinforced composite materials, and plates reinforced with stringers and ribs.

While the general theory of anisotropic plates is too complex to present here, one simpler plate configuration which is easier to analyze, often occurs in practice. This is the case of an orthotropic plate. A material exhibits orthotropic response if there are two orthogonal planes of material property symmetry. These two directions of symmetry normally lie within the horizontal plane of the plate (the xy plane in Fig. 24). If these directions of symmetry coincide with the x and y directions, the governing differential equation for equilibrium of a plate becomes¹⁵

$$D_{xx} \frac{\partial^4 w}{\partial x^4} + 2H \frac{\partial^4 w}{\partial x^2 \partial y^2} + D_{yy} \frac{\partial^4 w}{\partial y^4} = p \quad (58)$$

where

$$D_{xx} = \frac{1}{12} h^3 Q_{xx} \quad D_{yy} = \frac{1}{12} h^3 Q_{yy} \quad D_{xy} = \frac{1}{12} h^3 Q_{xy}$$

$$G_{xy} = \frac{1}{12} h^3 G \quad H = D_{xy} + 2G_{xy}$$

where h is the plate thickness, and G is the shear modulus of the material. The quantities Q_{xx} , Q_{yy} , Q_{xy} , and G characterize the linearly elastic, orthotropic stress–strain response of the material as given by

$$\begin{Bmatrix} \sigma_{xx} \\ \sigma_{yy} \\ \sigma_{xy} \end{Bmatrix} = \begin{bmatrix} Q_{xx} & Q_{xy} & 0 \\ Q_{xy} & Q_{yy} & 0 \\ 0 & 0 & G \end{bmatrix} \begin{Bmatrix} \varepsilon_{xx} \\ \varepsilon_{yy} \\ \gamma_{xy} \end{Bmatrix}$$

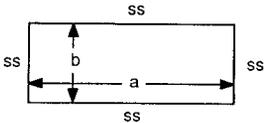

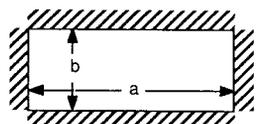

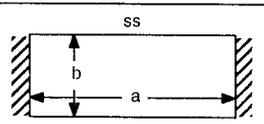

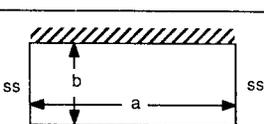

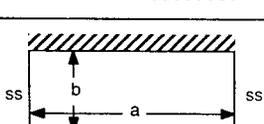

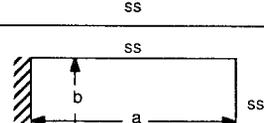

(See Section 7.2 for further discussion of orthotropic response.) The bending moments in terms of the curvatures have the form

$$M_x = - \left(D_{xx} \frac{\partial^2 w}{\partial x^2} + D_{xy} \frac{\partial^2 w}{\partial y^2} \right)$$

$$M_y = - \left(D_{yy} \frac{\partial^2 w}{\partial y^2} + D_{xy} \frac{\partial^2 w}{\partial x^2} \right)$$

$$M_{xy} = -2G_{xy} \frac{\partial^2 w}{\partial x \partial y}$$

It should be mentioned that the preceding equations are valid only for small deflection linear elastic, orthotropic response. In addition to symmetrically stacked composite laminated plates, corrugated plates, plates reinforced by closely spaced ribs and stiffeners, and reinforced concrete slabs can also be modeled as

orthotropic plates.¹² The problem of analyzing orthotropic plates reduces to determining D_{xx} , D_{yy} , D_{xy} , and G_{xy} . Once this has been accomplished, Eq. (58) can be solved by classical, energy, or numerical techniques just as is done for isotropic plates. Figure 27 gives approximate values of these constants for corrugated plates and rib and stiffener reinforced plates.

4.3 Buckling of Isotropic Plates

Critical Buckling Loads The classical isotropic plate theory discussed in Section 4.1 ignored the effects of in-plane forces. When such forces are large, they can significantly alter the response of the plate. If the in-plane forces are tensile, the plate will exhibit

an effective increase in stiffness with respect to lateral loads. If the in-plane forces are compressive, buckling of the plate may occur. Let N_x and N_y represent the in-plane normal forces per unit length in the x and y directions, respectively. Similarly, N_{xy} is the in-plane shear force per unit length. The governing differential equation for plate equilibrium takes the form

$$D \nabla^4 w = N_x \frac{\partial^2 w}{\partial x^2} + N_y \frac{\partial^2 w}{\partial y^2} + 2N_{xy} \frac{\partial^2 w}{\partial x \partial y} + p \quad (59)$$

By setting $p = N_{xy} = N_y = 0$, the critical buckling load for uniaxial compression can be obtained. Similarly, the critical buckling load for any combination of shear and

axial forces can be obtained. See Refs. 12–15 for details on Fourier series, energy, and numerical techniques for solving Eqs. (59). Figure 28 gives critical buckling stresses for plates with various boundary conditions. More extensive results can be found in Ref. 9.

Postbuckling Strength The postbuckling behavior of plates is quite different from that of columns. Whereas columns collapse as soon as the critical load is reached, plates can exhibit considerable postbuckling strength. As the deflection of the plate after buckling increases, the plate stiffness also increases. This behavior is due to the development of transverse tensile stresses subsequent to the start of buckling. Thus, while plate buckling is clearly an undesired component response, it does not necessarily result in catastrophic failure of the engineering structure.

4.4 Shells

A shell is an object that forms a curved surface. Usually, a shell is thin; that is, the thickness of a shell

is small compared to its radius of curvature. It is important to note that this definition of a thin shell is only for classical mechanics analysis of average stresses and deformations. The absolute thickness of a so-called thin shell may be critically important in other areas such as embrittlement of a ductile material caused by thickness and notches or flaw (see Section 8.3). Examples of shells include pressure vessels, soap films, and stadium domes. Whereas plates carry load by the development of bending stresses, shells carry load directly. The strength of a shell comes about primarily because of the way it carries load rather than because of the strength of the material of which it is made.

While even very thin shells will have some bending stiffness, the majority of the loads acting on a shell will be carried by stresses acting tangential to the shell's surface. In the classical membrane theory of shells, bending stiffness is neglected completely. Membrane theory is most applicable for shells of revolution such as shells having the shapes of hemispheres,

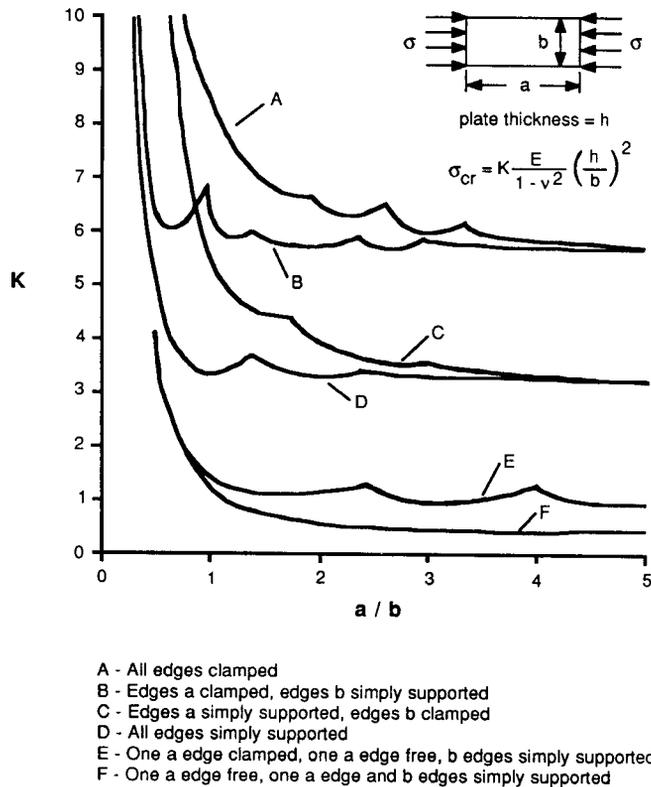

Fig. 28 Critical buckling stress for rectangular plates with various boundary conditions.

paraboloids, and cylinders. For shells of these shapes, classical solutions can be obtained.^{12,19} Because of the variety of shell shapes and the loadings imposed on them, it is difficult to compile a useful yet brief table of formulas. One of the more complete listings of results can be found in Ref. 16. Because of the common use of cylindrical shells as pressure vessels, this particular shell type is discussed in detail in Section 4.5. The previously mentioned potential problem with absolute thickness is especially important for pressure vessels but cannot be discussed here in detail (see Section 8.3 for background on fracture mechanics).

4.5 Cylinders

Thin-Walled Cylinders A cylinder can be considered thin provided its wall thickness is less than one-tenth its radius. Under such conditions, only membrane stresses need to be considered when the cylinder is pressurized internally. In addition, these membrane stresses are essentially constant throughout the wall thickness. If the cylinder is end capped and pressurized with an internal pressure p , the longitudinal stress

is given by

$$\sigma_l = \frac{pr}{2t} \quad (60)$$

where r is the inner radius of the cylinder and t is the wall thickness. Similarly, the transverse stress (hoop stress) is given by

$$\sigma_h = \frac{pr}{t} \quad (61)$$

For a thin-walled spherical pressure vessel, the tensile stress in any direction is given by Eq. (60).

Equations (60) and (61) are derived easily by considering the equilibrium forces acting on a cross section of the pressure vessel.

Thick-Walled Cylinders Thick-walled cylinders are used in many industrial fields. Examples include pressure vessels, gun tubes, and pipes. When the wall thickness is a significant fraction of the cylinder's radius, the tangential stresses can no longer be considered constant through the wall thickness. For an

end-capped cylinder, the stress distribution near the ends can become quite complex due to the effects of welds, joints, localized yielding, and so on. Thus, the stresses near the ends are commonly determined using experimental techniques. For sections far removed from the ends, however, analytical solutions are available. Assuming linear elastic isotropic response, the stresses are given by (Ref. 7, Chapter 3):

$$\sigma_l = \frac{p_1 r_1^2 - p_2 r_2^2}{r_2^2 - r_1^2} + \frac{F}{\pi(r_2^2 - r_1^2)} \quad (62a)$$

$$\sigma_h = \frac{p_1 r_1^2 - p_2 r_2^2}{r_2^2 - r_1^2} + \frac{r_1^2 r_2^2}{r^2(r_2^2 - r_1^2)}(p_1 - p_2) \quad (62b)$$

$$\sigma_r = \frac{p_1 r_1^2 - p_2 r_2^2}{r_2^2 - r_1^2} - \frac{r_1^2 r_2^2}{r^2(r_2^2 - r_1^2)}(p_1 - p_2) \quad (62c)$$

where σ_l = longitudinal stress

σ_h = hoop stress

σ_r = radial stress

p_1 = internal pressure

p_2 = external pressure

r_1 = inner radius of cylinder

r_2 = outer radius of cylinder

r = radial distance to point under consideration

F = longitudinal load applied to ends of cylinder

If temperature gradients exist through the thickness of the cylinder, the equations for the stresses are more complex (Ref. 8, Chapter 11).

Failure Criteria For thin-walled pressure vessels made of a ductile material, the maximum shear stress criterion or maximum distortion energy criterion is applicable (see Section 8.2). If a brittle material is used, or if the vessel is thick walled, it is important to consider the possibility of failure due to unstable crack propagation. Fracture-mechanics-based design should be used in such cases (see Section 8.3). If the vessel will be under considerable cyclic loading, then fatigue failure may occur (see Section 8.4). An extensive set of rules for the design of pressure vessels and piping has been prepared by the American Society of Mechanical Engineers (ASME).²⁰

Compound Cylinders under Internal Pressure

It is apparent from Eqs. (62) that all the stresses cannot be made arbitrarily small by making the outer radius of the cylinder arbitrarily large. In particular, the hoop stress along the inner radius ($r = r_1$) is always greater than the magnitude of the internal pressure, $\sigma_h > p_1$, and the radial stress is always less than $-\sigma_h$, $\sigma_r < -p_1$. Consequently, the maximum shear stress is always larger than p_1 . This situation limits the allowable internal pressure. In order to make more

efficient use of material, it is common practice to prestress the cylinder. This can be done by shrink-fitting a larger cylinder over the original or prestressing the cylinder to high enough pressures so that plastic flow occurs.⁷ Only the former technique will be discussed here.

In order to shrink-fit cylinders, the inner diameter of the larger cylinder must be slightly smaller than the outer diameter of the smaller cylinder. While at the same temperature, the smaller cylinder will not fit inside the larger. If the larger cylinder is heated, however, it will expand in size to the point where the smaller cylinder will fit inside. When the assembly is then brought back to room temperature, a compressive residual hoop stress will exist along the inner radius of the smaller cylinder. This compressive residual stress helps to counteract the tensile hoop stress that develops when internal pressure is applied to the assembly. Details of the procedures to be used for determining the final stress distribution and optimum design of compound cylinders can be found in Refs. 7 and 8.

4.6 Contact Stresses

Contact stresses are the stresses that develop when two solid bodies are pressed against each other. Knowledge of the magnitude of these stresses is important in the design of ball bearings, expansion rollers, and so on. The pioneering work in this field was performed by H. Hertz who is better known for his work with radio waves. The contact stress problem is a nonlinear one, and the analysis is difficult. The primary assumptions used in Hertz's theory are as follows:

1. The contacting bodies are linear elastic, homogeneous, and isotropic.
2. The zone of contact is small compared to the dimensions of the bodies.
3. No friction is present.

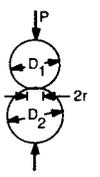

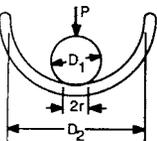

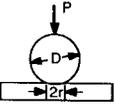

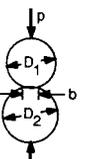

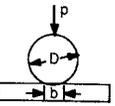

Hertz's formulas give the maximum compressive stress that occurs in the contact region, but not the maximum shear stress or maximum tensile stress. Table 7 gives formulas for the maximum stress and contact radius for some common cases. These formulas are based on the original work of Hertz. References 7–9 give more details on the problem of contact stresses.

5 NONLINEAR RESPONSE OF MATERIALS

5.1 Introduction to Plasticity

Plastic flow is said to have occurred in a component if the component does not return to its original shape upon removal of the applied loads. Theories of plasticity fall into two major categories: mathematical theories and physical theories. Mathematical theories provide useful, quantitative information on the plastic flow of materials from a macroscopic point of view. Physical theories help one explain why a material plastically flows this is done by looking at

Table 7 Stresses and Contact Area for Two Surfaces in Contact

Surface Types	Maximum Compressive Stress, σ (psi)	Radius r or Width b of Contact Area (in.)
 <p>sphere on a sphere</p>	$\sigma = 0.616 \left[PE^2 \left(\frac{D_1 + D_2}{D_1 D_2} \right)^2 \right]^{1/3}$	$r = 0.881 \left[\frac{P}{E} \left(\frac{D_1 D_2}{D_1 + D_2} \right) \right]^{1/3}$
 <p>sphere in a spherical socket</p>	$\sigma = 0.616 \left[PE^2 \left(\frac{D_1 - D_2}{D_1 D_2} \right)^2 \right]^{1/3}$	$r = 0.881 \left[\frac{P}{E} \left(\frac{D_1 D_2}{D_1 - D_2} \right) \right]^{1/3}$
 <p>sphere on a plate</p>	$\sigma = 0.616 \left[\frac{PE^2}{D^2} \right]^{1/3}$	$r = 0.881 \left[\frac{PD}{E} \right]^{1/3}$
 <p>cylinder on a cylinder</p>	$\sigma = 0.591 \sqrt{pE \left(\frac{D_1 + D_2}{D_1 D_2} \right)}$	$b = 2.15 \sqrt{\frac{P}{E} \left(\frac{D_1 D_2}{D_1 + D_2} \right)}$
 <p>cylinder on a plate</p>	$\sigma = 0.591 \sqrt{\frac{pE}{D}}$	$b = 2.15 \sqrt{\frac{pD}{E}}$

Note: Poisson's ratio = 0.3, E = modulus of elasticity (psi), P = load (lb), p = load per unit length (lb/in.), r , b , D_1 , D_2 , and D in inches.

the material's microstructure. From the viewpoint of the design engineer, the phenomenological approach offered by mathematical theories is the more useful of the two approaches.

Idealized Response The plastic flow of metals is extremely nonlinear, as is evident from the monotonic stress-strain curves shown later in Fig. 58. Accurate mathematical modeling of such material response is exceedingly difficult. In order to provide useful (but only approximate) predictions, several idealized stress-strain curves are often employed. These are illustrated in Fig. 29. The model of rigid, perfectly plastic behavior neglects elastic strains as well as strain-hardening effects. While this model may seem to be overly simplistic, it has proven useful in limit analysis as well as confine metal-forming processes

such as extrusion.³ The model of elastic, perfectly plastic behavior is useful for representing the initial yielding response of mild steels. The model of rigid, linear strain-hardening plastic behavior and the model of elastic, linear strain-hardening plastic behavior are useful for representing large plastic strains in strain-hardening materials.

Bauschinger Effect Low-carbon steels (mild steels) are among the most commonly used engineering materials. They are in a special class because of their sharp-yielding behavior and related phenomena described in the following.

If monotonic tension and compression tests are performed on homogeneous specimens of mild steel and the resulting true stress-strain curves are constructed, the two curves look almost identical. In particular,

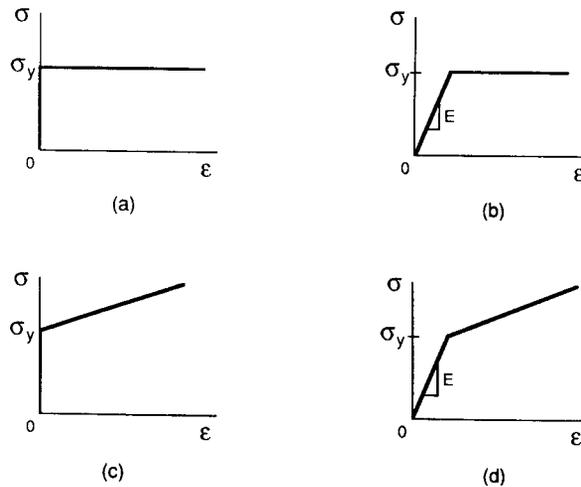

Fig. 29 Idealized stress–strain curves: (a) rigid, perfectly plastic; (b) elastic, perfectly plastic; (c) rigid, linear strain-hardening plastic; (d) elastic, linear strain-hardening plastic.

the yield strengths in tension and compression are essentially the same. If a specimen is first loaded in tension into the plastic range and then loaded in compression, the yield strength in compression (σ_{yc}) is generally much lower than the yield strength in tension (σ_{yt}) (Fig. 30). This phenomenon is known as the Bauschinger effect. It plays an important role in cyclic plasticity of these metals.

It is also worthwhile to note that plastic flow is an anisotropic phenomenon. If an initially isotropic material is loaded into the plastic regime and the load is then released, the material will no longer exhibit the same strength properties in all directions. For example, the yield strength of cold-rolled sheet will be substantially different in the thickness direction from that in the rolling direction.

Effects of Hydrostatic Pressure and Incompressibility It has been found that, except for extremely large pressures, hydrostatic pressure has a negligible effect on plastic deformations.²¹ Many theories of plasticity assume that the hydrostatic component of stress, $\sigma_{xx} + \sigma_{yy} + \sigma_{zz}$, does not influence the yield behavior of the material. Instead of using the stress tensor [Eq. (1)], it is often found convenient to work with the deviatoric stress tensor defined by

$$[\sigma_d] = \begin{bmatrix} \sigma_{xx} + p & \sigma_{xy} & \sigma_{xz} \\ \sigma_{yx} & \sigma_{yy} + p & \sigma_{yz} \\ \sigma_{zx} & \sigma_{zy} & \sigma_{zz} + p \end{bmatrix}$$

where $p = -\frac{1}{3}(\sigma_{xx} + \sigma_{yy} + \sigma_{zz})$.

It is also commonly assumed in theories of plasticity that plastic deformation is a constant-volume process. Provided the strains are small enough so that

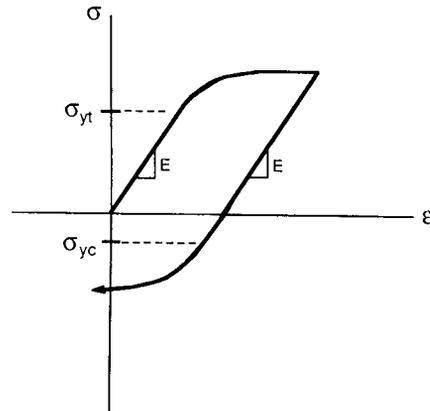

Fig. 30 Bauschinger effect.

product terms can be neglected, the assumption of incompressibility takes the form $\epsilon_{xx} + \epsilon_{yy} + \epsilon_{zz} = 0$.

Solution procedures for general problems using mathematical theories of plasticity are beyond the scope of this work. Details of such solution procedures can be found in Refs. 2 (Chapter 49) and 22.

Multiaxial Loadings A variety of theories exist for the yielding of ductile metals under multiaxial loading conditions. The most popular of these are the distortion energy theory and the maximum shear stress theory. Details of these theories are given in Section 8.2. Reference 22 provides a comparison of these two theories with experimental data obtained by various researchers.

Limit Analysis Limit analysis refers to the determination of the magnitude of the load that will cause plastic collapse of a structure. The plastic collapse load is that load at which the increment of deflection per unit increment of load becomes large. This phenomenon is referred to as uncontained plastic flow. In such situations, enough of the engineering component is undergoing plastic flow so that the remaining elastic regions play only a minor role in sustaining the applied loads. Since failure due to plastic collapse is the governing design criterion for many structures, limit analysis has received increasing attention over the years. It represents a more efficient design criterion than, for example, design based on the yield strength. In many structures, of course, other failure modes such as fatigue, brittle fracture, or buckling govern the design. Limit analysis is most useful in the design of beams and rigid-jointed frames made of mild steels.

In order to obtain quantitative results, the following two assumptions are made:

1. The material exhibits elastic, perfectly plastic response.
2. Changes in geometry of the structure for loads less than the limit load are insignificant

The advantages of limit load analysis, besides making more efficient use of material, is that the limit load can often be obtained through very simple calculations.

One of the biggest disadvantages is that the deflection for loads below the plastic collapse load are not determined. For some structures, these deflections may be so large as to govern the design, so that plastic collapse becomes irrelevant. Further details on limit analysis can be found in Refs. 2 and 22.

5.2 Plastic Response of Beams and Shafts

When analyzing the plastic response of beams and shafts, it is commonly assumed that the material to be used is elastic–plastic; that is, it behaves in an elastic, perfectly plastic manner (Fig. 29*b*).

Plastic Bending of a Rectangular Beam To illustrate the analysis procedures for determining plastic response of beams, the case of a beam of rectangular cross section undergoing pure bending is considered. The beam is assumed to have a width b and height $2h$. The moment of inertia is given by $I = b(2h)^3/12 = 2bh^3/3$. The maximum stress σ_m in the beam for elastic response occurs at the top and bottom edges ($y = \pm h$) (Fig. 31*a*). Its magnitude is given by Eq. (27):

$$|\sigma_m| = \frac{Mh}{I} = \frac{3M}{2bh^2}$$

The bending moment corresponding to the initiation of yield on the top and bottom edges of the beam,

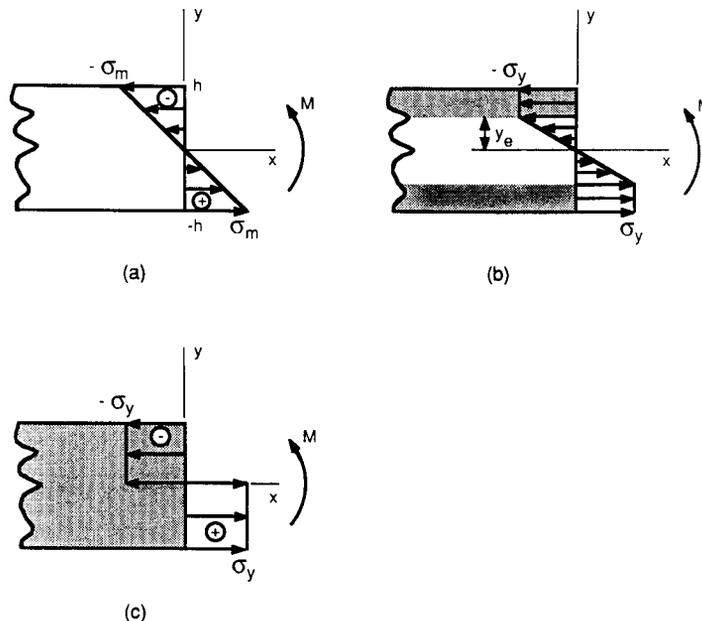

Fig. 31 Plastic deformations in a beam undergoing bending: (a) elastic response; (b) elastic–plastic response; (c) fully plastic response.

M_y , is given by $M_y = (\frac{2}{3})bh^2\sigma_y$, where σ_y is the yield strength of the material.

As the bending moment is further increased, plastic zones develop on the top and bottom of the beam (Fig. 31b). The stress is constant in these zones with a value of σ_y . Within the remaining elastic core, the stresses have the form

$$\sigma_x = -\frac{y}{y_e}\sigma_y$$

where y_e is half the height of the elastic core. The corresponding moment is given by

$$\begin{aligned} M &= -2 \int_0^{y_e} y \left(-\frac{y}{y_e}\sigma_y \right) (b dy) \\ &= -2 \int_{y_e}^h y(-\sigma_y)(b dy) \end{aligned}$$

Integrating this expression and simplifying it leads to

$$M = \frac{3}{2}M_y \left(1 - \frac{1}{3} \frac{y_e^2}{h^2} \right) \quad (63)$$

As y_e approaches zero, the beam becomes fully plastic, and plastic collapse is imminent (Fig. 31c). The bending moment for fully plastic collapse, M_p , is found by substituting $y_e = 0$ into Eq. (63): $M_p = 1.5M_y = bh^2\sigma_y$. By using limit analysis, this result can be found directly:

$$M_p = -2 \int_0^h (-y\sigma_y)(b dy) = bh^2\sigma_y$$

Similar expressions can be derived for the limit loads of other kinds of beam loadings. It is often convenient to introduce the plastic section modulus Z , which satisfies the following equation: $M_p = \sigma_y Z$. For the rectangular cross section just considered, $Z = bh^2$. Plastic section moduli for common steel shapes can be found in the *Manual of Steel Construction*.²³

Plastic Deformations in a Circular Shaft Undergoing Torsion The circular shaft is assumed to be solid with a radius c . The polar moment of inertia of the cross section is $J = 0.5\pi c^4$. The maximum shear stress for elastic response, τ_m , occurs on the outer surface of the shaft (Fig. 32a). Its value is given by Eq. (41):

$$\tau_m = \frac{Tc}{J} = \frac{2T}{\pi c^3}$$

Denoting the torque that will initiate yielding by T_y , it follows that

$$T_y = \frac{\pi}{2}c^3\tau_y$$

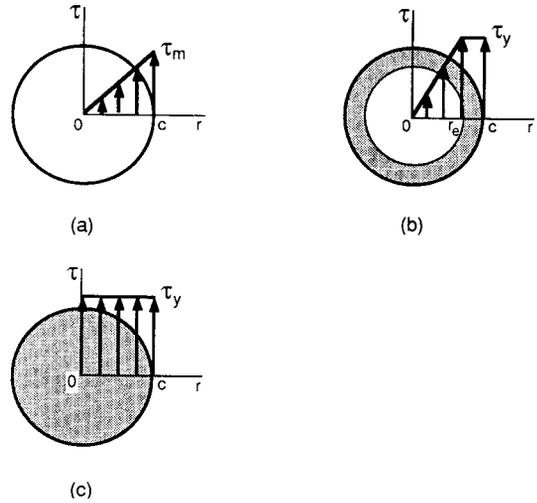

Fig. 32 Plastic deformations in a circular shaft undergoing torsion: (a) elastic response; (b) elastic-plastic response; (c) fully plastic response.

where τ_y is the yield strength in shear of the material.

As the torque is further increased, a plastic zone develops in the outer regions of the shaft (Fig. 32b). This plastic zone surrounds an elastic core. Within the plastic zone the shear stress is given by τ_y . In the elastic core, the shear stress has the form $\tau = (r/r_e)\tau_y$, where r is the radial distance to the point under consideration, and r_e is the radial distance to the edge of the elastic core. The corresponding torque can be found with the aid of Eq. (40):

$$T = \int_0^{r_e} r \left(\frac{r}{r_e}\tau_y \right) (2\pi r dr) + \int_{r_e}^c r(\tau_y)(2\pi r dr)$$

Integrating and simplifying this equation leads to

$$T = \frac{4}{3}T_y \left(1 - \frac{1}{4} \frac{r_e^3}{c^3} \right) \quad (64)$$

The torque corresponding to fully plastic deformation, T_p , is found by setting r_e equal to zero in Eq. (64):

$$T_p = \frac{4}{3}T_y = \frac{2}{3}\pi c^3\tau_y$$

Using limit analysis, this result can be obtained directly from Eq. (40) by setting $\tau = \tau_y$:

$$T_p = \int_0^c r(\tau_y)(2\pi r dr) = \frac{2}{3}\pi c^3\tau_y$$

5.3 Viscoelasticity

Viscoelasticity is the study of the time-dependent response of solid materials. Time, rate, and temperature effects must be considered when analyzing the viscoelastic response of materials. In particular, it is useful to know the homologous temperature T_h . This is defined as the ratio of the operating temperature T to the melting temperature of the material T_m : $T_h = T/T_m$. Both T and T_m must be expressed as absolute temperatures. For U.S. customary units, absolute temperature is measured in Rankines ($^{\circ}\text{R} = ^{\circ}\text{F} + 459.67$). If T_h is below 0.3, viscoelastic effects can usually be neglected. If T_h is greater than 0.5, viscoelastic phenomena will almost certainly play a role in the mechanical response of the material.

Creep and the Stress Rupture Test Creep refers to the time-dependent accumulation of strain in a component subjected to a constant stress. In a typical creep test, a slender specimen is subjected to a constant load rather than a constant stress. A schematic diagram of a creep curve that results from a constant-load test is shown in Fig. 33. The creep process can usually be divided into three stages. During primary creep, the creep rate is a decreasing function of time. This response is brought about due to strain-hardening effects. During secondary creep, also called steady-state creep, the creep rate is constant. During this stage, strain-hardening effects are balanced by the effects of increasing true stress amplitude due to decreasing cross-sectional area. During tertiary creep, the decreasing cross-sectional area becomes the controlling feature, and the creep rate rises rapidly until failure occurs. This response is somewhat analogous to the decrease in load amplitude during a tension test due to the necking down of the specimen (see Section 1.4).

It is possible, although difficult, to perform a creep test in which the true stress is maintained constant rather than the load. For such tests, tertiary creep is not observed. This indicates that tertiary creep is indeed due to a mechanical instability rather than representing actual material response. It is often found that the strain at which tertiary creep begins in a constant-load creep test is roughly the same as the strain at which necking

down begins in a tensile test. Even secondary creep is probably a misconception. For carefully controlled constant-true-stress creep tests, the creep rate is usually found to continuously decrease with time.²⁴

In spite of the aforementioned problems, constant-load creep testing, commonly referred to as stress rupture testing, is still the most common test method used to determine the viscoelastic properties of a material. In a typical testing series, the time to rupture is determined for a range of loads and temperatures. The data are then plotted as the engineering stress versus time to rupture on log-log coordinates.

Stress Relaxation Tests In a stress relaxation test, the strain is held constant, and the decrease in stress with time is recorded. The advantage of a stress relaxation test over a stress rupture test is that no mechanical instability arises. Thus, the stress relaxation test gives more representative material response than the stress rupture test. The primary disadvantage is that the stress must be continuously adjusted so as to keep the strain constant. This requires the use of sophisticated mechanical testing equipment. A schematic of the typical stress versus time response observed in a stress relaxation test is shown in Fig. 34. Unlike the three-stage response of a stress rupture test, a stress

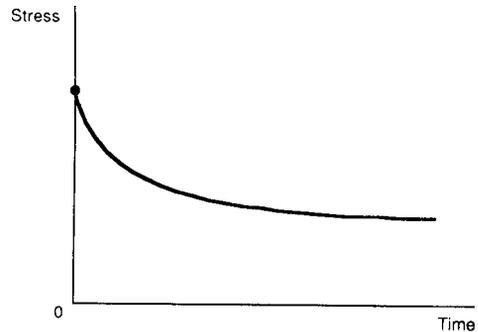

Fig. 34 Stress versus time for stress relaxation test.

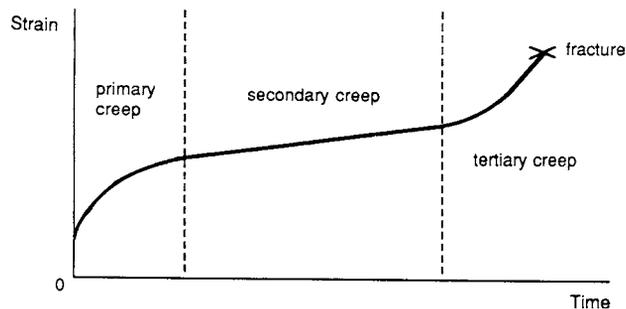

Fig. 33 Schematic diagram of typical creep curve.

relaxation test shows only one general response: a continuing decrease in the stress relaxation rate with time.

Linear Viscoelastic Models Viscoelastic response is sometimes modeled by using combinations of springs and dashpots. Two of the most commonly used of these models are the Maxwell model and the Kelvin–Voigt model (Fig. 35). In this figure, E is the stiffness of the spring, and η is the viscosity coefficient of the dashpot.

The Maxwell model consists of a spring and dashpot in series. This model predicts a linear creep rate (which is representative of secondary creep). The model predicts exponential decay of stress under constant strain conditions. This is the kind of response typically observed in stress relaxation tests of metals.

The Kelvin–Voigt model consists of a spring and dashpot in parallel. The creep response of this model is indicative of primary creep. This model does not exhibit stress relaxation, however.

It is clear that neither the Maxwell model nor the Kelvin–Voigt model is capable of completely describing the creep and stress relaxation response of common

materials. Even so, each model is applicable for certain stages of the creep process. These models are not necessarily useful for their ability to accurately predict material response, but rather for the simple visualization of viscoelastic response that they provide. More sophisticated spring-dashpot models are sometimes used. A good discussion of these models can be found in Ref. 25.

In the continuum mechanics approach to viscoelasticity, time-dependent response is modeled by using constitutive equations containing convolution integrals. The stress response $\sigma(t)$ for an arbitrary strain input $\varepsilon(t)$ has the form

$$\sigma(t) = \varepsilon(0)G(t) + \int_0^t G(t - \tau) \frac{d\varepsilon(\tau)}{d\tau} d\tau$$

where t represents time, $\varepsilon(0)$ is the strain corresponding to $t = 0$, and $G(t)$ is the relaxation modulus function (which is often a complicated function of time).²⁶ Similarly, the strain response due to an arbitrary stress

	Maxwell model	Kelvin-Voigt model
Schematic Diagram		
Governing Differential Equation	$\frac{1}{E} \frac{d\sigma}{dt} + \frac{\sigma}{\eta} = \frac{d\varepsilon}{dt}$	$\sigma = E\varepsilon + \eta \frac{d\varepsilon}{dt}$
Creep Response ($\sigma = \text{const.} = \sigma_0$)	 $\varepsilon = \frac{\sigma_0}{E} + \frac{\sigma_0}{\eta} t$	 $\varepsilon = \frac{\sigma_0}{E} (1 - e^{-tE/\eta})$
Stress Relaxation Response ($\varepsilon = \text{const.} = \varepsilon_0$)	 $\sigma = E\varepsilon_0 e^{-tE/\eta}$	 $\sigma = E\varepsilon_0$

Fig. 35 Models for viscoelastic response.

input is given by

$$\varepsilon(t) = \sigma(0)J(t) + \int_0^t J(t - \tau) \frac{d\sigma(\tau)}{d\tau} d\tau$$

where $\sigma(0)$ is the stress corresponding to $t = 0$, and $J(t)$ is the creep compliance function. It can be shown that $G(t)$ and $J(t)$ satisfy

$$\int_0^t G(t - \tau) \frac{dJ(\tau)}{d\tau} d\tau = h(t)$$

where $h(t)$ is the unit step function. Thus, determination of $G(t)$ using a stress relaxation test automatically prescribes $J(t)$. Similarly, determining $J(t)$ using a constant-true-stress creep test automatically prescribes $G(t)$. Therefore, the continuum mechanics approach to viscoelasticity rests on the assumption that creep and stress relaxation are simply different manifestations of the same material response. While the continuum mechanics approach to viscoelasticity can lead to powerful methods of analysis, these methods are generally exceedingly difficult to implement in practice.

5.4 Elastic Stability and Column Buckling

When a slender column is subjected to small compressive loads, the column axially shortens according to $\delta = PL/AE$, where δ is the axial shortening, P is the applied load, A is the cross-sectional area, E is the elastic modulus of the material, and L is the column length. If continually larger loads are applied, a load is reached at which the column suddenly bows out sideways. This load is referred to as the critical or buckling load of the column. These sideways deformations are normally too large to be acceptable; consequently, the column is considered to have failed. For slender columns, the axial stress corresponding to

the critical load is generally below the yield strength of the material. Since the stresses in the column just prior to buckling are within the elastic range, the failure is referred to as elastic buckling. Of course, once the column has buckled, large sideways deformations may cause some plastic flow to occur. The term *elastic stability* is commonly used to designate the study of elastic buckling problems. For short columns, failure may be governed by yielding or rupture of the column while it is still axially straight. Failure of short columns may also be caused by inelastic buckling; that is, large sideways deformations that occur when the nominal axial stress is greater than the yield strength.

Besides columns, other structural components that are prone to buckling include plates, shells, and frames. The discussion here will be limited to columns. Buckling of plates is described in Section 4.3. Buckling of frames and shells, as well as torsional buckling phenomena, are discussed in Ref. 27.

Theory of Column Buckling The first studies of the elastic buckling of columns were performed by Euler in the mid-eighteenth century. The governing differential equation for the elastic stability of a pinned–pinned column is given by (see Fig. 36):

$$y'' = \frac{d^2y}{dx^2} = \frac{M}{EI} \tag{65}$$

where E is the elastic modulus, M is the moment acting on the cross section, and I is the moment of inertia of the cross section. For this equation to govern the buckling of the column, I must be the minimum moment of inertia of the cross section. Also, in using this equation, one assumes linear elastic, isotropic response. From statics, $M = -Py$. Equation (65) thus becomes

$$EIy'' + Py = 0 \tag{66}$$

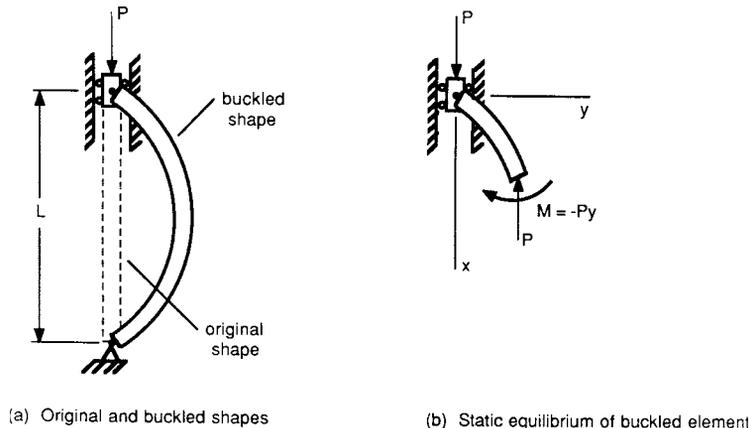

Fig. 36 Pinned–pinned Euler column: (a) original and buckled shapes; (b) static equilibrium of buckled element.

This is a second-order, homogeneous, linear differential equation with constant coefficients. Its general solution takes the form

$$y = A \sin \lambda x + B \cos \lambda x \quad (67)$$

where $\lambda^2 = P/EI$ and A and B are constants.

Four boundary conditions can be applied to solve for A and B in Eq. (67). Two of these conditions are

$$y'' = \begin{cases} 0 & \text{at } x = 0 \\ 0 & \text{at } x = L \end{cases}$$

where the primes denote differentiation with respect to x . These conditions are known as natural boundary conditions. They result from the fact that the moments at the pin connections must be zero. Two other boundary conditions are

$$y = \begin{cases} 0 & \text{at } x = 0 \\ 0 & \text{at } x = L \end{cases}$$

These are known as forced boundary conditions. They result from the geometric constraints that exist. Using either the forced or the natural boundary conditions results in the same two possible solutions:

$$A = 0 \quad \text{and} \quad B = 0$$

or

$$\sin \lambda L = 0 \quad \text{and} \quad B = 0$$

The first of these solutions ($A = 0$ and $B = 0$) is known as the trivial solution. It represents the condition that the beam is still straight. The second solution leads to

$$\lambda L = n\pi \quad n = 0, 1, 2, 3, \dots$$

Using $\lambda^2 = P/EI$,

$$P = \frac{n^2 \pi^2 EI}{L^2} \quad n = 0, 1, 2, 3, \dots$$

Clearly, $n = 0$ corresponds to no load being applied to the column. The minimum load for which buckling will occur corresponds to $n = 1$. This critical buckling load P_{cr} is given by

$$P_{cr} = \frac{\pi^2 EI}{L^2} \quad (68)$$

Equation (68) is often referred to as Euler's formula. If I is expressed in terms of the radius of gyration

and area of the cross section, $I = r^2 A$, Eq. (68) can be expressed in terms of the critical buckling stress:

$$\sigma_{cr} = \frac{\pi^2 E}{(L/r)^2}$$

The quantity L/r is referred to as the slenderness ratio of the column. The deflected shape is found from Eq. (67): $y = A \sin(\pi x/L)$. The deflected shape is hence sinusoidal in nature. Since the constant A cannot be prescribed, the magnitude of the deflected shape is indeterminate using this approach.

Equation (66) is valid only for a pinned-pinned column. For other end conditions, a different second-order differential equation applies. It has been shown by Timoshenko and Gere²⁸ that a single fourth-order differential equation applicable to all end conditions can be employed. This equation has the form

$$y^{iv} + \lambda^2 y'' = 0 \quad (69)$$

This differential equation has the general solution

$$y = A \sin \lambda x + B \cos \lambda x + Cx + D \quad (70)$$

where A , B , C , and D are constants. Application of the four available boundary conditions allows for determination of P_{cr} and three of the constants. One of the constants (either A or B) is indeterminate. Thus, the magnitude of the deflected shape cannot be determined using this classical technique either.

Effective Column Length For end conditions other than pinned-pinned, it is common to express the Euler buckling load in the form

$$P_{cr} = \frac{\pi^2 EI}{L_e^2}$$

where L_e is the effective column length. Figure 37 provides effective column lengths and mathematical boundary conditions for a variety of end conditions. The mathematical boundary conditions are used in conjunction with Eq. (70) to obtain L_e . See Ref. 27 for further details.

Imperfect Columns In reality, columns are never perfectly straight. Instead, they have some initial eccentricity, often denoted by e , as shown in exaggerated form in Fig. 38. If e is known or can be estimated, the maximum deflection as a function of load can be obtained as

$$y_{\max} = e \left[\sec \left(\frac{L}{2} \sqrt{\frac{P}{EI}} \right) - 1 \right]$$

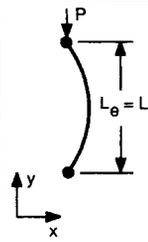

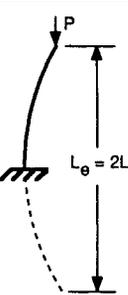

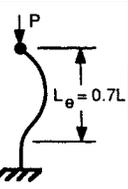

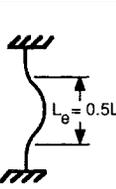

Column type:	Pinned-pinned	Fixed - free	Fixed-pinned	Fixed-fixed
Effective length:				
Boundary Conditions:	$x = 0, y = 0$ $x = L, y = 0$ $x = 0, y'' = 0$ $x = L, y'' = 0$	$x = 0, y = 0$ $x = 0, y' = 0$ $x = L, y'' = 0$ $x = L, y''' + k^2 y' = 0$	$x = 0, y = 0$ $x = 0, y' = 0$ $x = L, y = 0$ $x = L, y'' = 0$	$x = 0, y = 0$ $x = 0, y' = 0$ $x = L, y = 0$ $x = L, y' = 0$

Fig. 37 Effective lengths and boundary conditions for various columns.

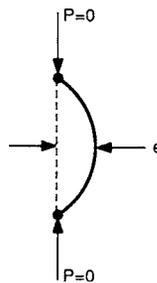

Fig. 38 Initially eccentric column.

The maximum compressive stress is given by

$$\sigma_{\max} = \frac{P}{A} \left[1 + \frac{ec}{r^2} \sec \left(\frac{L}{2} \sqrt{\frac{P}{EI}} \right) \right] \quad (71)$$

where c is the distance from the neutral axis to the outermost compressed fiber of the cross section. All other symbols have been previously defined. Equation (71) is referred to as the secant formula. It gives the maximum stress that exists in a column for a given applied load (assuming elastic response throughout the column). For design purposes, the maximum stress is set equal to the yield strength (or to the fracture stress for brittle materials), and the corresponding critical load P_{cr} is found by trial and error. The appropriate factor of safety is applied to this load. The factor of safety must not be applied to the stress since the relation between stress and load in Eq. (71) is nonlinear. Figure 39 gives

a comparison of the secant and Euler formulas for a mild steel.

The secant formula can be used for columns that are eccentrically loaded if e is taken as the eccentricity due to the load plus the initial eccentricity of the column.

Inelastic Buckling For very short columns, the critical stress corresponds to the compressive strength of the material. For very long columns, the Euler critical stress is applicable. For intermediate length columns, failure often occurs at stresses below that predicted by the Euler critical stress or the compressive strength. The effects of residual stresses, especially in rolled carbon steel columns, play an important role in the buckling behavior of intermediate length columns. The tangent modulus theory is sometimes useful in dealing with intermediate length columns. In this theory the elastic modulus in Euler's formula, E , is replaced by the tangent modulus E_T . The tangent modulus corresponding to a given stress is the slope of the stress-strain curve at that stress level. For elastic response, E and E_T are identical. In equation form, the tangent modulus theory is given by

$$P_{cr} = \frac{\pi^2 E_T I}{L_e^2} \quad (72)$$

where E_T is the slope of the stress-strain curve at the critical stress. Equation (72) is sometimes referred to as the Engesser equation. It is valid only for a rectangular cross section bent about its weak axis. Because use of the tangent modulus theory requires a detailed knowledge of a material's stress-strain curve, it is difficult to implement in practice. Simplified column formulas are more commonly used.

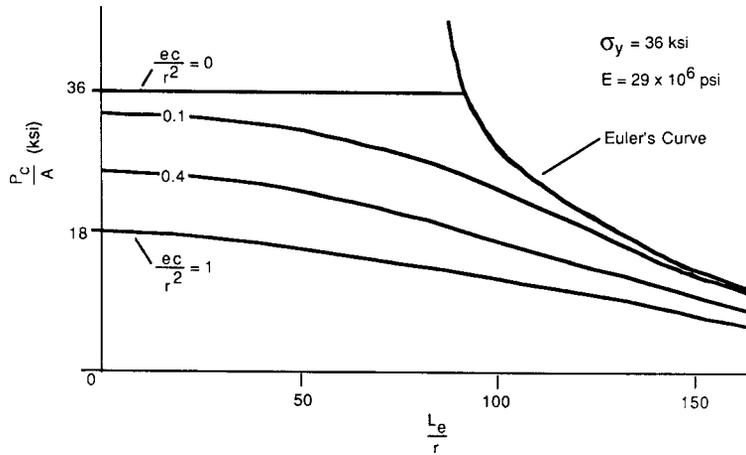

Fig. 39 Comparison of Euler and secant formulas.

Simplified Column Formulas Because of the complexities of the tangent modulus theory, a number of simpler formulas have been proposed:

$$\frac{P_c}{A} = \begin{cases} \sigma_0 - C \left(\frac{L_e}{r}\right)^2 & \text{(parabolic)} & (73) \\ \frac{\sigma_0}{1 + C \left(\frac{L_e}{r}\right)^2} & \text{(Gordon-Rankine)} & (74) \\ \sigma_0 - C \left(\frac{L_e}{r}\right) & \text{(straight line)} & (75) \end{cases}$$

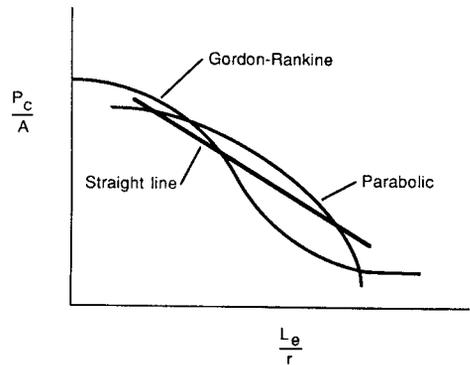

Fig. 40 Simplified column formulas.

where P_c/A is the average buckling stress, σ_0 is the compressive strength of the material, C is a material constant, L_e is the effective column length, and r is the radius of gyration of the cross section. The constants σ_0 and C may not be the same in each formula, even for the same material, since they are adjusted to provide a best fit to experimental data. Equations (73)–(75) are displayed graphically in Fig. 40.

Steel Columns Because of the variation in cooling rates of different regions of a hot rolled wide-flang member, large compressive residual stresses can develop. Cold rolling of steel members can also result in significant residual stresses. These residual stresses must be allowed for (by appropriate factors of safety) when designing against column buckling. The current American Institute of Steel Construction (AISC) specification for buckling of steel columns is as follows.²⁹

For slenderness ratios less than C_c , where $C_c = (2\pi^2 E/\sigma_y)^{0.5}$, the column buckling formula is given

by

$$\sigma_a = \frac{\sigma_y \{1 - [(\frac{1}{2}C_c^2)(L_e/r)^2]\}}{FS} \quad (76)$$

where σ_a = allowable compressive stress

L_e/r = slenderness ratio

$$FS = \frac{5}{3} + 3(L_e/r)/8C_c - (L_e/r)^3/8C_c^3$$

For slenderness ratios greater than C_c , the Euler equation is used with a built-in factor of safety of 1.92:

$$\sigma_a = \frac{\pi^2 E}{1.92(L_e/r)^2} \quad (77)$$

Aluminum Columns The Aluminum Association provides three formulas for use with each aluminum alloy.³⁰ For short columns, the allowable compressive

stress is constant with respect to slenderness ratio. For intermediate columns, a straight-line relationship similar to Eq. (75) is used. For long columns, a Euler formula is used.

Timber Columns The American Institute of Timber Construction specifies the use of Euler's formula with a factor of safety of 2.727:

$$\sigma_a = \frac{\pi^2 E}{2.727(L_e/r)^2} \quad (78)$$

Of course, the allowable stress must not exceed the allowable compressive strength parallel to the grain.³¹

6 ENERGY METHODS

6.1 Strain Energy and Strain Energy Density

Axial Loading Consider the case of a uniform rod on which an axial load P is acting. Assume that the axis of the rod is in the x direction. The work done by the load P in extending the rod from its original length L to a length $L + \Delta L$ is given by

$$U = \int_0^{\Delta L} P dx$$

where U is known as the strain energy of the rod. It is normally expressed in foot-pounds or inch-pounds.

The strain energy density u is defined as the strain energy per unit volume. For the case of an axially loaded uniform rod,

$$u = \frac{U}{V} = \frac{1}{AL} \int_0^{\Delta L} P dx = \int_0^{\epsilon} \sigma_{xx} d\epsilon_{xx} \quad (79)$$

where V is the volume of the rod, and A is its cross-sectional area. It is apparent from Eq. (79) that the strain energy density for the case of axial loading of a rod represents the area under the stress-strain diagram. Strain energy density has units of inch-pounds per cubic inches.

For linear elastic, isotropic response, $\epsilon_{xx} = \sigma_{xx}/E$, where E is the elastic modulus. Equation (79) becomes

$$u = \frac{\sigma_{xx}^2}{2E} \quad (80)$$

The total strain energy of the uniform rod is

$$U = uV = \frac{\sigma_{xx}^2}{2E} (AL) = \frac{P^2 L}{2AE}$$

If the cross section of the rod varies along the length of the rod, the total strain energy must be found by

integration of Eq. (80):

$$U = \int \frac{\sigma_{xx}^2}{2E} dV \quad (81)$$

It should be kept in mind that Eqs. (80) and (81) apply to a linear elastic, isotropic rod undergoing axial loading.

The modulus of resilience u_y represents the area under the stress-strain diagram up to the yield strength (Fig. 41). Assuming that the yield strength and proportional limit coincide, u_y can be written as

$$u_y = \frac{\sigma_y^2}{2E} \quad (82)$$

where σ_y is the yield strength of the material. The modulus of resilience is important because it represents the energy per unit volume that a material can absorb without yielding.

General State of Loading Assuming linear elastic, isotropic response, the strain energy density can be expressed in several equivalent forms,

$$u = \begin{cases} \frac{1}{2} \{ \sigma_{xx} \epsilon_{xx} + \sigma_{yy} \epsilon_{yy} + \sigma_{zz} \epsilon_{zz} + \sigma_{xy} \gamma_{xy} + \sigma_{yz} \gamma_{yz} + \sigma_{zx} \gamma_{zx} \} & (83a) \\ \frac{1}{2E} \{ \sigma_{xx}^2 + \sigma_{yy}^2 + \sigma_{zz}^2 - 2\nu(\sigma_{xx}\sigma_{yy} + \sigma_{yy}\sigma_{zz} + \sigma_{zz}\sigma_{xx}) + 2(1+\nu)(\sigma_{xy}^2 + \sigma_{yz}^2 + \sigma_{zx}^2) \} & (83b) \\ G \left\{ \epsilon_{xx}^2 + \epsilon_{yy}^2 + \epsilon_{zz}^2 + \frac{\nu e^2}{1-2\nu} + \frac{1}{2}(\gamma_{xy}^2 + \gamma_{yz}^2 + \gamma_{zx}^2) \right\} & (83c) \end{cases}$$

where $e = \epsilon_{xx} + \epsilon_{yy} + \epsilon_{zz}$. The total strain energy of a component is found by integrating any of Eqs. (83) over the volume of the component.

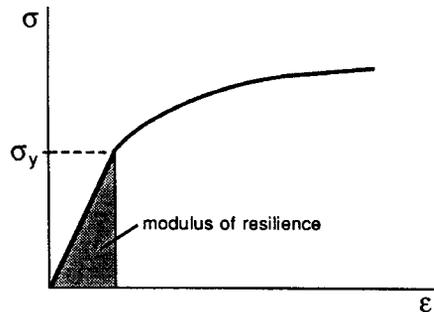

Fig. 41 Definition of modulus of resilience.

Strain Energy in Bending For the case of a beam in pure bending, the flexural stress is given by $\sigma_x = -My/I$, where M is the applied moment, I is the moment of inertia of the cross section, and y is the distance from the neutral axis to the point under consideration (see Section 2.2 for details). All other stresses are zero. Equation (83b) becomes

$$u = \frac{M^2 y^2}{2EI^2}$$

and thus

$$U = \int_0^L \frac{M^2}{2EI^2} \left(\int y^2 dA \right) dx$$

where L is the length of the beam, and dA represents an infinitesimal element of the cross-sectional area. Noting that $I = \int y^2 dA$,

$$U = \int_0^L \frac{M^2}{2EI} dx \quad (84)$$

Strain Energy Due to Transverse Shear For a beam subjected to transverse loads, the total strain energy consists of strain energy due to bending [as given by Eq. (84)] and strain energy due to shear as given by

$$U = \int_0^L \frac{kV(x)^2}{2GA} dx \quad (85)$$

where A is the cross-sectional area, $V(x)$ is the shear force at a distance x , and K is a constant that depends on the cross section of the beam. Values of K for various cross sections are as follows⁷:

Cross Section	K
Rectangular	1.20
Circular	≈ 1.11
Thin-walled cylinder	2.00
I section	1.20
Closed, thin-walled box section	1.00

For the I section, A should be the area of the flanges. For the closed, thin-walled box section, A should be the area of the webs.

Strain Energy in Torsion For the case of a circular rod of length L undergoing torsion, the strain energy can be expressed in the form

$$U = \int_0^L \frac{T^2}{2JG} dx \quad (86)$$

where T is the applied torque, G is the shear modulus, and J is the polar moment of inertia of the cross section. If the cross section is uniform along the length of the rod, Eq. (86) reduces to

$$U = \frac{T^2 L}{2JG}$$

Example 6. Determine the strain energy of a cantilever beam of length L consisting of a uniform rectangular cross section (width = b , height = h), taking into account both shear and bending effects (see Fig. 42).

Solution. The moment of inertia is given by $I = bh^3/12$. The moment at a longitudinal distance x from the applied load ($0 \leq x \leq L$) takes the form $M = Px$. The shear force is constant along the length of the beam with a value of P . By Eq. (84), the strain energy due to bending is

$$U_b = \int_0^L \frac{P^2 x^2}{2E(\frac{1}{12}bh^3)} dx = \frac{2P^2 L^3}{Ebh^3}$$

From Eq. (85), with $K = 1.20$, the strain energy due to shear is

$$U_v = \int_0^L \frac{1.20P^2}{2Gbh} dx = \frac{3P^2 L}{5Gb}$$

The total strain energy of the beam is thus

$$U = U_b + U_v = U_b \left(1 + \frac{3Eh^2}{10GL^2} \right)$$

For isotropic materials, $E/G < 3$. Thus, provided $h/L < 0.1$, neglecting the strain energy due to shear results in an error of less than 1%. This is why shear effects in long, slender beams are normally ignored.

6.2 Castigliano's Theorems

Complementary Energy In Section 6.1, the strain energy density u for the case of axial loading was defined to be the area under the stress-strain curve.

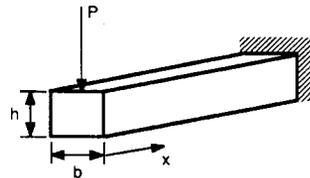

Fig. 42 Cantilever beam for use with Examples 6–9.

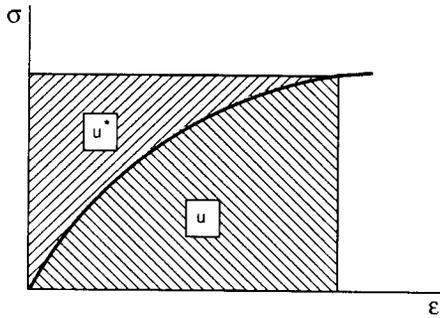

Fig. 43 Definitions of strain energy density and complementary energy density.

The complementary energy density u^* is defined as the area above the stress–strain diagram (Fig. 43). For multiaxial states of stress, the visualization of complementary energy is more difficult. The total complementary energy of a structure, U^* , is given by $U^* = \int u^* dV$. See Ref. 14 for details.

Castigliano's First Theorem Consider linear elastic structures that dissipate no energy and undergo small displacements. Also consider conservative forces, that is, forces that keep their orientations as the structure deforms. Castigliano's first theorem states that the load P_i that corresponds to a displacement D_i is given by the partial derivative of the strain energy with respect to D_i . In equation form,

$$P_i = \frac{\partial U}{\partial D_i} \quad (87)$$

Castigliano's Second Theorem Once again consider linear elastic structures subjected to conservative forces and undergoing small displacements. Castigliano's second theorem states that the displacement D_i due to an applied load P_i equals the partial derivative of the complementary energy with respect to P_i . In equation form,

$$D_i = \frac{\partial U^*}{\partial P_i} \quad (88)$$

For linear elastic response, $U = U^*$, so that U and U^* can be interchanged in Eqs. (87) and (88).

It can be shown that a similar relationship holds for moments and angular displacements. In equation form,

$$\theta_i = \frac{\partial U^*}{\partial M_i} \quad (89)$$

where θ_i is the angular displacement at point i due to the applied moment M_i .

Example 7. Using Castigliano's second theorem, determine the end displacement of a cantilever beam loaded at its end. Neglect shear effects.

Solution. From Example 6, the strain energy is given by

$$U = U_b = \frac{P^2 L^3}{6EI}$$

For linear elastic response, $U = U^*$, thus

$$\Delta = \frac{\partial U}{\partial P} = \frac{PL^3}{3EI}$$

This answer agrees with the results obtained using beam deflection theory (Section 2.4).

Example 8. For the beam of Example 7, determine the end slope.

Solution. Since no end moment is applied, a fictitious moment, M , is created. Its value will be set equal to zero after differentiating the strain energy expression. The strain energy due to P and M is given by

$$U = \int_0^L \frac{(M + Px)^2}{2EI} dx$$

Differentiating this expression with respect to M gives

$$\theta = \frac{\partial U}{\partial M} = \int_0^L \frac{2(M + Px)}{2EI} dx$$

Setting $M = 0$ and integrating leads to

$$\theta = \int_0^L \frac{Px}{EI} dx = \frac{PL^2}{2EI}$$

Again, this answer agrees with beam deflection theory.

Castigliano's theorems can also be used to solve statically indeterminate problems. Details can be found in most books on advanced mechanics of materials.

6.3 Impact Stresses

An interesting application of energy methods is in the determination of stresses due to impact loadings, such as a weight dropped onto a beam. In order to solve impact problems using simple energy methods, the following two assumptions are made:

1. No energy is dissipated during impact.
2. The striking body does not bounce off the structure.

In essence, these two assumptions require that all of the kinetic energy of the striking object is transferred to the structure. To solve an impact problem, it is assumed that the kinetic energy of the striking object equals the strain energy induced in the structure.

Example 9. Determine the maximum stress induced in a uniform cantilever beam of rectangular cross section (height = h , width = b) if a weight W is dropped from a height h_0 above the free end of the beam.

Solution. Assuming the end deflection of the beam is negligible compared to h_0 , the energy transferred to the beam by the weight is simply Wh_0 . From Example 6, the strain energy of the beam (neglecting shear effects) is

$$U = \frac{P_w^2 L^3}{6EI}$$

where P_w is the static load that would bring about the same strain energy in the beam as does the weight. Thus,

$$Wh_0 = \frac{P_w^2 L^3}{6EI} \quad \text{or} \quad P_w = \sqrt{\frac{6EIWh_0}{L^3}}$$

The maximum stress in the beam is given by

$$\sigma_{\max} = \frac{Mc}{I} = \frac{P_w L(h/2)}{I} = \frac{h}{2} \sqrt{\frac{6EWh_0}{LI}}$$

In general, for a structure to efficiently resist an impact load, it should have the following properties¹⁰:

1. Possess a large volume.
2. Have a low modulus of elasticity and high yield strength.
3. Have as uniform a shape as possible so that the stresses are evenly distributed.

7 COMPOSITE MATERIALS

7.1 Introduction to Composite Materials

Definition of a Composite Material There is no universally accepted definition of what constitutes a composite material. In everyday usage, a composite is something made up of several parts. In engineering, whether or not a given material should be considered a composite depends on the scale of viewing:

At the atomic level, any material consisting of more than one kind of atom could be considered a composite. With this definition only pure elements would not be composites.

At the microscopic level, any material composed of more than one phase could be considered a composite. For example, steel is a composite since it is a multiphase alloy of carbon and iron.

At the macroscopic level, only materials consisting of two or more macroscopic constituents are called composites. An example is glass fiber embedded in an epoxy matrix.

The following definition of composite materials is provided by Schwartz³²:

“A composite material is a material system composed of a mixture or combination of two or more macroconstituents differing in form and/or material composition and that are essentially insoluble in each other.”

Classification of Composite Materials Composites can be classified in a variety of ways such as by the matrix constituent (i.e., metal matrix, ceramic matrix, and resin matrix composites). More commonly, classification is based on the structural constituents. This leads to three common types of composite materials:

1. Fiber composites are composed of fiber embedded in a matrix.
2. Particulate composites consist of particles embedded in a matrix.
3. Laminated composites are composed of layers of various materials.

Advantages of Composites Some of the advantages of composites over conventional materials include the following:

1. Higher specific strength (i.e., strength per unit weight)
2. Higher specific stiffness (i.e., stiffness per unit weight)
3. The ability to custom design the properties of a composite for a specific application

Many other advantages exist for certain composites as discussed in the technical literature.

7.2 Orthotropic Elasticity

While composites offer higher specific strength and stiffness than many conventional materials, they suffer from the fact that their mechanical behavior is more difficult to understand. In the most general case, a material can display anisotropic stress-strain response that requires 21 material constants to describe the elastic behavior. In comparison, only 2 elastic constants are needed to describe isotropic response. For unidirectional, fiber-reinforced materials such as shown in Fig. 44, there are 3 mutually orthogonal planes of material symmetry. This reduces the required number of elastic constants from 21 to 9. A material having

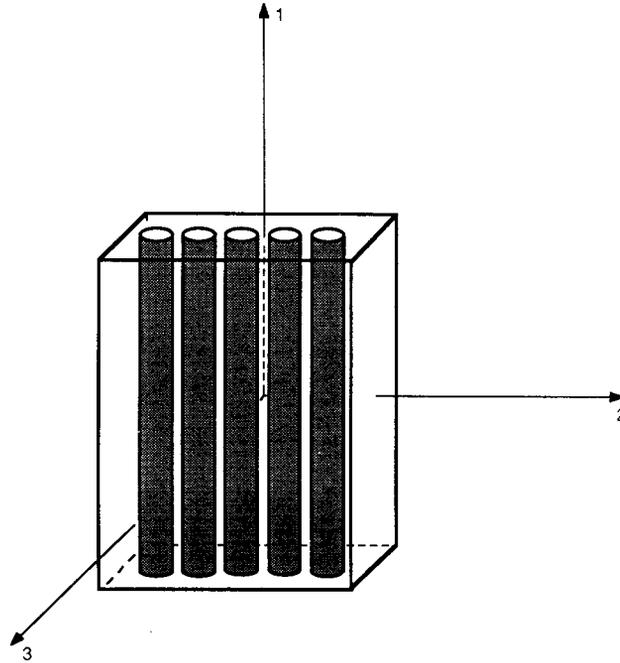

Fig. 44 Principal material directions for unidirectionally reinforced lamina.

such symmetry is said to be orthotropic. Assuming the 1, 2, and 3 directions are the principal directions of material symmetry, the stress-strain relationships are

$$\begin{Bmatrix} \sigma_1 \\ \sigma_2 \\ \sigma_3 \\ \sigma_{23} \\ \sigma_{31} \\ \sigma_{12} \end{Bmatrix} = \begin{bmatrix} C_{11} & C_{12} & C_{13} & 0 & 0 & 0 \\ C_{12} & C_{22} & C_{23} & 0 & 0 & 0 \\ C_{13} & C_{23} & C_{33} & 0 & 0 & 0 \\ 0 & 0 & 0 & C_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & C_{55} & 0 \\ 0 & 0 & 0 & 0 & 0 & C_{66} \end{bmatrix} \begin{Bmatrix} \epsilon_1 \\ \epsilon_2 \\ \epsilon_3 \\ \gamma_{23} \\ \gamma_{31} \\ \gamma_{12} \end{Bmatrix} \quad (90)$$

where $[C_{ij}]$ is known as the stiffness matrix. The shear strains (γ_{12} , γ_{23} , and γ_{31}) represent engineering shear strains. Equation 90 can be inverted to give strains in terms of stresses:

$$\begin{Bmatrix} \epsilon_1 \\ \epsilon_2 \\ \epsilon_3 \\ \gamma_{23} \\ \gamma_{31} \\ \gamma_{12} \end{Bmatrix} = \begin{bmatrix} S_{11} & S_{12} & S_{13} & 0 & 0 & 0 \\ S_{12} & S_{22} & S_{23} & 0 & 0 & 0 \\ S_{13} & S_{23} & S_{33} & 0 & 0 & 0 \\ 0 & 0 & 0 & S_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & S_{55} & 0 \\ 0 & 0 & 0 & 0 & 0 & S_{66} \end{bmatrix} \begin{Bmatrix} \sigma_1 \\ \sigma_2 \\ \sigma_3 \\ \sigma_{23} \\ \sigma_{31} \\ \sigma_{12} \end{Bmatrix} \quad (91)$$

where $[S_{ij}]$ is known as the compliance matrix. Note that both the stiffness and compliance matrices are symmetric. Also, they are matrix inverses of each other. The components of the stiffness matrix can be related to the components of the compliance matrix by

the following expressions:

$$\begin{aligned} C_{11} &= \frac{S_{22}S_{33} - S_{23}^2}{S} & C_{12} &= \frac{S_{13}S_{23} - S_{12}S_{33}}{S} \\ C_{22} &= \frac{S_{33}S_{11} - S_{13}^2}{S} & C_{13} &= \frac{S_{12}S_{23} - S_{13}S_{22}}{S} \\ C_{33} &= \frac{S_{11}S_{22} - S_{12}^2}{S} & C_{23} &= \frac{S_{12}S_{13} - S_{23}S_{11}}{S} \\ C_{44} &= \frac{1}{S_{44}} & C_{55} &= \frac{1}{S_{55}} & C_{66} &= \frac{1}{S_{66}} \end{aligned} \quad (92)$$

where

$$\begin{aligned} S &= S_{11}S_{22}S_{33} - S_{11}S_{23}^2 - S_{22}S_{13}^2 - S_{33}S_{12}^2 \\ &\quad + 2S_{12}S_{23}S_{13} \end{aligned}$$

The converse relationship (i.e., S_{ij} 's in terms of C_{ij} 's) can be obtained by interchanging the symbols C and S everywhere in Eqs. (92).

Engineering Constants In order to predict material behavior, it is necessary to determine the material constants in either Eq. (90) or (92). It is convenient to introduce the following engineering constants³³:

E_1, E_2, E_3 Elastic moduli in the 1, 2, and 3 directions, respectively. Thus, $E_i = \sigma_i/\epsilon_i$ for $\sigma_i = \sigma$ and all other stresses being zero.

G_{12} , G_{23} , G_{31} Shear moduli in the 1–2, 2–3, and 3–1 planes, respectively.

ν_{ij} Poisson's ratio for transverse strain in the j direction when the specimen is stressed in the i direction. Hence, $\nu_{ij} = -\varepsilon_j/\varepsilon_i$ for $\sigma_i = \sigma$ and all other stresses being zero.

The compliance matrix can be rewritten as

$$[S_{ij}] = \begin{bmatrix} \frac{1}{E_1} & -\frac{\nu_{21}}{E_2} & -\frac{\nu_{31}}{E_3} & 0 & 0 & 0 \\ -\frac{\nu_{12}}{E_1} & \frac{1}{E_2} & -\frac{\nu_{32}}{E_3} & 0 & 0 & 0 \\ -\frac{\nu_{13}}{E_1} & -\frac{\nu_{23}}{E_2} & \frac{1}{E_3} & 0 & 0 & 0 \\ 0 & 0 & 0 & \frac{1}{G_{23}} & 0 & 0 \\ 0 & 0 & 0 & 0 & \frac{1}{G_{31}} & 0 \\ 0 & 0 & 0 & 0 & 0 & \frac{1}{G_{12}} \end{bmatrix} \quad (93)$$

Because of the symmetry of the compliance matrix ($S_{ij} = S_{ji}$), it is apparent that

$$\frac{\nu_{ij}}{E_i} = \frac{\nu_{ji}}{E_j}$$

In terms of the engineering constants, the stiffness matrix components take the form

$$\begin{aligned} C_{11} &= \frac{1 - \nu_{23}\nu_{32}}{E_2 E_3 \Delta} \\ C_{12} &= \frac{\nu_{21} + \nu_{31}\nu_{23}}{E_2 E_3 \Delta} = \frac{\nu_{12} + \nu_{32}\nu_{13}}{E_1 E_3 \Delta} \\ C_{13} &= \frac{\nu_{31} + \nu_{21}\nu_{32}}{E_2 E_3 \Delta} = \frac{\nu_{13} + \nu_{12}\nu_{23}}{E_1 E_2 \Delta} \\ C_{22} &= \frac{1 - \nu_{31}\nu_{13}}{E_1 E_3 \Delta} \\ C_{23} &= \frac{\nu_{32} + \nu_{12}\nu_{31}}{E_1 E_3 \Delta} = \frac{\nu_{23} + \nu_{21}\nu_{13}}{E_1 E_2 \Delta} \\ C_{33} &= \frac{1 - \nu_{12}\nu_{21}}{E_1 E_2 \Delta} \\ C_{44} &= G_{23} \quad C_{55} = G_{31} \quad C_{66} = G_{12} \end{aligned}$$

where

$$\Delta = \frac{1 - \nu_{12}\nu_{21} - \nu_{23}\nu_{32} - \nu_{31}\nu_{13} - 2\nu_{21}\nu_{32}\nu_{13}}{E_1 E_2 E_3}$$

7.3 Plane Stress

For orthotropic response under plane stress conditions, the in-plane stress–strain relationships are given by

$$\begin{Bmatrix} \varepsilon_1 \\ \varepsilon_2 \\ \gamma_{12} \end{Bmatrix} = \begin{bmatrix} S_{11} & S_{12} & 0 \\ S_{12} & S_{22} & 0 \\ 0 & 0 & S_{66} \end{bmatrix} \begin{Bmatrix} \sigma_1 \\ \sigma_2 \\ \sigma_{12} \end{Bmatrix}$$

and

$$\begin{Bmatrix} \sigma_1 \\ \sigma_2 \\ \sigma_{12} \end{Bmatrix} = \begin{bmatrix} Q_{11} & Q_{12} & 0 \\ Q_{12} & Q_{22} & 0 \\ 0 & 0 & Q_{66} \end{bmatrix} \begin{Bmatrix} \varepsilon_1 \\ \varepsilon_2 \\ \gamma_{12} \end{Bmatrix}$$

where the compliance coefficients (S_{ij}) are the same as in Eq. (93). The components Q_{ij} , sometimes referred to as the reduced stiffnesses, can be expressed in terms of the compliance coefficients as

$$\begin{aligned} Q_{11} &= \frac{S_{22}}{S_{11}S_{22} - S_{12}^2} & Q_{22} &= \frac{S_{11}}{S_{11}S_{22} - S_{12}^2} \\ Q_{12} &= -\frac{S_{12}}{S_{11}S_{22} - S_{12}^2} & Q_{66} &= \frac{1}{S_{66}} \end{aligned}$$

7.4 Stress–Strain Relationships for Arbitrary Orientations

In Section 7.2, the stress–strain relationships with respect to the principal material directions were presented. Unfortunately, the principal material directions often do not coincide with the coordinates that naturally fit the geometry of the structure. For plane stress conditions, Mohr's circle can be used to transform stresses or strains; however, the principal stresses and strains do not necessarily occur at the same orientation. For an xy coordinate system located at an angle θ with respect to the principal material coordinates (Fig. 45),

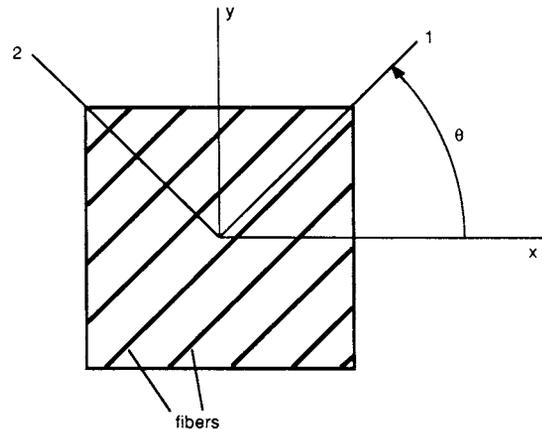

Fig. 45 Arbitrary in-plane orientation of xy coordinate axes.

the stress–strain relationships take the form

$$\begin{Bmatrix} \sigma_x \\ \sigma_y \\ \sigma_{xy} \end{Bmatrix} = \begin{bmatrix} \bar{Q}_{11} & \bar{Q}_{12} & \bar{Q}_{16} \\ \bar{Q}_{12} & \bar{Q}_{22} & \bar{Q}_{26} \\ \bar{Q}_{16} & \bar{Q}_{26} & \bar{Q}_{66} \end{bmatrix} \begin{Bmatrix} \varepsilon_x \\ \varepsilon_y \\ \gamma_{xy} \end{Bmatrix} \quad (94)$$

where

$$\begin{aligned} \bar{Q}_{11} &= Q_{11} \cos^4 \theta + 2(Q_{12} + 2Q_{66}) \sin^2 \theta \cos^2 \theta \\ &\quad + Q_{22} \sin^4 \theta \\ \bar{Q}_{12} &= (Q_{11} + Q_{22} - 4Q_{66}) \sin^2 \theta \cos^2 \theta \\ &\quad + Q_{12}(\sin^4 \theta + \cos^4 \theta) \\ \bar{Q}_{22} &= Q_{11} \sin^4 \theta + 2(Q_{12} + 2Q_{66}) \sin^2 \theta \cos^2 \theta \\ &\quad + Q_{22} \cos^4 \theta \\ \bar{Q}_{16} &= (Q_{11} - Q_{12} - 2Q_{66}) \sin \theta \cos^3 \theta \\ &\quad + (Q_{12} - Q_{22} + 2Q_{66}) \sin^3 \theta \cos \theta \\ \bar{Q}_{26} &= (Q_{11} - Q_{12} - 2Q_{66}) \sin^3 \theta \cos \theta \\ &\quad + (Q_{12} - Q_{22} + 2Q_{66}) \sin \theta \cos^3 \theta \\ \bar{Q}_{66} &= (Q_{11} + Q_{22} - 2Q_{12} - 2Q_{66}) \sin^2 \theta \cos^2 \theta \\ &\quad + Q_{66}(\sin^4 \theta + \cos^4 \theta) \end{aligned}$$

or alternatively

$$\begin{Bmatrix} \varepsilon_x \\ \varepsilon_y \\ \gamma_{xy} \end{Bmatrix} = \begin{bmatrix} \bar{S}_{11} & \bar{S}_{12} & \bar{S}_{16} \\ \bar{S}_{12} & \bar{S}_{22} & \bar{S}_{26} \\ \bar{S}_{16} & \bar{S}_{26} & \bar{S}_{66} \end{bmatrix} \begin{Bmatrix} \sigma_x \\ \sigma_y \\ \sigma_{xy} \end{Bmatrix} \quad (95)$$

where

$$\begin{aligned} \bar{S}_{11} &= S_{11} \cos^4 \theta + (2S_{12} + S_{66}) \sin^2 \theta \cos^2 \theta \\ &\quad + S_{22} \sin^4 \theta \\ \bar{S}_{12} &= S_{12}(\sin^4 \theta + \cos^4 \theta) \\ &\quad + (S_{11} + S_{12} - S_{66}) \sin^2 \theta \cos^2 \theta \\ \bar{S}_{22} &= S_{11} \sin^4 \theta + (2S_{12} + S_{66}) \sin^2 \theta \cos^2 \theta \\ &\quad + S_{22} \cos^4 \theta \\ \bar{S}_{16} &= (2S_{11} - 2S_{12} - S_{66}) \sin \theta \cos^3 \theta \\ &\quad - (2S_{22} - 2S_{12} - S_{66}) \sin^3 \theta \cos \theta \\ \bar{S}_{26} &= (2S_{11} - 2S_{12} - S_{66}) \sin^3 \theta \cos \theta \\ &\quad - (2S_{22} - 2S_{12} - S_{66}) \sin \theta \cos^3 \theta \end{aligned}$$

$$\begin{aligned} \bar{S}_{66} &= 2(2S_{11} + 2S_{22} - 4S_{12} - S_{66}) \sin^2 \theta \cos^2 \theta \\ &\quad + S_{66}(\sin^4 \theta + \cos^4 \theta) \end{aligned}$$

If $\gamma_{xy} = 0$ in Eq. (94), the xy orientation corresponds to the principal strain directions. However, since $\sigma_{xy} = Q_{16}\varepsilon_{xx} + Q_{26}\varepsilon_{yy}$, this is seldom the direction of the principal stresses. Similarly, when $\sigma_{xy} = 0$ in Eq. (95), it is seldom true that $\gamma_{xy} = 0$. This fact is very important since some theories of lamina strength are based on principal strains, while others are based on principal stresses.

7.5 Biaxial Strength Theories

Several theories are available for predicting the strength of lamina under in-plane biaxial loading. Some of the simpler of these theories are now discussed.

Maximum-Strength Theory Maximum-strength theory states that the lamina is safe provided the stresses in the principal material directions are less than the ultimate strengths in these directions. Hence, the lamina is safe provided

$$\sigma_1 < X_t \quad \sigma_2 < Y_t \quad \sigma_{12} < S$$

for tension, and

$$|\sigma_1| < |X_c| \quad |\sigma_2| < |Y_c|$$

for compression. In these inequalities, X_t is the tensile strength in the 1 direction, X_c is the compressive strength in the 1 direction, Y_t is the tensile strength in the 2 direction, Y_c is the compressive strength in the 2 direction, and S is the in-plane shear strength.

Maximum-Strain Theory Maximum-strain theory is similar to the maximum-strength theory except that the stresses are replaced by strains. Thus, the material is safe provided

$$\varepsilon_1 < \varepsilon_1^{ut} \quad \varepsilon_2 < \varepsilon_2^{ut} \quad |\gamma_{12}| < S_\varepsilon$$

for tension, and

$$|\varepsilon_1| < \varepsilon_1^{uc} \quad |\varepsilon_2| < \varepsilon_2^{uc}$$

for compression. In these inequalities, ε_1^{ut} is the maximum tensile strain at failure for loading in the 1 direction, ε_1^{uc} is the maximum compressive strain at failure for loading in the 1 direction, ε_2^{ut} is the maximum tensile strain at failure for loading in the 2 direction, ε_2^{uc} is the maximum compressive strain at failure for loading in the 2 direction, and S_ε is the shear strain at failure for an in-plane shear test of the lamina.

Tsai–Hill Theory It should be noted that the maximum stress and maximum strain theories assume no interaction between modes of failure. As such, these theories can lead to inaccurate predictions of strength. The Tsai–Hill theory states that failure is imminent when the following inequality is satisfied

$$\left(\frac{\sigma_1}{X}\right) - \left(\frac{\sigma_1\sigma_2}{X^2}\right) + \left(\frac{\sigma_2}{Y}\right)^2 + \left(\frac{\sigma_{12}}{S}\right)^2 \geq 1$$

where X is the ultimate strength in the 1 direction, Y is the ultimate strength in the 2 direction, and S is the in-plane shear strength of the lamina. The Tsai–Hill theory is easy to use and gives reasonably good results for many kinds of composite lamina. Note that it does not differentiate between tensile and compressive strengths, however.

More sophisticated lamina failure theories are available. A thorough review of these is given in Ref. 34.

Laminates A lamina is a single layer of composite material with fiber running in one direction. A laminate consists of several individual laminae stacked one on top of another and bonded together to form a single component. Theories for predicting the stress–strain relationships and failure strengths of composite laminates are available, but they are too complex to be presented here (see Ref. 34 for a thorough review of these theories). Further details on the mechanics of composite materials can be found in Refs. 33–38.

8 THEORIES OF STRENGTH AND FAILURE

8.1 Stress Concentrations

Large increases in stresses occur near abrupt changes in geometry such as holes, notches, fillets, and cracks. With regards to mechanics of materials, these geometrical discontinuities are referred to as stress raisers or stress concentrations. For some simple geometries, the effect of stress raisers on the stress distribution can be determined using the theory of elasticity. For complicated geometries, however, numerical or experimental techniques represent more practical means of determining the stress distribution.

The theoretical stress concentration factor, K_t , is defined by

$$K_t = \frac{\sigma_{\max}}{\sigma_{\text{avg}}} \quad (96)$$

where σ_{\max} is the maximum stress that occurs in the vicinity of the stress concentration, and σ_{avg} is the average stress that acts at the minimal cross-sectional area. For example, consider the case of a hole in a semi-infinite plate under uniaxial loading (Fig. 46). Far away from the hole, the longitudinal stress is given by $\sigma = P/wt$, where P is the applied load, w is the plate width, and t is the plate thickness. Along the line AB in Fig. 46, the average longitudinal stress is higher

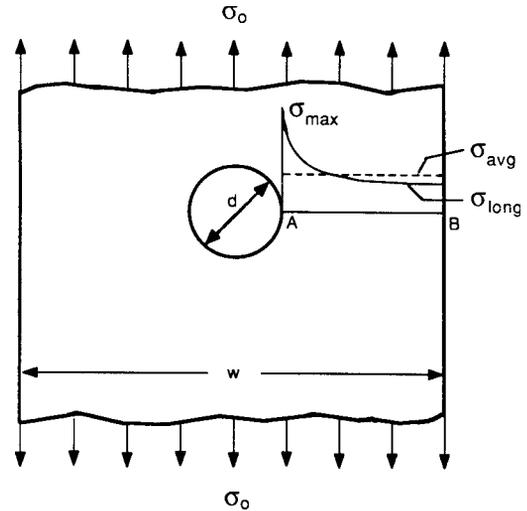

Fig. 46 Hole in a semi-infinite plate.

due to the reduced cross-sectional area caused by the presence of the hole. Thus,

$$\sigma_{\text{avg}} = \frac{P}{(w-d)t}$$

where d is the hole diameter. The actual stress distribution along the line AB is not constant at σ_{avg} , but rather it varies as shown in the figure. The maximum longitudinal stress occurs at the edge of the hole.

Stress concentration factors provide a quick method for estimating the severity of a given stress raiser. Extensive tables of these factors for a wide variety of situations are available in the literature.^{9,39} Stress concentration factors should be used with caution in design, however, since several important issues are neglected:

1. Stress concentration factors are normally given for uniaxial states of loading. In many instances, there is a combined state of loading (e.g., biaxial loading of a plate with a hole).
2. Even when the far-field loading is uniaxial, the geometrical discontinuity induces a state of biaxial stresses in its immediate vicinity.
3. If the maximum stress exceeds the yield strength, a plastic zone develops. The maximum stress predicted by Eq. (96) is too high in such circumstances.

It is apparent from the last of these statements that the use of the stress concentration factor can lead to overly conservative design in the case of a ductile material. It is possible, however, for normally ductile

materials to exhibit brittle behavior. This is especially true if the component thickness is large enough to induce a state of plane strain. In such cases, the use of the stress concentration factor in design can lead to nonconservative predictions. This apparent dilemma can be explained by the application of modern theories of fracture mechanics. Further details are provided in Sections 8.2 and 8.3.

8.2 Classical Theories of Static Failure

Ductile versus Brittle Material Behavior For materials exhibiting extremely ductile behavior, such as mild steel at room temperature, design against failure is often based on the yield strength. Roughly speaking, a material can be considered to be ductile if it exhibits an elongation of at least 5% in a standard tension test.⁴⁰ It is important to recognize, however, that materials are in fact neither ductile nor brittle. Instead, materials are ductile in some circumstances and brittle in others. For example, while most mild steels display considerable ductility at room temperature, the ductility tends to decrease as the temperature is lowered. In fact, a rapid decrease in ductility often occurs over a narrow temperature range (see Section 8.3 for further details). In general, several other factors besides temperature can induce brittle behavior in what are normally considered to be ductile materials. These include the presence of notches, corrosive environments, and very rapid rates of loading.⁴¹

Maximum-Shear-Stress Theory The maximum-shear-stress theory states that a region of material in a component yields when the maximum shear stress at that point equals the maximum shear stress at yield of a tensile specimen of the same material. From Section 1.3, $\tau_{\max} = (\sigma_1 - \sigma_3)/2$, where σ_1 and σ_3 are the algebraically largest and smallest principal stresses, respectively. For the case of a uniaxial tension specimen at yield, $\sigma_3 = 0$ and $\sigma_1 = \sigma_y$. The maximum-shear-stress theory takes the form

$$\tau_{\max} = \frac{1}{2}(\sigma_1 - \sigma_3) = \frac{1}{2}\sigma_y \quad \text{at yield} \quad (97)$$

This theory is relatively simple to use and normally results in conservative predictions. For biaxial states of loading, σ_1 and σ_3 are determined easily using Mohr's circle.

For a state of pure shear, $\tau_{\max} = \tau_y$ at yield. The maximum shear stress theory thus predicts a value of 0.5 for the ratio of the yield strength in torsion to the yield strength in tension,

$$\frac{\tau_y}{\sigma_y} = 0.5$$

Distortion Energy Theory The distortion energy theory, also known as the von Mises–Hencky theory, is based on the assumption that yielding occurs at a

point in a component when the total distortional energy per unit volume at that point equals the distortional energy per unit volume in a tensile specimen at yield. The distortion energy per unit volume, u_d , is given by

$$u_d = \frac{1}{12G} [(\sigma_{xx} - \sigma_{yy})^2 + (\sigma_{yy} - \sigma_{zz})^2 + (\sigma_{zz} - \sigma_{xx})^2 + 6(\sigma_{xy}^2 + \sigma_{zx}^2 + \sigma_{yz}^2)]$$

or, in terms of the principal stresses,

$$u_d = \frac{1}{6G} (\sigma_1^2 + \sigma_2^2 + \sigma_3^2 - \sigma_1\sigma_2 - \sigma_1\sigma_3 - \sigma_2\sigma_3)$$

For a tensile specimen at yield, $\sigma_1 = \sigma_y$ and $\sigma_2 = \sigma_3 = 0$. Accordingly, $u_d = \sigma_y^2/6G$ in this case. The distortion energy theory can therefore be rewritten as

$$\sigma_1^2 + \sigma_2^2 + \sigma_3^2 - \sigma_1\sigma_2 - \sigma_1\sigma_3 - \sigma_2\sigma_3 = \sigma_y^2 \quad \text{at yield} \quad (98)$$

For a state of pure shear, $\sigma_1 = \tau$, $\sigma_2 = 0$, and $\sigma_3 = -\tau$. Using the distortion energy theory, the relationship between yield in shear and tension is

$$\tau_y^2 + 0 + \tau_y^2 - 0 - 0 - 0 = \sigma_y^2$$

or

$$\frac{\tau_y}{\sigma_y} = 0.577$$

Comparison of Theories for Yielding For most ductile materials, the distortion energy theory gives more accurate results than the maximum-shear-stress theory.²² For a biaxial state of loading, the out-of-plane principal stress is zero. Denoting the in-plane principal stresses by σ_a and σ_b , it is possible to graphically portray the two theories. This has been done in Fig. 47. It is seen that the maximum-shear-stress theory is represented by a hexagon, while the distortion energy theory is represented by an ellipse. In general, both theories give reasonably good results for plane stress conditions. While the distortion energy theory is usually more accurate, its use can result in slightly nonconservative predictions. On the other hand, use of the maximum shear stress theory almost always leads to slightly conservative predictions.

Maximum-Normal-Stress Theory The maximum-normal-stress theory is generally used for calculating the failure stress for brittle materials. It states that a component fails when its maximum principal stress, σ_1 , exceeds the ultimate strength as determined by a tensile test. This theory should be used with caution. For plane stress situations, this theory gives reasonable results if both in-plane principal stresses are tensile. It can be grossly inaccurate, however, when the in-plane principal stresses are of opposite sign.⁴²

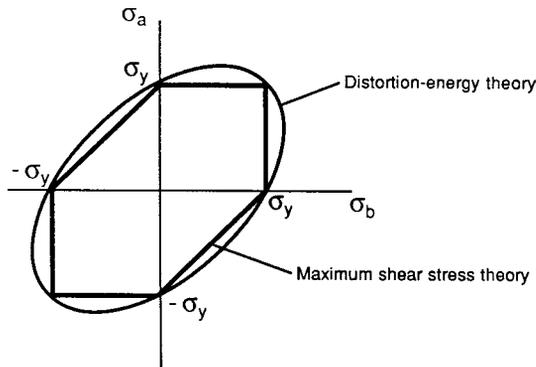

Fig. 47 Comparison of theories of yielding for plane stress conditions.

Coulomb–Mohr Theory The Coulomb–Mohr theory is used almost exclusively for predicting failure of brittle materials. It is based on the ultimate strengths of a material in tension and compression, σ_{ut} and σ_{uc} , respectively. In general, brittle materials exhibit a larger ultimate strength in compression than in tension. To apply the Coulomb–Mohr theory, Mohr's circles are drawn corresponding to the states of stress at failure for tension and compression specimens. The tangent lines to these circles are then drawn. The theory states that failure occurs for any state of stress that produces a Mohr's circle as large as the envelope of the σ_{ut} and σ_{uc} circles and their tangent lines. That is, if the Mohr's circle for the state of stress under consideration extends out to or beyond the shaded region in Fig. 48, failure is imminent.

Figure 48b shows a graphical representation of the Coulomb–Mohr theory for a state of plane stress. It should be noted that this theory is identical to the maximum-normal-stress theory in the first quadrant. In general, the Coulomb–Mohr theory gives conservative

results. It is the best classical theory available for estimating failure of brittle materials. In modern design, it is better to use the theory of fracture mechanics to estimate failure loads rather than the Coulomb–Mohr theory because the presence of even a very small flaw in a brittle material can lead to failure at loads much lower than those predicted by the Coulomb–Mohr theory.

8.3 Fracture Mechanics

Fracture mechanics is that branch of mechanics that deals with the ability of a material to resist crack propagation under a given set of loading and environmental conditions. Modern fracture mechanics can be divided into two major categories: linear elastic fracture mechanics (LEFM) and elastic–plastic fracture mechanics (EPFM). Before discussing these topics, some background information regarding the nature of brittle fracture must be presented.

Brittle Fracture Brittle fracture involves the rapid propagation of a crack leading to failure of the component. Little energy is absorbed by the component, and only a small amount of plastic deformation occurs. Crack propagation is conventionally considered under three basic modes of loading as shown in Fig. 49. Mode I loading involves an opening or tensile mode. It is the most common loading encountered in practice. Mode II loading represents an in-plane shearing mode. Mode III represents an out-of-plane shearing mode. Because of the prevalence of mode I loading in practice and the relative ease in experimentation and analysis, a majority of investigations have focused on this cracking mode. As mentioned in Section 8.2, several factors can cause a normally ductile material to behave in a brittle fashion. These include reduced temperatures, high strain rates, corrosive environments, and the presence of notches.

On a macroscopic level, for uniaxial states of loading, a brittle fracture results in a relatively flat fracture surface with only small amounts of slanted surfaces.

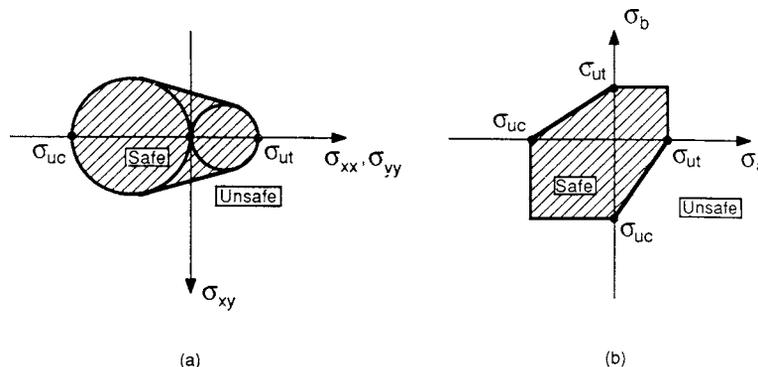

Fig. 48 Coulomb–Mohr theory for brittle failure.

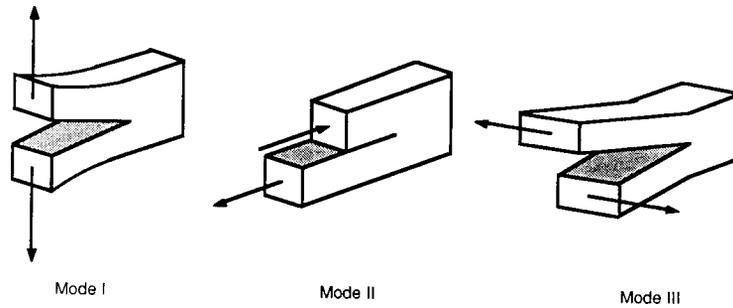

Fig. 49 Basic modes of loading for crack propagation.

The slanted surfaces, commonly referred to as shear lips, are indicative of plastic deformation. In a uniaxial test specimen, these shear lips are at approximately a 45° angle to the applied load axis since the maximum shear stress occurs along planes at this angle. For a ductile fracture, the fracture surface is rougher, and considerable shear lip formations are present.

On a microscopic level, the fracture process can appear quite complicated. For isotropic homogeneous metals, three common microstructural failure modes are microvoid coalescence, cleavage fracture, and intergranular fracture. Cleavage and intergranular fracture are often associated with a brittle failure, while microvoid coalescence is most often associated with ductile failure. This categorization is not always accurate, however. Further information on microscopic fracture analysis can be found in Refs. 43–45.

Linear Elastic Fracture Mechanics The theory of linear elastic fracture mechanics is based on the assumption that the zone of plastic deformation at the tip of a crack is small. In this case, the stress

distributions near the tip of a crack can be determined using the theory of elasticity. Assuming the crack tip is infinitel sharp, the stresses near the crack tip are given by (Fig. 50):

$$\sigma_{xx} = \frac{K}{\sqrt{2\pi r}} \cos \frac{\theta}{2} \left(1 - \sin \frac{\theta}{2} \sin \frac{3\theta}{2} \right)$$

$$\sigma_{yy} = \frac{K}{\sqrt{2\pi r}} \cos \frac{\theta}{2} \left(1 + \sin \frac{\theta}{2} \sin \frac{3\theta}{2} \right)$$

$$\sigma_{xy} = \frac{K}{\sqrt{2\pi r}} \left(\sin \frac{\theta}{2} \cos \frac{\theta}{2} \cos \frac{3\theta}{2} \right)$$

where the parameter K is known as the stress intensity factor. These equations were first derived by Westergaard.⁴⁶ It is apparent that these equations predict infinite stresses at the crack tip ($r = 0$). In reality, yielding occurs at the crack tip and limits the maximum stresses attained. The stress intensity factor K is a function of the crack geometry and the

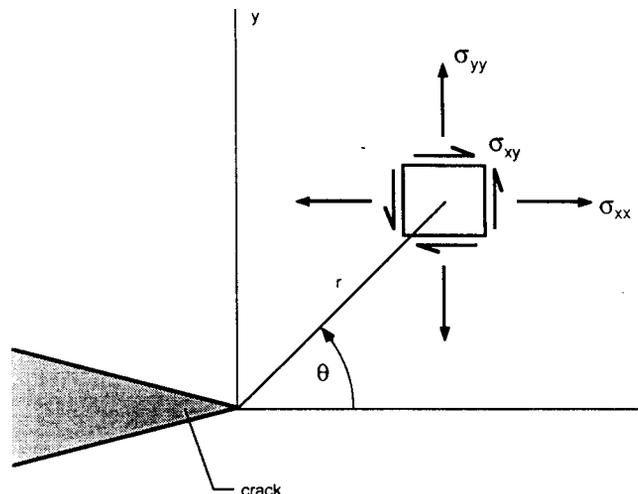

Fig. 50 Stresses near a crack tip.

applied loads. Extensive tabulations of K for a variety of geometries and loading conditions can be found in the literature.^{47,48} For a center crack of length $2a$ in an infinite sheet, the stress intensity factor is given by $K = \sigma\sqrt{\pi a}$ (Fig. 51a). For an edge crack of length a in a semi-infinite sheet, $K \approx 1.1\sigma\sqrt{\pi a}$ (Fig. 51b). As the crack length increases, the stress intensity factor rises sharply. In essence, K is a measure of the severity of the crack tip (for a given component, loading, and crack length). If the applied load is increased high enough, rapid failure due to unstable crack propagation occurs. The value of the stress intensity factor at which failure occurs is known as the fracture toughness of the particular component, K_c . For a component of specific in-plane dimensions, the fracture toughness varies with thickness as shown in Fig. 52. For very thin specimens, there is little resistance to cracking, and the fracture toughness is low. For moderate thicknesses where considerable plastic flow can occur, plane stress conditions prevail, and maximum toughness is achieved. As the thickness is further increased, transverse stresses begin to develop near the crack tip. These stresses limit the ability of the material near the crack tip to yield, which in turn reduces the fracture toughness of the component. If the component is made thick enough, a state of plane strain exists in the midthickness near the crack tip. The fracture toughness reaches a minimum value at this point. Further increases in thickness do not change its value. This limiting value of toughness is known as the plane strain fracture toughness and is denoted by K_{Ic} . The subscript I indicates that the toughness value is for a

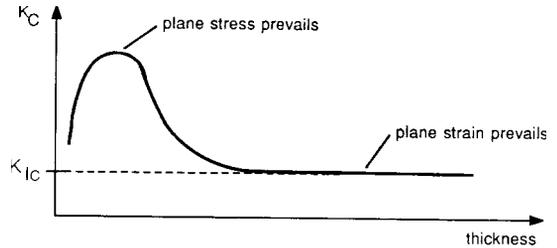

Fig. 52 Variation of fracture toughness with thickness.

mode I loading situation. In general, the fracture toughness, K_c , depends on both component geometry and material, whereas the plane strain fracture toughness is considered a material property when the thickness is sufficiently large. Since K_{Ic} represents a lower bound on the fracture toughness, its use in design should lead to conservative predictions. Table 8 lists values of plane strain fracture toughness for a variety of materials along with the associated yield strengths. It must be noted that the values given represent averages. Considerable variation in reported plane strain fracture toughness values is not uncommon. More extensive tables for K_{Ic} can be found elsewhere.^{49,50} Standardized testing procedures for determining K_{Ic} values can be found in Ref. 51.

Transition Temperature Phenomenon Face-centered-cubic metals, such as aluminum, copper, and

nickel, show little variation in their mechanical properties with moderate changes in temperature. In contrast, the strength and toughness of body-centered-cubic metals, such as ferritic alloys, are often quite sensitive to temperature and strain rate effects. In order to study temperature effects, some means of measuring toughness is required. While performing K_{Ic} tests over a range of temperatures would probably provide the most reliable data, the cost of performing these tests often precludes their use. The most common technique employed is the Charpy test. This test consists of dropping an impact hammer pendulum onto a small notched specimen. The energy absorbed by the specimen during fracture is given by $W(h_i - h_f)$ where W is the weight of the hammer, h_i is the initial height of the hammer, and h_f is the maximum height to which the hammer swings after impacting the specimen. The primary disadvantages of the Charpy test are that the small specimen size may allow for considerable plasticity at the crack tip and that it is a rather severe test (a single blow causing fracture). The occurrence of plasticity may result in overly optimistic toughness

values. Other means of measuring toughness include the drop weight tear test and the dynamic tear test.⁵²

Whatever technique is used for measuring toughness (and the choice is important), one common trend that is observed in low-strength ferritic steels and some other alloys is that a sudden drop in material toughness occurs over a fairly narrow temperature range (Fig. 53a). This is known as the transition temperature phenomenon. The temperature corresponding to the lower toughness end of this transition is known as the nil ductility temperature (NDT). In general, the measured value for the NDT depends on the testing technique used, specimen thickness, and material. For thicker specimens, plastic flow is constrained, and the NDT rises (Fig. 53b).

Elastic-Plastic Fracture Mechanics While LEFM has proven to be a very powerful design tool, its use is not always appropriate. For high-toughness materials or thin components experiencing plane stress conditions near a crack tip rather than

**Fig. 53** Transition temperature phenomenon.

plane strain conditions, LEFM leads to overly conservative design restrictions. Also, large specimen sizes are often required to bring about plane strain conditions for K_{Ic} determination. These large specimens can be expensive to fabricate and difficult to test. For all these reasons and others, considerable research in the field of elastic-plastic fracture mechanics has been done during the past 20 years. The most notable work has been the J integral originally defined by Rice to be a path-independent line integral for two-dimensional crack problems.⁵³ It was later concluded that the value of the J integral, J , is a measure of the stress and strain singularity near a crack tip. In this regard, J for the plastic case is analogous to the stress intensity factor K for the linear elastic case.

It has been shown that, in the linear elastic range, the critical value of J required to cause unstable crack propagation, J_{Ic} , is related to the plane strain fracture toughness by

$$J_{Ic} = \frac{1 - \nu^2}{E} K_{Ic}^2 \quad (99)$$

where E and ν are Young's modulus and Poisson's ratio, respectively. The advantage of determining J_{Ic} instead of K_{Ic} is that much smaller specimen sizes can be used. A standard procedure for determining J_{Ic} has been adopted by the American Society for Testing and Materials.⁵⁴

In addition to providing an alternative technique for determining plane strain fracture toughness, the J integral may be used to determine whether a given cracked component is stable with respect to crack initiation and propagation when the material near the crack tip deforms plastically (i.e., when the size of the plastic zone ahead of the crack tip is substantial).⁵⁵

Fracture Mechanics Design To apply fracture mechanics in design, it is necessary to know the loading conditions, specimen geometry, and crack configuration. If no cracks are known to be present, the maximum crack size that could have been overlooked by nondestructive inspection should be used. Once these conditions are known, the stress intensity factor K can be determined. This value of K is then compared to the critical stress intensity factor, K_c . If K is larger than K_c , the design is unsafe. In a more general sense, given any two of K_c , σ , and a (fracture toughness, applied stress, and crack length, respectively), the third can be determined since the three are related by the following condition: Unstable crack propagation occurs when the value of K reaches K_c , where $K = K_0 \sigma \sqrt{\pi a}$. Here, K_0 is a constant that depends on the specimen geometry and loading conditions. For example, $K_0 = 1$ for uniaxial loading of an infinite plate with a through-thickness center crack of length $2a$ (Fig. 51a). For large component thicknesses, K_c will be equal to K_{Ic} . Since K_c values as a function of thickness are not commonly available for

most materials, it is common to use K_{Ic} values even when component thicknesses are too small to bring about plane strain conditions. This can lead to overly conservative design.

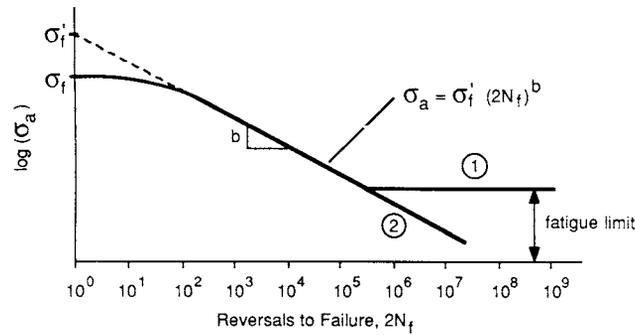

8.4 Fatigue

Fatigue investigations concern the effects of cyclic stresses and strains on the mechanical integrity of a structural component. If enough cycles are applied to a component, it is possible for failure to occur even though the maximum stress never exceeded the ultimate strength of the material. It is often useful to classify fatigue problems into two regimes: high-cycle fatigue (cycles to failure $> 10^4$) and low-cycle fatigue (cycles to failure $< 10^4$). This classification needs to be refined in some cases. It is often necessary to further classify the fatigue loading of a given component. If the operating temperature of the material is a sizable fraction of its melting temperature, creep of the material can become substantial. In such cases, theories for creep fatigue must be employed. Another important distinction is whether the cyclic loads imposed on the component result in uniaxial or multiaxial states of stress.

Looked at simplistically, the fatigue process can be divided into three categories: initiation of a dominant macrocrack, propagation of this crack, and final failure of the component. In rough terms, a macrocrack exists if the crack length is large compared to the microstructure grain size. For high-cycle fatigue, the majority of the life is spent in initiating a macrocrack. In low-cycle fatigue, propagation of a macrocrack can consume over half the life.

Two distinct approaches to fatigue analysis have evolved. In the classical approach, empirical models are developed that relate the imposed loading conditions to the cycles to failure. In the fracture mechanics approach, crack propagation rates are related to the cyclic change in stress intensity factors. The resulting relationship is then integrated to give the cycles to failure. In the application of either approach, two steps need to be performed. First of all, the expected cyclic loading history of the component should be estimated. The obtaining of these data is known as load spectrum analysis. Second, the response of the material to the applied cyclic loading must be known. These data are obtained by laboratory testing under controlled conditions. Finally, the laboratory results must be correlated with the expected service loads so that a life prediction can be made.

High-Cycle Fatigue In high-cycle fatigue testing, a fully reversed loading is applied to a specimen, and the number of cycles to failure is recorded. When this is done for a variety of load amplitudes, an $S-N$ plot can be constructed (Fig. 54). In this diagram, the log of the applied stress amplitude is plotted versus the log of the reversals to failure. For every cycle applied, two reversals in the direction of applied loading must occur (one reversal when the maximum stress is obtained and

- ① material exhibiting a fatigue limit
- ② material not exhibiting a fatigue limit

Fig. 54 Schematic representation of an S-N diagram.

the other when the minimum stress is obtained). Thus, if the number of cycles to fracture is designated by N_f , the number of reversals to failure is $2N_f$. For many materials, this S-N plot shows a linear relationship over an extensive portion. Within this region, the applied true stress amplitude, σ_a , can be related to the number of reversals to failure by

$$\sigma_a = \sigma'_f (2N_f)^b \tag{100}$$

where σ'_f and b are material constants known as the fatigue strength coefficient and fatigue strength exponent, respectively. The constant b is also commonly referred to as Basquin's exponent. For some materials, this linear relationship is valid from $2N_f = 1$ (which is equivalent to the tension test in the lower limit). In such cases, the fatigue strength coefficient, σ'_f , is equal to the true fracture strength, σ_f .

Some materials exhibit a stress amplitude below which no failures occur. This stress amplitude is known as the fatigue limit or endurance limit of the material. This phenomenon is observed in mild steels, for example. Most nonferritic metals behave differently. In these cases the fatigue strength (instead of a fatigue limit) is defined as the stress amplitude required to bring about failure in a specific number of cycles (normally, $N_f = 10^8$).⁵⁶

When relating the results from laboratory testing, as given by an S-N diagram, to structural components, it is necessary to consider many additional factors such as stress concentrations, surface finish quality, residual stresses, and so on. Accurate accounting of the influence of these factors on the fatigue life of the component requires considerable experience. Further details can be found in Ref. 57.

Effect of Mean Stress on Fatigue Life In the previous discussion, it was assumed that the fatigue

loading was fully reversed as shown in Fig. 55a. It is common in actual components to find a mean stress σ_m superimposed on the reversed loading. Tensile mean stresses (Fig. 55b) tend to reduce the fatigue life while compressive mean stresses (Fig. 55c) tend to increase the life. Several empirical relationships have been devised to account for mean stress effects. The most commonly used of these is the modified Goodman diagram (Fig. 55d). In this diagram, the alternating stress amplitude is plotted versus the mean stress. The ordinate is chosen to be the stress amplitude for a given cyclic life. The abscissa is taken to be the ultimate strength of the material. The line connecting these two points represents combinations of stress amplitudes and superimposed mean stresses that give the same fatigue life as for the selected fully reversed stress amplitude. Thus, given the desired cyclic life and σ_a , the allowable mean stress can be determined. Similarly, given N_f and σ_m , σ_a can be determined. This empirical technique is easy to use and leads to reasonably accurate results for many materials.

Low-Cycle Fatigue When performing laboratory tests in the low-cycle fatigue regime ($N_f < 10^4$ cycles), it is common to control the strain amplitude rather than the stress amplitude. Considerable plastic flow can occur in low-cycle fatigue testing. If the stress-strain response for a complete cycle is plotted, the resulting diagram is known as a hysteresis loop (Fig. 56). A considerable amount of information is contained in this diagram. The area within the hysteresis loop represents the work per unit volume done on the material in a single cycle. Most of this work is dissipated as heat. The vertical distance between the tips of the hysteresis loop is the stress range $\Delta\sigma$. The horizontal distance between the tips of the hysteresis loop represents the applied strain range $\Delta\varepsilon$. The maximum width of the loop is known as the plastic strain range $\Delta\varepsilon_p$. The elastic strain range $\Delta\varepsilon_e$ is given by

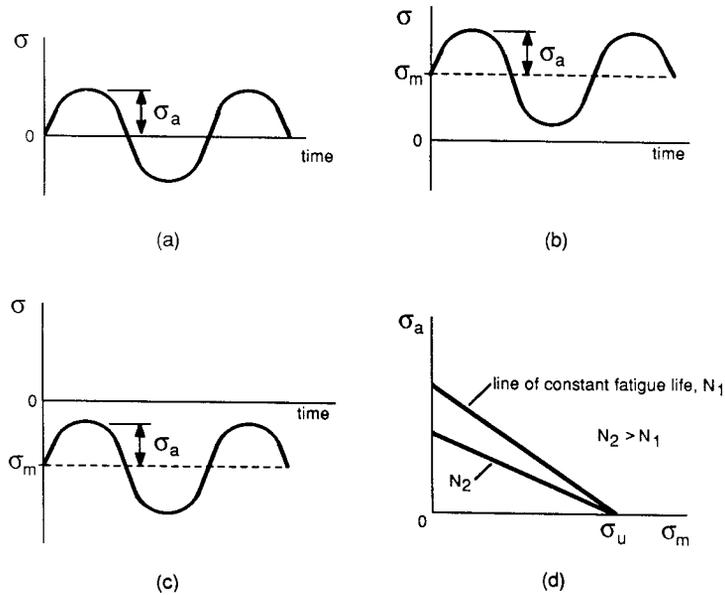

Fig. 55 Mean stress effects in fatigue: (a) fully reversed loading; (b) tensile mean stress; (c) compressive mean stress; (d) modified Goodman diagram.

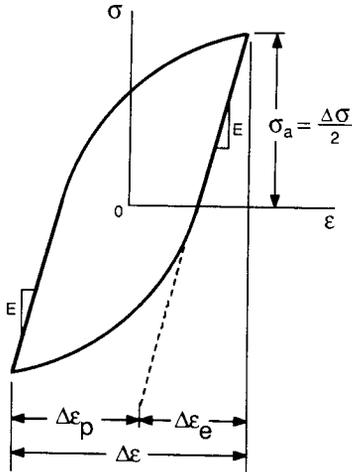

Fig. 56 Hysteresis loop.

$\Delta\epsilon_e = \Delta\epsilon - \Delta\epsilon_p$. Young's modulus is given by the slope of the initial unloading portion of each half of the hysteresis loop. For many materials, the plastic strain range is not constant for each cycle. Instead, some materials show a cyclic hardening effect (i.e., $\Delta\epsilon_p$ decreases with increasing cycles), while others show a cyclic softening effect (i.e., $\Delta\epsilon_p$ increases with increasing cycles). Usually, a material stabilizes by the time the half-life is reached.

If the log of the total strain amplitude, $\log(\Delta\epsilon/2)$, is plotted versus the log of the reversals to failure, a strain-life curve is obtained (Fig. 57). It is often instructive to include the plastic and elastic strain amplitudes, as measured at the half-life, as well. These elastic and plastic strain versus life curves are often straight lines. The plastic strain versus life line is described by the well-known Coffi -Manson equation.⁵⁸

$$\frac{1}{2}\Delta\epsilon_p = \epsilon'_f (2N_f)^c \quad (101)$$

where ϵ'_f is the fatigue ductility coefficient and c is the fatigue ductility exponent. For most materials, ϵ'_f is between $0.5\epsilon_f$ and $1.5\epsilon_f$, where ϵ_f is the true strain at fracture as measured in a tension test (see Section 1.4). The exponent c is usually found to be between -0.5 and -0.7 . Thus, if low-cycle fatigue data are lacking, the assumptions $\epsilon'_f = \epsilon_f$ and $c = -0.6$ should give reasonable results.

The elastic strain versus life line is described by dividing Eq. (100) by Young's modulus E :

$$\frac{\Delta\epsilon_e}{2} = \frac{\sigma_a}{E} = \frac{\sigma'_f}{E} (2N_f)^b \quad (102)$$

By combining Eqs. (101) and (102), a relationship between total strain amplitude and reversals to failure

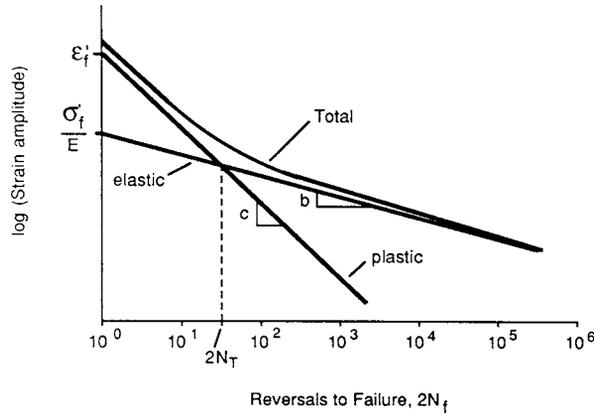

Fig. 57 Strain-life curve.

is obtained:

$$\frac{\Delta \epsilon}{2} = \frac{\Delta \epsilon_e}{2} + \frac{\Delta \epsilon_p}{2} = \frac{\sigma'_f}{E} (2N_f)^b + \epsilon'_f (2N_f)^c$$

The fatigue properties of some selected materials are given in Table 9.

Another important parameter obtained from the strain-life curve is the transition fatigue life, $2N_T$. This is the number of reversals corresponding to the intersection of the elastic and plastic strain versus life lines ($\Delta \epsilon_e/2 = \Delta \epsilon_p/2$). For lives less than $2N_T$, plastic strains dominate the fatigue process and a material's ductility is of great importance. For lives greater than $2N_T$, elastic strains are the dominant strains, and a material's strength is of greater importance than its ductility. It is not surprising that high-strength, low-ductility materials show a short transition life (sometimes N_T is at a few cycles) while lower-strength, ductile materials tend to have a high transition life.

By equating $\Delta \epsilon_p/2$ to $\Delta \epsilon_e/2$ in Eqs. (100) and (101), respectively, the following equation for the transition life is obtained:

$$2N_T = \left(\frac{\epsilon'_f E}{\sigma'_f} \right)^{1/(b-c)}$$

The transition fatigue life is more satisfactory to distinguish the low- and high-cycle regimes of a particular material than an arbitrary number of cycles such as 10^4 .

Cyclic Stress-Strain Diagram For components that undergo significant dynamic loading, design based on the monotonic stress-strain curve may lead to poor results. This is because many materials exhibit significant changes in strength properties due to cyclic loading. These changes are not necessarily due to the development of a macroscopic crack, but rather represent

Table 9 Fatigue Properties of Selected Alloys

global changes in the material's microstructure. Some materials exhibit cyclic hardening while others exhibit cyclic softening and still others are relatively stable with respect to cyclic loading. Thus, when designing components that undergo significant dynamic loading, the cyclic stress-strain diagram should be used.

Several techniques exist for construction of a cyclic stress-strain curve. In one commonly used procedure, the tips of stabilized hysteresis loops from a number of strain-controlled fatigue tests are connected together to form a smooth curve. In another single-specimen technique, the specimen is cycled at higher and higher strain amplitudes. At each amplitude, enough cycles are performed to obtain a relatively stable hysteresis loop, but not so many cycles as to significantly damage the specimen. Again, the tips of the hysteresis loops so obtained are connected together to form a smooth

curve. Some examples of cyclic stress-strain diagrams and the corresponding monotonic curves are provided in Fig. 58.

If true stress and true strain are used to construct the cyclic stress-strain diagram, a relationship similar to Eq. (22) is often found to be valid:

$$\sigma_a = K' \left(\frac{1}{2} \Delta \varepsilon_p \right)^{n'}$$

where σ_a is the steady-state true stress amplitude, $\Delta \varepsilon_p / 2$ is the corresponding plastic strain amplitude, K' is the cyclic strength coefficient, and n' is the cyclic strain-hardening exponent. The value of n' is usually between 0.10 and 0.20. In general, metals with high monotonic strain-hardening exponents ($n > 0.15$) cyclically harden while those with low values of

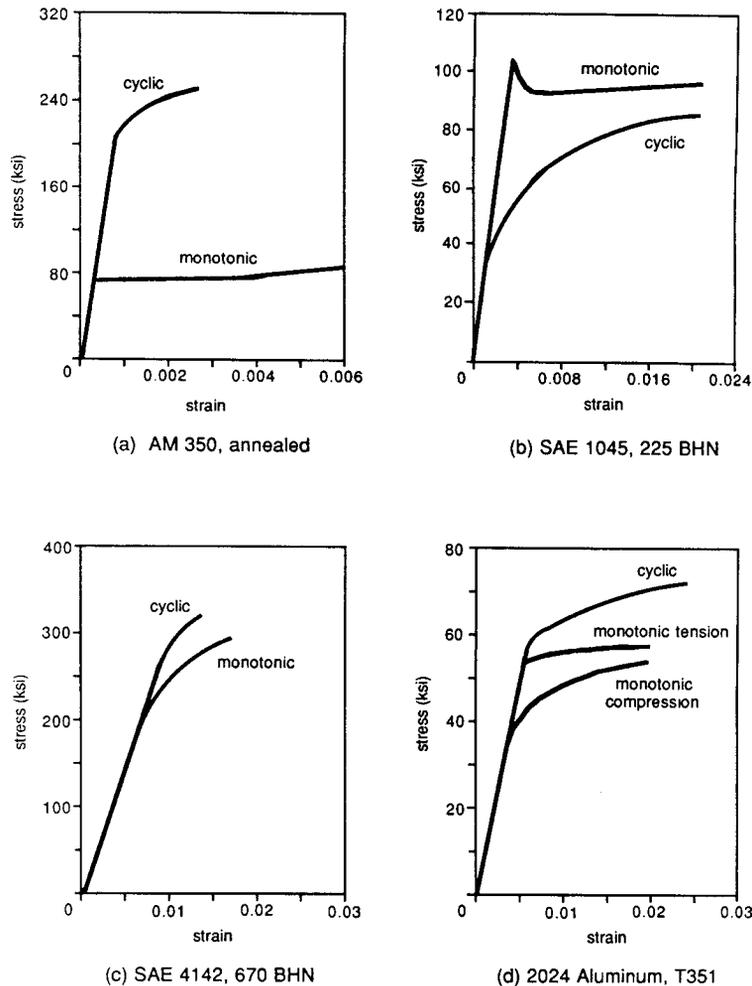

Fig. 58 Examples of some monotonic and cyclic stress-strain diagrams.

n ($n < 0.15$) cyclically soften. It can be shown, by considering energy quantities, that⁵⁹

$$n' = \frac{b}{c}$$

This equation provides a correlation between fatigue properties and cyclic stress–strain properties. If typical values for c and b of -0.6 and -0.9 , respectively, are substituted into this equation, a value for n' of 0.15 results. This is in good agreement with the fact that n' is usually found to be between 0.1 and 0.2 for most metals.

Theories of Cumulative Damage Constant amplitude cyclic loading does not occur in most real situations. Instead, the loading is most often random (e.g., the loadings on a car axle) or consists of distinct blocks of loading at given amplitudes (e.g., machinery operated at several discrete speeds). In order to estimate fatigue life under these conditions, a theory of cumulative damage is required.

For simple block-loading situations, the most commonly used theory is the Palmgren–Miner rule (also known as Miner’s rule, or as the linear cumulative damage theory). This theory states that the fraction of life exhausted by the i th block loading is given by n_i/N_{fi} , where n_i is the number of cycles applied in the i th block and N_{fi} is the number of cycles to failure of a virgin specimen cycled at the same load amplitude as used in the i th block. Clearly, an S – N or strain–life diagram is required to use this theory since N_f data are needed. Failure is assumed to occur when the total fraction of life exhausted becomes equal to one. That is,

$$\sum_i \frac{n_i}{N_{fi}} = \frac{n_1}{N_{f1}} + \frac{n_2}{N_{f2}} + \frac{n_3}{N_{f3}} + \dots = 1 \quad \text{at failure}$$

In using the Palmgren–Miner rule, one assumes that fatigue damage accumulates in a linear fashion. In other words, the damage accumulated per cycle must be the same early and late in the cycling sequence for a given block loading. In reality, this is often not the case. Even so, this empirical rule or modified versions of it usually give satisfactory results.

For components undergoing random loading, it is necessary to obtain or estimate a typical portion of the loading history of the component. As previously mentioned, this is referred to as load spectrum analysis. Once this is done, more sophisticated models for fatigue damage accumulation, such as rain flow counting, can be applied. An excellent discussion of fatigue life estimation techniques is provided in Ref. 60.

Creep and Fatigue There are many situations in modern engineering in which a material must be subjected to cyclic loads at temperatures that are relatively near the melting point of the material. Some examples include turbine blades in aircraft jet engines,

nuclear pressure vessels, and solder joints used in electronics interconnection technology. Under these circumstances, the standard theories of fatigue presented previously are no longer adequate. Instead, theories for creep fatigue need to be applied. The two most commonly used theories are the Robinson–Taira theory⁶¹ and the theory of strain range partitioning.⁶²

The Robinson–Taira theory has the form

$$\sum_i \frac{n_i}{N_{fi}} + \sum_i \frac{t_i}{t_{ri}} = 1 \quad \text{at failure}$$

where n_i = number of cycles applied at i th loading

N_{fi} = number of cycles to failure at i th loading

t_i = time spent at i th stress amplitude σ_i

t_{ri} = time to creep failure at stress level of σ_i

Note the similarity between the Robinson–Taira equation and the Palmgren–Miner rule. In fact, the Robinson–Taira equation reduces to the Palmgren–Miner rule when creep damage is insignificant. The Robinson–Taira equation is displayed graphically in Fig. 59. For some materials (such as 304 stainless steel), this equation can lead to very nonconservative predictions. A modification of the Robinson–Taira equation, which forms the basis for an ASME code, helps alleviate this problem.

The theory of strain range partitioning (SRP) was developed at the National Aeronautics and Space Administration (NASA) Lewis Research Center in the early 1970s. It involves the partitioning of a hysteresis loop obtained from a region of a structural member into four basic strain components: plastic–plastic ($\Delta\varepsilon_{pp}$), creep–creep ($\Delta\varepsilon_{cc}$), plastic–creep ($\Delta\varepsilon_{pc}$), and creep–plastic ($\Delta\varepsilon_{cp}$). The idealized hysteresis loops for these four strain components are shown in Fig. 60a. Only one of $\Delta\varepsilon_{pc}$ and $\Delta\varepsilon_{cp}$ can be present in any real hysteresis loop. Strain–life plots for all four types

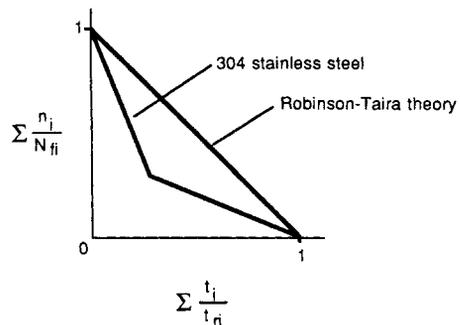

Fig. 59 Robinson–Taira theory for creep fatigue.

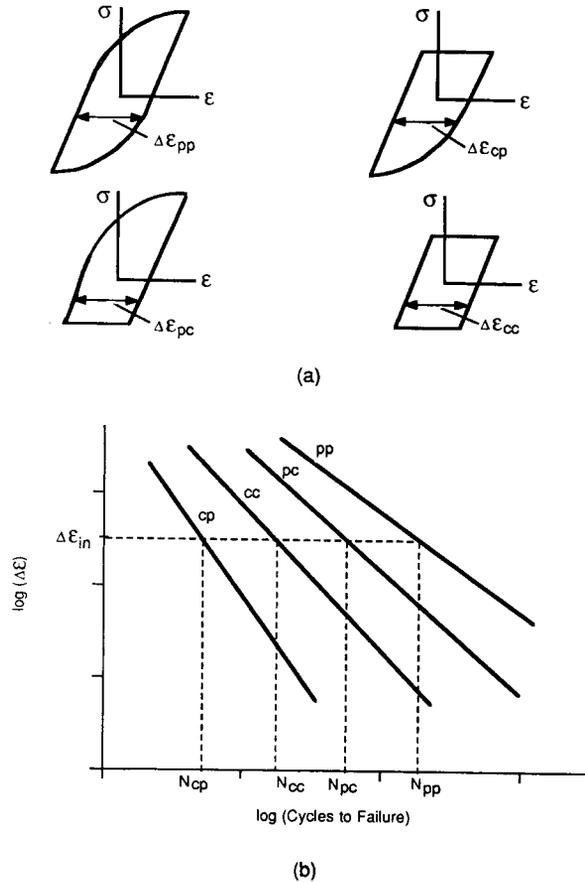

Fig. 60 Strain range partitioning components: (a) idealized hysteresis loops for four strain range components; (b) strain-life plots for four strain range components.

of strain components must be obtained from laboratory testing. Once these strain-life plots are obtained, the predicted life of the structural member, N_{pred} , is obtained using a linear interactive damage rule,

$$\frac{1}{N_{pred}} = \frac{F_{pp}}{N_{pp}} + \frac{F_{cc}}{N_{cc}} + \frac{F_{pc}}{N_{pc}} + \frac{F_{cp}}{N_{cp}}$$

where $F_{pp} = \Delta\epsilon_{cc}/\Delta\epsilon_{in}$, $F_{cc} = \Delta\epsilon_{cc}/\Delta\epsilon_{in}$, and so on. The quantity $\Delta\epsilon_{in}$ is the total inelastic strain range of the structural member's hysteresis loop. That is, $\Delta\epsilon_{in} = \Delta\epsilon_{pp} + \Delta\epsilon_{cc} + \Delta\epsilon_{pc} + \Delta\epsilon_{cp}$ (where one of $\Delta\epsilon_{pc}$ and $\Delta\epsilon_{cp}$ must be zero). N_{pp} is the number of cycles to failure if $\Delta\epsilon_{in}$ were made up solely of plastic-plastic strains. Similar definition hold for N_{cc} , N_{pc} , and N_{cp} . Figure 60b should provide for further understanding of these quantities.

For isothermal fatigue, the modified Robinson-Taira theory and the theory of strain range partitioning both give reasonable results. While the theory of strain range

partitioning is more complicated to use and can involve considerable laboratory testing, it usually leads to life predictions that are within a factor of 2 or 3 of actual results.

For thermal fatigue situations (i.e., situations in which large temperature fluctuations occur within each cycle), no theories have yet gained broad acceptance. An excellent overview of highly regarded theories is given in Ref. 63.

Multiaxial Fatigue When attempting to predict fatigue lives under multiaxial loading conditions, many new factors must be considered. First of all, it must be known whether the loading is proportional (i.e., $\sigma_1/\sigma_2 = \text{constant}$ throughout time) as shown in Fig. 61a, or nonproportional. Nonproportional loading can be further divided into in-phase (Fig. 61b) and out-of-phase (Fig. 61c) situations. It must also be known if the cycling is periodic, as shown in Fig. 61, or of a block-loading or random-loading nature. If a point on the free surface of a component is being analyzed,

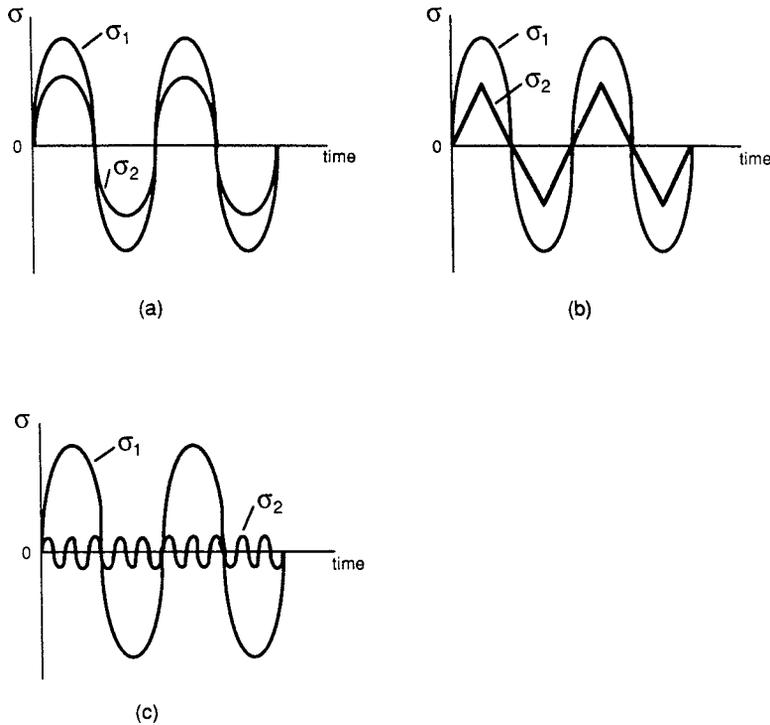

Fig. 61 Distinct examples of multi-axial cyclic loading: (a) proportional loading; (b) in-phase nonproportional loading; (c) out-of-phase nonproportional loading.

it should be noted that the orientation of the principal stresses (or strains) with respect to the free surface can have a major influence on the fatigue life. Only theories for periodic, in-phase, proportional loading are considered here. Excellent reviews of the available theories for multi-axial fatigue can be found in Refs. 64–66.

Some of the earliest work on multi-axial fatigue centered around modifying static yield theories for fatigue situations. The results were the maximum normal stress theory,

$$S_f = \sigma_{a1}$$

the maximum-shear-stress theory,

$$S_f = \frac{1}{2}(\sigma_{a1} - \sigma_{a3})$$

or

$$e_f = \frac{1}{2}(\epsilon_{a1} - \epsilon_{a3})$$

and the energy-of-distortion theory,

$$S_f = \frac{1}{2} [(\sigma_{a1} - \sigma_{a2})^2 + (\sigma_{a1} - \sigma_{a3})^2 + (\sigma_{a2} - \sigma_{a3})^2]^{1/3}$$

$$e_f = \frac{2}{3} [(\epsilon_{a1} - \epsilon_{a2})^2 + (\epsilon_{a1} - \epsilon_{a3})^2 + (\epsilon_{a2} - \epsilon_{a3})^2]^{1/2}$$

In these equations, σ_{ai} is the amplitude of the i th principal stress. Similarly, ϵ_{ai} is the amplitude of the i th principal strain, and S_f and e_f are stress and strain parameters, respectively, used to predict fatigue life. While each of these theories has been found to be applicable under certain loading conditions, each one can lead to serious errors in life prediction under other conditions.

A more successful approach that has been used by many investigators is to account for the effects of hydrostatic pressure on fatigue life. One of the more useful versions of these theories has the form

$$\left(\frac{\sigma_{a1} - \sigma_{a3}}{2} \right) + K_{N_f} \left(\frac{\sigma_{a1} + \sigma_{a3}}{2} \right) = C_{N_f}$$

where K_{N_f} and C_{N_f} are empirically determined parameters applicable to a certain fatigue life, N_f . The first term in parentheses represents the maximum-shear-stress amplitude, while the second term represents the normal stress acting on the plane of maximum shear. For low-cycle fatigue analysis, strain amplitudes should be used instead of stress amplitudes. Although this modern approach to multi-axial fatigue tends to give reasonably accurate results, considerable amounts of laboratory data must be acquired for its application.

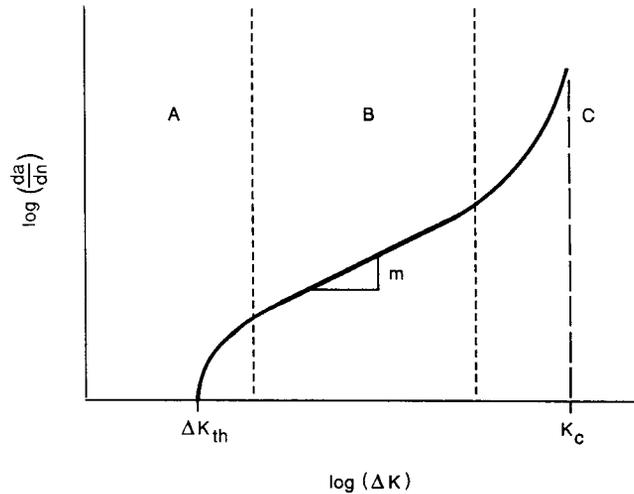

Fig. 62 Variation of fatigue crack growth rate with ΔK .

Damage-Tolerant Design The damage-tolerant design approach to fatigue analysis is based on LEFM. In the usual approach, an initial crack size is assumed or known via nondestructive testing. Using LEFM techniques, the number of cycles required to propagate the crack to a size at which component failure occurs is determined. The primary disadvantage of damage-tolerant design is that, in many high-cycle fatigue applications, the initiation of a fatigue crack may entail a majority of the component life. Thus, assuming a certain initial crack size when none is actually present may lead to an overly conservative design. Neglecting this disadvantage, damage-tolerant design can be useful in many applications:

1. Given the desired service life, the smallest initial flaw size that would lead to failure at the end of the service life can be determined. Nondestructive testing that can detect this flaw size must be employed to assure the minimum desired service life.
2. If a flaw is discovered during routine in-service inspection (such as occurs with inspection of aircraft), the remaining safe life of the component before replacement is necessary can be assessed.

The primary relationship used in damage-tolerant design is the Paris equation⁶⁷

$$\frac{da}{dN} = A(\Delta K)^m \quad (103)$$

where da/dN is the crack growth rate, ΔK is the change in stress intensity factor in a single cycle, and A and m are material constants. The constant m is usually

between 2 and 4 for most metals. Equation (103) is not valid for all values of ΔK ; instead, it is applicable only within a certain range as shown in Fig. 62. Region A in the figure is often referred to as the threshold regime. Equation (103) is not valid in this region. In fact, for values of ΔK below the threshold intensity factor range, ΔK_{th} , no fatigue cracks should propagate. There is still some debate over the proper use of ΔK_{th} in design. In region B of Fig. 62, material response is relatively stable, and Eq. (103) is valid. In region C, crack propagation becomes unstable, and failure is imminent.

In order to apply the Paris equation for life prediction, the initial crack size and stress range must be such that $\Delta K > \Delta K_{th}$. Also, it must be possible to compute ΔK as a function of crack length. If these two things can be done, the Paris equation can be integrated to give the number of cycles until ΔK is so large that unstable crack propagation occurs. A wealth of information on damage-tolerant design can be found in Ref. 68.

1 INTRODUCTION

This chapter deals with the nondestructive inspection of materials, components, and structures. The term *nondestructive inspection* (NDI) or *nondestructive evaluation* (NDE) is defined as that class of physical and chemical tests that permit the detection and/or measurement of significant properties or the detection

of defects in a material without impairing its usefulness. The inspection process is often complicated by the fact that many materials are anisotropic, and most NDI techniques were developed for isotropic materials such as metals. The added complication due to the anisotropy usually means that an inspection is more complicated than it would be with isotropic materials.

Inspection of complex materials and structures is frequently carried out by comparing the expected inspection data with a standard and noting any significant deviations. This means a well-defined standard must be available for calibration of the inspection

*Reprinted from *Mechanical Engineers' Handbook*, Vol. 1, Wiley, New York, 2006, with permission of the publisher.

instrumentation. Furthermore, standards also must contain implanted flaws that mimic those that naturally occur in the material or structure to be inspected. Without a well-defined standard to calibrate the inspection process, the analysis of NDI results can be significantly in error. For example, to estimate the amount of porosity in a cast component from ultrasonic measurements, standard calibration specimens with calibrated levels of porosity must be available to calibrate the instrumentation. Without such standards, estimation of porosity from ultrasonic data is a highly speculative process.

This chapter covers some important and some less well-known NDI tests. Since information on the less frequently used tests is not generally in standard texts, additional sources of information are listed in the References.

Inspection instrumentation must possess four qualities in order to receive widespread acceptance in the NDI community:

1. *Accuracy.* The instrument must accurately measure a property of the material or structure that can be used to infer either its properties or the presence of flaws
2. *Reliability.* The instrument must be highly reliable, that is, it must consistently detect and quantify flaw or a property with a high degree of reliability. If an instrument is not reliable, then it may not detect flaw that can lead to failure of the component, or it may indicate the presence of a flaw where none exists. The detection of a phantom flaw can mean that an adequate component is rejected, which is a costly error.
3. *Simplicity.* The most frequently used instruments are those used by factory or repair technicians. The inspection community rarely uses highly skilled operators due to the cost constraints.
4. *Low Cost.* An instrument need not be low cost in an absolute sense. Instead, it must be inexpensive relative either to the value of the component under test or to the cost of a failure or aborted mission. For example, in the aircraft industry as much as 12% of the value of the component may be spent on inspection of a flight-critical aircraft component.

1.1 Information on Inspection Methods

To the engineer confronted by a new inspection requirement, there may arise the question of where to find pertinent information regarding an inspection procedure and its interpretation. Fortunately, many potential sources of information about instrumentation and techniques are available for NDI, and a brief examination of this literature is presented here. Many of these references were generated because of the demands of materials used in flight-critical aerospace structures. In this chapter, we will refer only to scientific and engineering books and journals that one would reasonably expect to find in a well-provisioned library.

With the rise of the Internet, there are now many electronic sources of information available on the World Wide Web. These include library catalogs, societal home pages, online journals devoted to inspection, home pages of instrument manufacturers with online demonstrations of their capabilities and inspection services, inspection software, and online forums devoted to solving inspection problems. The References provide many such sources. However, with new electronic sources appearing daily, it is only a brief snapshot of those available at the beginning of the twenty-first century. For those new to the technology, American Society for Testing and Materials (ASTM) standards are particularly valuable because they give very detailed directions on many NDE techniques. More importantly, they are widely accepted standards for inspections. The References also provides sources for those situations where standard inspection methods are not sufficient to detect the material condition of interest.

General NDE Reference Books General overviews to NDE techniques are provided in Refs. 1–22. The reader will note that some of these citations are not recent, but they are included because of their value to the engineer who does not possess formal training in the latest inspection technologies. Additionally, some older works were included because of their clarity of presentation, completeness, or usefulness to the inspection of complex structures.

NDE Journals The periodical literature is often a source of the latest research results for new or modified inspection methodologies.^{5,23–28} Some excellent journals are no longer available but are still a valuable source of information or may contain data available nowhere else. Whenever possible, World Wide Web addresses are provided to give the reader ready access to this material.

1.2 Electronic References

There are many useful electronic references for those working in NDE technology. Only a few of the many useful sites on the World Wide Web are included here. Many sites contain links to other sites that contain information on a special topic of interest to the reader. Because the Web is constantly being updated, the list in the References represents a very brief snapshot of the information available to the NDE community. Some useful sites associated with government agencies were not included due to space limitations. The Web addresses provided are associated with NDE societies,^{5,6,27,30–36} institutes,^{7,8,10,38–40} government agencies,^{25,38,41} and general-interest sites.^{26,33,35,42–44} There are also many references for the reader interested in using or modifying existing NDE techniques.^{31,45–47}

1.3 Future NDE Capabilities

At this point, the reader might be tempted to ask if there are new technologies on the horizon that will

enable more cost-effective, anticipatory inspection or monitoring of materials and structures. The answer to this is an emphatic yes. There are new developments in solid-state detectors that should significantly affect both inspection capability and cost. For example, optical and X-ray detectors now give the inspector the ability to rapidly scan large areas of structures for defects. Many new developments in these areas are the outgrowth of advances in noninvasive medical imaging. By coupling this technology with computer algorithms that search an image, the inspection of large areas can be automated, providing more accurate inspections with much less operator fatigue. Hopefully, this technological advance will remove much of the drudgery of detecting the rather small number of flaws in an otherwise large population of satisfactory components.

The area of data fusion is just beginning to be explored in the NDE field. This means that data collected with one technique can be combined with another technique to detect a range of flaws not detected when either is used independently. Data from several techniques can then be coupled at the basic physics level to provide a more complete description of the microstructural details of a material than is now possible.

Finally, the development of new semiconductor-based devices, microelectromechanical systems (MEMS) and radio-frequency identification (RFID) allows the implantation of monitoring devices into a material at the time of manufacture to enable real-time structural health monitoring. These devices will permit the inspector to detect and quantify material or structural degradation remotely. This should also enable management of the components and structures for optimum usage over their lifetimes. Remote inspection and tracking of material degradation should reduce the burden of inspection while giving the inspector the ability to examine areas of structure that are now called "hidden." For more information about this rapidly evolving area the reader is referred to the literature.^{29,33,48-50}

A brief review of the commonly used NDI methods are listed in Table 1 along with types of flaws that each method detects and the advantages and disadvantages of each technique. For detailed information regarding the capabilities of any particular method, the reader is referred to the literature. A good place to start any search for the latest NDE technology is the home page of the American Society for Nondestructive Testing.⁶

2 LIQUID PENETRANTS

Liquid penetrants are used to detect surface-connected discontinuities, such as cracks, porosity, and laps, in solid, nonporous materials.⁵¹ The method uses a brightly colored visible or fluorescent penetrating liquid that is applied to the surface of a cleaned part. During a specific "dwell time," the liquid enters the discontinuity and is then removed from the surface of the part in a separate step. The penetrant is drawn from the flaw to the surface by a developer to provide an

indication of surface-connected defects. This process is depicted schematically in Figs. 1–4. A penetrant indication of a flaw in a turbine blade is shown in Fig. 5.

2.1 Penetrant Process

Both technical societies and military specifications require a classification system for penetrants. Society documents (typically ASTM E165)⁵¹ categorize penetrants into visible and fluorescent depending on the type of dye used. In each category, there are three types, depending on how the excess penetrant is removed from the part. These are water washable, postemulsifiable and solvent removable.

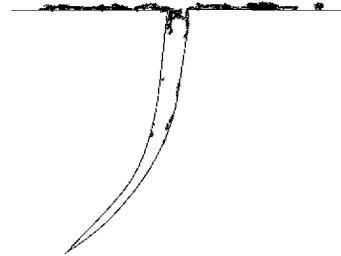

Fig. 1 Representation of part surface before cleaning for penetrant inspection.

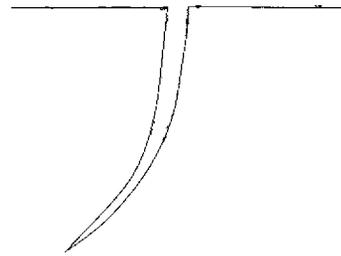

Fig. 2 Part surface after cleaning and before penetrant application.

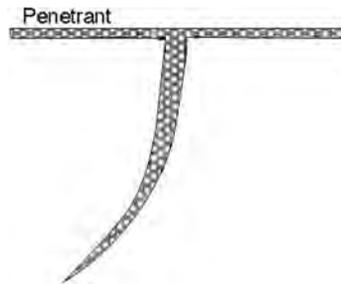

Fig. 3 Part after penetrant application.

Table 1 Capabilities of the Common NDI Methods

Method	Typical Flaws Detected	Typical Application	Advantages	Disadvantages
Radiography	Voids, porosity, inclusions, and cracks	Castings, forging, weldments, and structural assemblies	Detects internal flaws; useful on a wide variety of geometric shapes; portable; provides a permanent record	High cost; insensitive to thin laminar flaws, such as tight fatigue cracks and delaminations; potential health hazard
Liquid penetrants technique	Cracks, gouges, porosity, laps, and seams open to a surface	Castings, forging, weldments, and components subject to fatigue or stress-corrosion cracking	Inexpensive; easy to apply; portable; easily interpreted	Flaw must be open to an accessible surface, level of detectability operator dependent
Eddy current inspection	Cracks and variations in alloy composition or heat treatment, wall thickness, dimensions	Tubing, local regions of sheet metal, alloy sorting, and coating thickness measurement	Moderate cost; readily automated; portable	Detects flaws that change conductivity of metals; shallow penetration; geometry sensitive
Magnetic particles method	Cracks, laps, voids, porosity, and inclusions	Castings, forging, and extrusions	Simple; inexpensive; detects shallow subsurface flaws as well as surface flaws	Useful on ferromagnetic materials only; surface preparation required; irrelevant indications often occur; operator dependent
Thermal testing	Voids or disbonds in both metallic and nonmetallic materials, location of hot or cold spots in thermally active assemblies	Laminated structures, honeycomb, and electronic circuit boards	Produces a thermal image that is easily interpreted	Difficult to control surface emissivity and poor discrimination between flaw types
Ultrasonic methods	Cracks, voids, porosity, inclusions and delaminations, and lack of bonding between dissimilar materials	Composites, forgings, castings, and weldments and pipes	Excellent depth penetration; good sensitivity and resolution; can provide permanent record	Requires acoustic coupling to component; slow; interpretation of data is often difficult

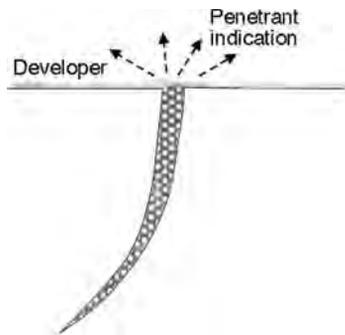

Fig. 4 Representation of part after excess penetrant has been removed and developer has been applied.

The first step in penetrant testing (PT) or inspection is to clean the part. This critical step is one of the most neglected phases of the PT procedure. Since PT only detects flaws that are open to the surface, the flaw and part surface must be free of dirt, grease, oil, water, chemicals, and other foreign materials that might block the penetrant's entrance into a defect. Typical cleaning procedures use vapor degreasers, ultrasonic cleaners, alkaline cleaners, or solvents.

After the surface is clean, a liquid penetrant is applied to the part by dipping, spraying, or brushing. In this step, the penetrant on the surface is wicked into the flaw. In the case of tight or narrow surface openings, such as fatigue cracks, the penetrant must be allowed to remain on the part for a minimum of 30 min to completely fill the flaw. High-sensitivity fluorescent dye penetrants are used for this type of inspection.

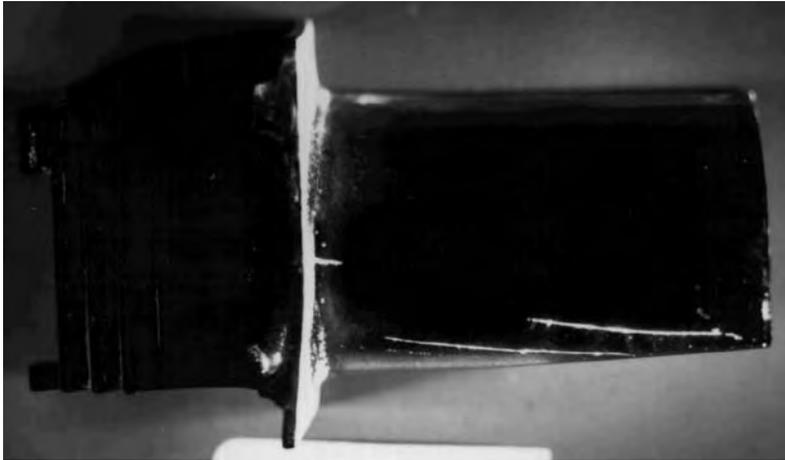

Fig. 5 Penetrant indication of crack running along edge of jet engine turbine blade. Ultraviolet illumination causes the extracted penetrant to fluoresce.

After the dwell time, excess penetrant is removed by one of the processes mentioned previously. For water-based penetrants an emulsifier is sprayed onto the part and again a dwell time is observed. Water is then used to remove the penetrant from the surface of the part. In some cases, the emulsifier is included in the penetrant, so one only needs to wash the part after the penetrant has had time to penetrate the flaw. These penetrants are therefore called “water washable.” Of course, the emulsifier reduces the brightness of any flaw indication because it dilutes the penetrant. Ideally, only the surface penetrant is removed with the penetrant in the flaw left undisturbed.

The final step in a basic penetrant inspection is the application of a fine powder developer. This may be applied either wet or dry. The developer aids in wicking the penetrant from the flaw and provides a suitable background for its detection. The part is then viewed under a suitable illumination—either an ultraviolet or a visible source. A typical fluorescence penetrant indication for a crack in a jet engine turbine blade is shown in Fig. 5.

2.2 Reference Standards

Several reference standards are used to check the effectiveness of liquid penetrant systems. One of the oldest and most often used methods involves applying penetrant to hard chromium-plated brass panels. The panel is bent to place the chromium in tension, producing a series of cracks in the plating. These panels are available in sets containing fine, medium, and coarse cracks. The panels are used to classify penetrant materials by sensitivity and to detect degrading changes in the penetrant process.

2.3 Limitations of Penetrant Inspections

The major limitation of liquid penetrant inspection is that it can only detect flaws that are open to the surface. Other inspection methods must be used to detect subsurface defects. A factor that may inhibit the effectiveness of liquid penetrant inspection is surface roughness. Rough surfaces are likely to produce false indications by trapping penetrant, therefore, PT is not suited to the inspection of porous materials. Other penetrant-like methods are available for porous components—see the discussion of filtered particle inspection in Ref. 51.

3 RADIOGRAPHY

In radiography used in NDE, the projected X-ray attenuations of a multitude of paths through a specimen are recorded as a two-dimensional image on a recording media, usually film. One might ask if the newer solid-state X-ray imaging technologies used in medicine also apply to NDE. The answer is yes, as will be discussed in the latter part of this section. The most used recording medium is still film because it is the simplest to apply and provides a resolution of subtle details not currently available with solid-state detectors. However, this situation may not be the case much longer as rapid progress is being made in the development of solid-state detectors with significantly enhanced resolution capabilities. Therefore, since this chapter is written at the beginning of the twenty-first century, when film usage for inspection is still commonplace, this portion of the chapter approaches radiography from the standpoint of film-based recording. Since most quantitative relationships for film also apply to solid-state detectors, the material presented should be applicable for the near future.

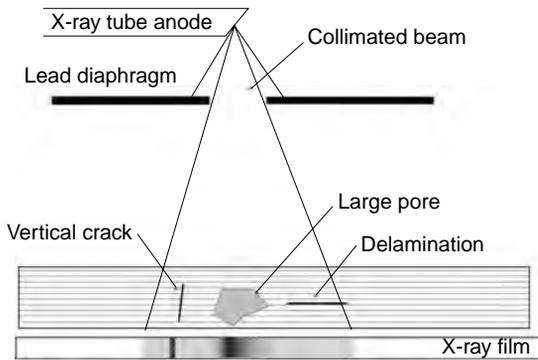

Fig. 6 Schematic radiograph with typical flaws.

The radiography testing (RT) process is shown schematically in Fig. 6. RT records any feature that changes the attenuation of the X-ray beam as it traverses the component. This local change in attenuation produces a change in the intensity of the X-ray beam, which translates into a change in the density, or darkness, on a film. This change in brightness may appear as a distinct shadow or in some cases a delicate shadow on the radiograph. The inspector is greatly aided in detecting a flaw or discrepancy in a part by his or her knowledge of part shape and its influence on the radiographic image. Flaws, which do not change the attenuation of the X-ray beam on passage through the part, are not recorded. For example, a delamination in a laminated specimen is not visible because there is no local change in attenuation of the X-ray beam as it transverses the part. Conversely, flaws that are oriented parallel to the X-ray path do not attenuate the beam as much, allowing more radiation to expose the film and appearing darker than the surrounding image. An example of a crack in the correct orientation to be visible on a radiograph of a piece of tubing is shown in Fig. 7.

3.1 Generation and Absorption of X Radiation

X radiation can be produced from a number of processes. The most common method of generating X rays is with an electron tube in which a beam of energetic

electrons impacts a metal target. As the electrons are rapidly decelerated by this collision, a wide band of X radiation is produced, analogous to white light. This band of radiation is referred to as *Bremsstrahlung* or braking radiation. These high-energy electrons produce short-wavelength energetic X rays. The relationship between the shortest wavelength radiation and the highest voltage applied to the tube is given by

$$\lambda = \frac{12,336}{\text{voltage}}$$

where λ is the wavelength in angstroms and is the shortest wavelength of the X radiation produced. The more energetic the radiation, the more penetrating powers it possesses, and very high energy radiation is used on dense materials such as metals. While it is possible to analytically predict what X-ray energy would provide the best image for a specific material and geometry, a simpler method of determining the optimum X-ray energy is shown in Fig. 8. Note that high-energy X-ray beams are used for dense materials, for example, steels, or for thick low-density materials, for example, large plastic parts. An alternative method to using this figure is to use the radiographic equivalence factors given in Table 2.⁵² Aluminum is the standard material for X-ray tube voltages below 100 keV, while steel is the standard above this voltage. When radiographing another material, its thickness is multiplied by the factor in this table to obtain the equivalent thickness of the standard material. The radiographic parameters are set up for this thickness of aluminum or steel. When used in this manner, good radiographs can be obtained for most parts. For example, assume that one must radiograph a 0.75-in.-thick piece of brass with a 400-keV X-ray source. The inspector should multiply the 0.75 in. of brass by the factor of 1.3 to obtain 0.98. This means that an acceptable radiograph of the brass plates would be obtained with the same exposure parameters as would be used for 0.98 in. (approximately 1 in.) of steel.

Radiation for RT can also be obtained from the decay of radioactive sources. In this case, the process is usually referred to as gamma radiography. These radiation sources have several characteristics that differ from X-ray tubes. First, gamma radiation is very nearly

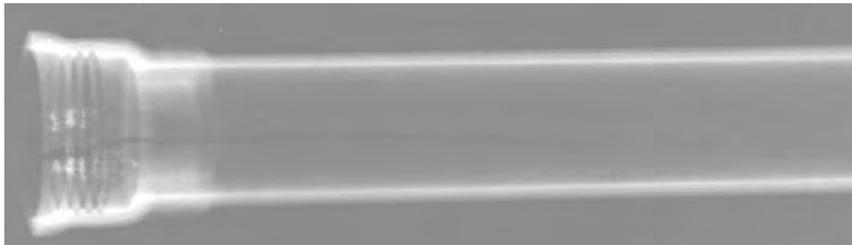

Fig. 7 Radiograph of crack in end of aluminum tubing.

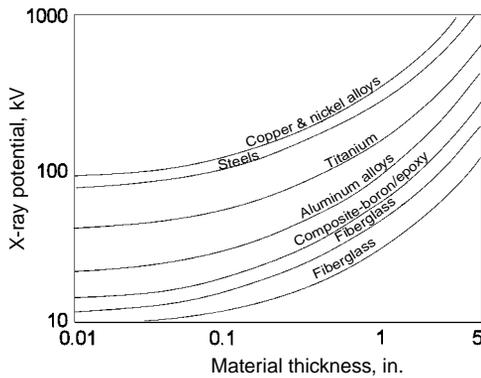

Fig. 8 Plot of X-ray tube voltage versus thickness of several industrial materials.

monochromatic; that is, the spectrum of radiation contains only one or two dominant energies. Second, the energies of most sources are on the order of millions-of-volts range, making this source ideal for inspecting highly attenuating materials or very large structures. Third, the small size of these sources permits them to be used in tight locations where an X-ray tube could not fit. Fourth, since the gamma-ray source is continually decaying, adjustments to the exposure time must be made in order to achieve consistent results over time. Finally, the operator must always remember that the source is continually on and is therefore a persistent safety hazard! Aside from these differences, gamma radiography differs little from standard practice, so no further distinction between the two will be given.

3.2 Neutron Radiography

Neutron radiography⁵³ may be useful to inspect some materials and structures. Because the attenuation of

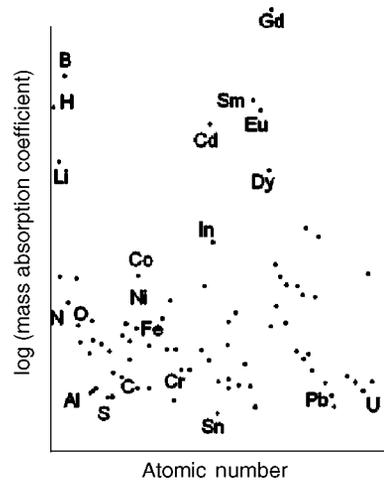

Fig. 9 Plot of mass absorption coefficient for neutron radiography versus atomic number.

neutrons is not related to the elemental composition of the part, some elements can be more easily detected than others. While X rays are most heavily absorbed by high-atomic-number elements, this is not true of neutrons, as shown in Fig. 9. In Fig. 10 two aluminum panels are bonded with an epoxy adhesive. The reader can discern that hydrogen adsorbs neutrons more than aluminum does, and thus the missing adhesive is easily detectable.

Neutron radiography, however, does have several constraints. First, neutrons do not expose radiographic film and therefore a fluorescent medium is often used to produce light, which exposes the film. The image produced in this manner is not as sharp and well defined as that from X rays. Second, at present there is

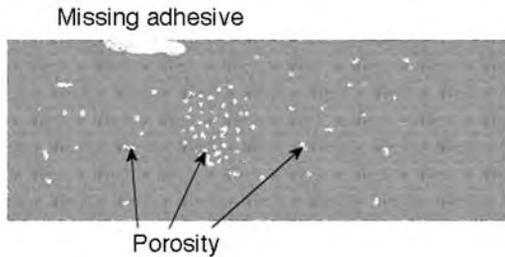

Fig. 10 Representation of neutron radiograph showing flaws in adhesive bond.

no portable high-flu source of neutrons. This means that a nuclear reactor is most often used to supply the neutron radiation. Although neutron radiography has these severe restrictions, at times there is no alternative, and the utility of this method outweighs its expense and complexity.

3.3 Attenuation of X Radiation

An appreciation of how radiographs are interpreted requires a fundamental understanding of X-ray absorption. The relationship governing this phenomenon is Beer's law:

$$I = I_0 e^{-\mu x}$$

where I , I_0 = transmitted and incident X-ray beam intensities, respectively

μ = attenuation coefficient of material, cm^{-1}

x = thickness of specimen, cm

Since the attenuation coefficient is a function of both the composition of the specimen and the wavelength of the X rays, it would be necessary to calculate or measure it for each wavelength used in RT. However, it is possible to calculate the attenuation coefficient of a material for a specific X-ray energy using the mass absorption coefficient μ_m as defined below. The mass absorption coefficients for most elements are readily available for a variety of X-ray energies,⁵⁴

$$\mu_m = \frac{\mu}{\rho}$$

where μ = attenuation coefficient of an element, cm^{-1}

ρ = density, g/cm^3

The mass absorption coefficient for the material is obtained, at a specific X-ray energy, by multiplying the μ_m of each element by its weight fraction in a material and summing these quantities. Multiplying this sum by the density of the material yields its attenuation coefficient for the material. This procedure is often

not used in practice because the results are valid only for a narrow band of wavelengths. Radiographic equivalency factors are used instead. This process points out that each element in a material contributes to the attenuation coefficient by an amount proportional to its amount in the material.

3.4 Film-Based Radiography

The classical method of recording an X-ray image is with film. Because of the continued importance of this medium of recording and the fact that much of the technology associated with it is applicable to newer solid-state recording methods, this section explores film radiography in some detail.

The relationship between the darkness produced on an X-ray film and the quantity of radiation impinging on it is shown by log-log plots of darkness, or film density, and relative exposure (Figs. 11 and 12). Varying the time of exposure, intensity of the beam, or specimen thickness changes the density, or darkness, of the image. The slope of the curve along its linear portion is referred to as the film gamma, γ . Film has characteristics that are analogous to electronic devices: The greater the gamma or amplification capability of the film, the smaller its dynamic range—the range of exposures over which density is linearly related to thickness. If it is necessary to use a high-gamma film to detect very subtle flaw in a part with a wide range of thicknesses, then it is necessary to use several different film types in the same cassette or package. In this way, each film will be optimized for flaw detection in a narrow thickness range of the part.

Using this information, one may calculate the minimum detectable flaw size for a specific RT inspection. A simple method is available to check the radiographic

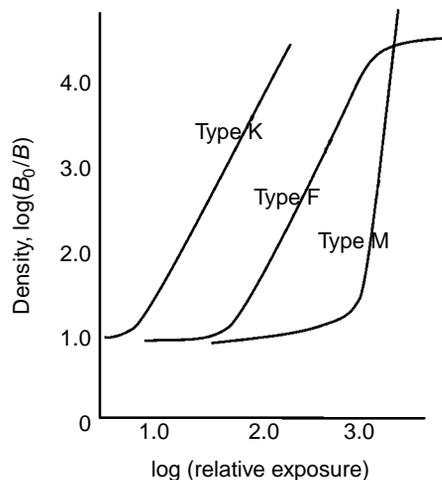

Fig. 11 Density or darkness of X-ray film versus relative exposure for three common films.

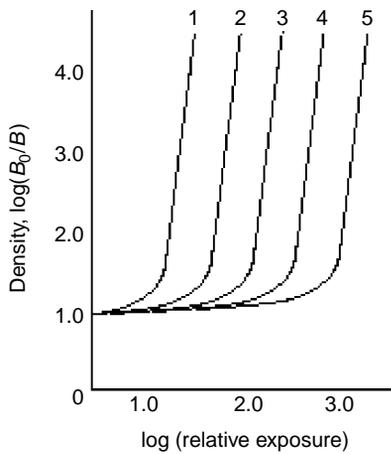

Fig. 12 Density versus relative exposure for films that could be used in multiple film exposure to obtain optimum flaw detectability in complex part.

procedure to determine if this detectability has been achieved on the film. This method does not ensure that the radiograph was taken with the specimen in the proper orientation; it merely provides a method of checking for proper execution of a radiographic procedure; see Section 3.5.

Using a knowledge of the minimum density difference that is detectable by the average radiographic inspector, the following equation relates the radiographic sensitivity, *S*, to radiographic parameters:

$$S = \frac{2.3}{\gamma\mu x}$$

where *S* is the radiographic sensitivity in percent, γ is the film gamma, μ is the attenuation coefficient of the specimen material, and *x* is the maximum thickness of the part associated with a particular radiographic film. The radiographer uses a penetrameter to determine if this sensitivity was achieved. Table 3 give the

Table 3 Radiographic Sensitivity with Thinnest Penetrameter and Smallest Hole Visible on Radiograph

Sensitivity, <i>S</i> (%)	Quality Level (% <i>T</i> – Hole Diameter)
0.7	1 – 1 <i>T</i>
1.0	1 – 2 <i>T</i>
1.4	2 – 1 <i>T</i>
2.0	2 – 2 <i>T</i>
2.8	2 – 4 <i>T</i>
4.0	4 – 2 <i>T</i>

sensitivity *S* in percent and the expected RT performance in penetrameter values (see Section 3.5).

3.5 Penetrameter

An example of a penetrameter is shown schematically in Fig. 13, while its image on a radiograph is shown in Fig. 14. While there are many types of penetrameters, this one was chosen because it is easily related to radiographic sensitivity. The penetrameter is simply a thin strip of metal or polymeric material⁵⁵ in which three holes of varying sizes are drilled or punched. It is composed of the same material as the specimen and has a thickness 1, 2, or 4% of maximum part thickness. The holes in the penetrameter have diameters that are 1*T*, 2*T*, and 4*T*. The sensitivity achieved for each radiographic is determined by noting the smallest hole just visible in the thinnest penetrameter on a film and using Table 3 to determine the sensitivity achieved. By calculating the radiographic sensitivity and then noting the level achieved in practice, the radiographic process can be quantitatively evaluated. While this procedure does not offer any guarantee of flaw detection, it is useful in evaluating the effectiveness of the RT process.

Almost all variables of the radiographic process may be easily and rapidly changed with the aid of tables, graphs, and nomograms, which are usually provided by film manufacturers free of charge. For more information, the reader is referred to the commercial literature.

3.6 Real-Time Radiography

While film radiography represents the bulk of radiographic NDE performed at this time (the beginning

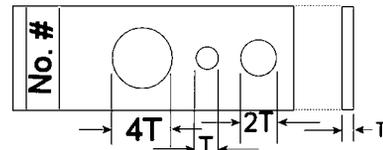

Fig. 13 Schematic of typical film penetrameter.

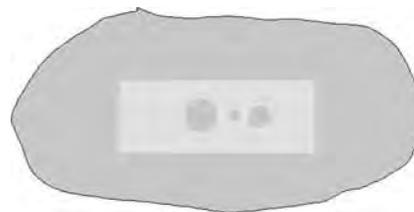

Fig. 14 Radiograph of penetrameter shown in Figure 13. The 1*T* hole is just visible, indicating the resolution obtained in the radiograph.

of the twenty-first century), new methods of both recording the data and analyzing it are coming into widespread usage. For example, filmless radiography (FR) and real-time radiography (RTR) use solid-state detectors and digital signal processing (DSP) software instead of film to record and enhance the radiographic image. These methods have many advantages, along with some disadvantages. For example, FR permits viewing a radiographic image while the specimen is being moved. This often permits the detection of flaws that would normally be missed in conventional film radiography because of the limited number of views or exposures taken—remember that the X-ray beam must pass along a crack or void for it to be detectable. Additionally, the motion of some flaws enhances their detectability because they present the inspector with a different image as a function of time. Additionally, image enhancement techniques can now be economically and rapidly applied to these images because of the availability of inexpensive, fast computing hardware. The disadvantage of RTR is its lower resolution compared to film. Typical resolution capabilities of RTR or FR systems are in the range of 4 to perhaps 20 line pairs/mm, while film resolution capabilities are in the range of 10–100 line pairs/mm. This means some very fine flaws may not be detectable with FR and the inspector must resort to film. However, in cases where resolution is not the limiting factor, the benefit of software image enhancement can be significant. While the images on film may also be enhanced using the image processing schemes, they cannot be performed in real or near real time, as can be done with an electronic system.

3.7 Computed Tomography

Another advance in industrial radiography has been the incorporation of computed tomography (CT) into the repertoire of the radiographer. Unfortunately, CT has not been exploited to its fullest extent principally due to the high cost of instrumentation. The capability of CT to link NDE measurements with engineering design and analysis gives this inspection a unique ability to provide quantitative estimates of performance not associated with NDE.

The principal advantage of this method is that it produces an image of a thin slice of the specimen under examination. This slice is parallel to the path of the X-ray beam that passes through the specimen, in contrast to the shadowgraph image produced by traditional radiography shown in Fig. 7. Whereas the shadowgraph image can be difficult to interpret, the computed CT image does not contain information from planes outside the thin slice.

A comparison between CT and traditional film radiography is best made with images from these two modalities. Figure 7 shows a typical radiograph where one can easily see the image of the top and bottom surfaces of the tube under inspection. The reader can contrast this with the image in Fig. 15, a CT image of a flashlight. The individual components of the flashlight are easily visible and any misplacement of its components or defects in its assembly can be easily detected. An image with a finer scale that reveals the microstructural details of a pencil is shown in Fig. 16. Clearly visible are not only the key features and even the growth rings of the wood. In fact, the details of the growth during each season are visible as

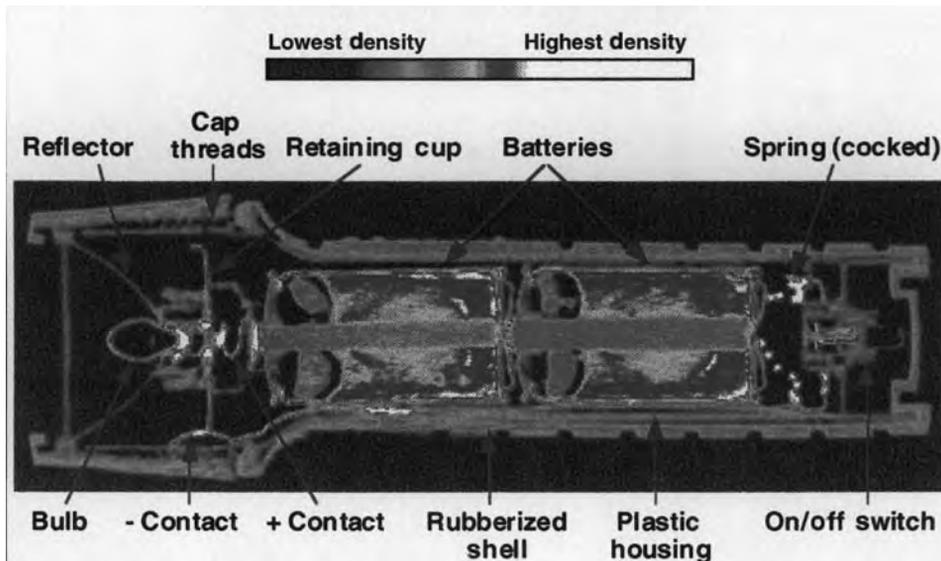

Fig. 15 Computed tomography image of flashlight showing details of internal structure.

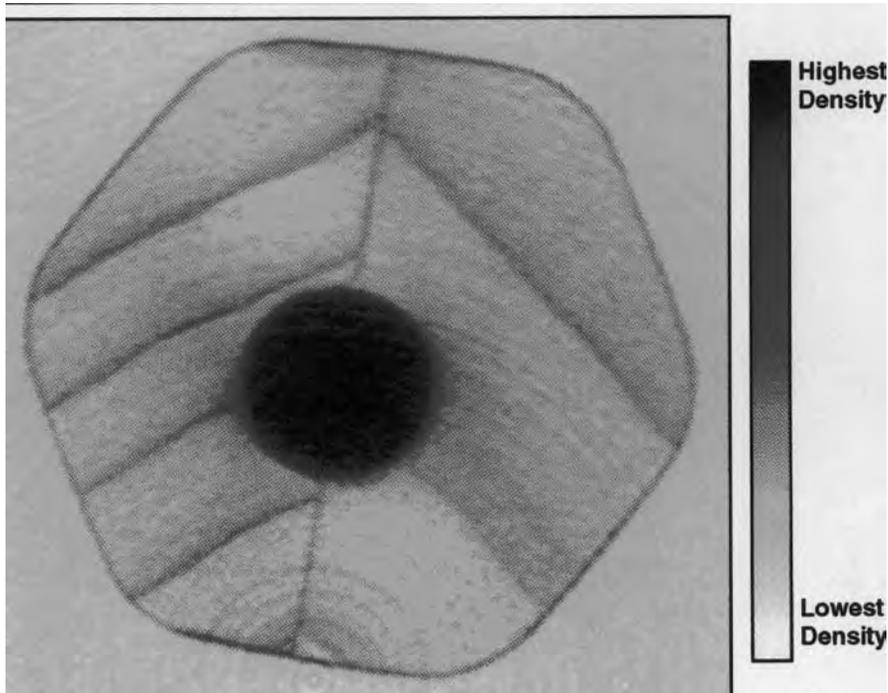

Fig. 16 Computed tomograph of pencil. The reader will note the yearly growth rings and even the growth variations within a single growing season.

rings within rings. The information in the CT image contrasted with conventional radiographs is striking. First, the detectability of a defect is independent of its position in the image. This is not the case with the classical radiograph, where the defect detectability decreases significantly with depth in the specimen because the defect represents a smaller change in the attenuation of the X-ray beam as the depth increases. Second, the defect detectability is very nearly independent of its orientation. This again is clearly not the case with classical radiography. New applications for CT are constantly being discovered. For example, with a digital CT image it is possible to search for various flaw conditions using computer analysis and relieve the inspector of much of the tedium of examining structures for the odd flaw. In addition, it is possible to link the digital CT image with finite-element analysis software to examine precisely how the flaws present will affect such parameters as stress distribution, heat flow and the like. With little effort, one could analyze the full three-dimensional performance of many engineering structures.

4 ULTRASONIC METHODS

Ultrasonic inspection methods utilize high-frequency sound waves to inspect the interior of solid parts. Sound waves are mechanical or elastic disturbances or

waves that propagate in fluid and solid media. Ultrasonic testing (UT) or inspection is similar to the angler who uses sonar to detect fish.⁵⁶ The government and various technical societies have developed standard practice specifications for UT. These include ASTM specifications 214-68, 428-71, and 494-75 and military specification MIL-1-8950H. Acoustic and ultrasonic testing can take many forms, from simple coin tapping to the transmission and reception of very high frequency or ultrasonic waves into a part to analyze its internal structure.

UT instruments operating in the frequency range between 20 and 500 kHz are referred to as *sonic* instruments, while those that operate above 500 kHz are called *ultrasonic*. To generate and receive ultrasonic waves, a piezoelectric transducer is employed to convert electrical signals to sound waves and back again. The usual form of a transducer is a piezoelectric crystal mounted in a waterproof housing that is electrically connected to a pulsar (transmitter) and a receiver. In the transmit mode a high-voltage, short-duration electrical spike is applied to the crystal, causing it to rapidly change shape and emit an acoustic pulse. In the receive mode, sound waves or returning echoes compress the piezoelectric crystal, producing an electrical signal that is amplified and processed by the receiver. This process is shown schematically in Fig. 17.

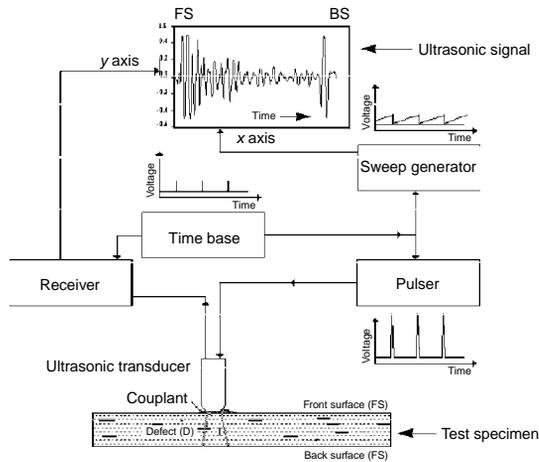

Fig. 17 Schematic of ultrasonic data collection and display in A-scan mode.

4.1 Sound Waves

Ultrasonic waves have physical characteristics such as wavelength (λ), frequency (f), velocity (v), pressure (p), and amplitude (a). The following relationship between wavelength, frequency, and sound velocity is valid for all sound waves:

$$f\lambda = v$$

For example, the wavelength of longitudinal ultrasonic waves of frequency 2 MHz propagating in steel is 3 mm and the wavelength of shear waves is about half this value, 1.6 mm. The relation between the sound pressure and the particle amplitude is

$$p = 2\pi f\rho va$$

where p is density, f is the frequency of the sound wave, v is its velocity, and a the amplitude.

Ultrasonic waves are reflected from boundaries between different materials or media. Each medium has characteristic acoustic impedance and reflection occur in a manner similar to those observed with electrical signals. The acoustic impedance Z of any media capable of supporting sound waves is defined by

$$Z = \rho v$$

where ρ = density of medium, g/cm^3
 v = velocity of sound along direction of propagation

Materials with high acoustic impedance are often referred to as sonically hard, in contrast to sonically soft materials with low impedances. For example, steel

($Z = 7.7 \text{ g/cm}^3 \times 5.9 \text{ km/s} = 45.4 \times 10^6 \text{ kg/m}^2\cdot\text{s}$) is sonically harder than aluminum ($Z = 2.7 \text{ g/cm}^3 \times 6.3 \text{ km/s} = 17 \times 10^6 \text{ kg/m}^2\cdot\text{s}$). The Appendix at the end of this chapter lists the acoustic properties of many common materials.

4.2 Reflection and Transmission of Sound

Almost all acoustic energy incident on air–solid interfaces is reflected because of the large impedance mismatch between air and most solids. For this reason, a medium with impedance close to that of the part is used to couple the sonic energy from the transducer into the part. A liquid couplant has obvious advantages for parts with a complex geometry, and water is the couplant of choice for most inspection situations. The receiver, in addition to amplifying the returning echoes, also time gates the returning echoes between the front surface and rear surfaces of the component. Thus, any unusually occurring echo is displayed separately or used to set off an alarm, as shown in Fig. 17. This method of displaying the voltage amplitude of the returning pulse versus time or depth (if acoustic velocity is known) at a single point in the specimen is known as an A scan. In this figure, the first signal corresponds to a reflection from the front surface (FS) of the part and the last signal corresponds to the reflection from its back surface (BS). The signal or echo between the FS and BS is from the defect in the middle of the part.

The portion of sound energy that is either reflected from or transmitted through each interface is a function of the impedances of the medium on each side of that interface. The reflection coefficient R (ratio of the sound pressures or intensities of the reflected and incident waves) and the power reflection coefficient R_{pwr} (ratio of the power in the reflected and incident sound waves) for normally incident waves onto an interface are given as

$$R = \frac{p_r}{p_i} = \frac{Z_1 - Z_2}{Z_1 + Z_2} \quad R_{\text{pwr}} = \frac{I_r}{I_i} = \left(\frac{Z_1 - Z_2}{Z_1 + Z_2} \right)^2$$

Likewise, the transmission coefficient T and T_{pwr} are defined as

$$T = \frac{p_t}{p_i} = \frac{2Z_2}{Z_1 + Z_2} \quad T_{\text{pwr}} = \frac{I_t}{I_i} = \frac{4(Z_2/Z_1)}{[1 + (Z_2/Z_1)]^2}$$

where I_i , I_r and I_t are the incident, reflected and transmitted acoustic field intensities, respectively; Z_1 is the acoustic impedance of the medium from which the sound wave is incident; and Z_2 is impedance of the medium into which the wave is transmitted. From these equations one can calculate the reflection and transmission coefficient for a planar wave containing air, $Z_1 = 450 \text{ kg/cm}^2\cdot\text{s}$, located in a steel part, $Z_2 = 45.4 \times 10^6 \text{ kg/m}^2\cdot\text{s}$. In this case, the reflection

coefficient for the flange is virtually -1.0 . The minus sign indicates a phase change of 180° for the reflected pulse (note that the defect signal in Fig. 17 is inverted or phase shifted by 180° from the FS signal). Effectively no acoustic energy is transmitted across an air gap, necessitating the use of water as a coupling media in ultrasonic testing. Using the acoustic properties of common materials given in the Appendix the reader can make a number of simple, yet informative, calculations.

Thus far, our discussion has involved only longitudinal waves. This is the only wave that travels through fluid such as air and water. The particle motion in this wave, if one could see it, is similar to the motion of a spring, or a Slinky toy, where the displacement and wave motion are collinear (the oscillations occur along the direction of propagation). The wave is called compressional or dilatational since both compressional and dilatational forces are active in it. Audible sound waves are compressional waves. This wave propagates in liquids and gases as well as in solids. However, a solid medium can also support additional types of waves such as shear and Rayleigh or surface waves. Shear or transverse waves have a particle motion that is analogous to what one sees in an oscillating rope. That is, the displacement of the rope is perpendicular to the direction of wave propagation. The velocity of this wave is about half that of compressional waves and is only found in solid media, as indicated in the Appendix. Shear waves are often generated when a longitudinal wave is incident on a fluid–solid interface at angles of incidence other than 90° . Rayleigh or surface waves have elliptical wave motion, as shown in Fig. 18, and penetrate the surface for about one wavelength; therefore, they can be used to detect surface and very near surface flaws. The velocity of Rayleigh waves is about 90% of the shear wave velocity. Their generation requires a special device, or wedge as shown in Fig. 18, which enables an incident ultrasonic wave on the sample at a specific angle that is characteristic of the material (Rayleigh angle). The reader can find more details in the scientific literature.^{57–59}

4.3 Refraction of Sound

The direction of propagation of acoustic waves is governed by the acoustic equivalent of Snell's law. Referring to Fig. 19, the direction of propagation is determined with the equation

$$\frac{\sin \theta_i}{c_I} = \frac{\sin \theta_r}{c_I} = \frac{\sin \gamma_L}{b_I} = \frac{\sin \theta_t}{c_{II}} = \frac{\sin \gamma_T}{b_{II}}$$

where c_I is the velocity of the incident longitudinal wave, c_I and b_I are the velocities of the longitudinal and shear reflected waves, and c_{II} and b_{II} are the velocities of the longitudinal and shear transmitted waves in solid II. In the water–steel interface, there is no reflected shear wave because these waves do not propagate in fluid such as water. In this case, the above relationship is simplified. Since the water has a lower longitudinal wave speed than either the longitudinal or shear wave speeds of the steel, the transmitted acoustic waves are refracted away from the normal. If the incident wave approaches the interface at increasing angles, there will be an angle above which there will be no transmitted acoustic wave in the higher wave speed material. This angle is referred to as a critical angle. At this angle, the refracted wave travels along the interface and does not enter the solid. A computer-generated curve is shown in Fig. 20 in which the normalized acoustic energy that is reflected and refracted at a water–steel interface is plotted as a function of the angle of the incident longitudinal wave. Note that a longitudinal or first critical angle for steel occurs at 14.5° . Likewise, the shear or second critical angle occurs at about 30° . If the angle of incidence is increased above the first critical angle but less than the second critical angle, only the shear wave is generated in the metal and travels at an angle of refraction described by Snell's law. Angles of incidence above the second critical angle produce a complete reflection of the incident acoustic wave; that is, no acoustic energy enters the solid. At a specific angle of incidence (Rayleigh angle) surface

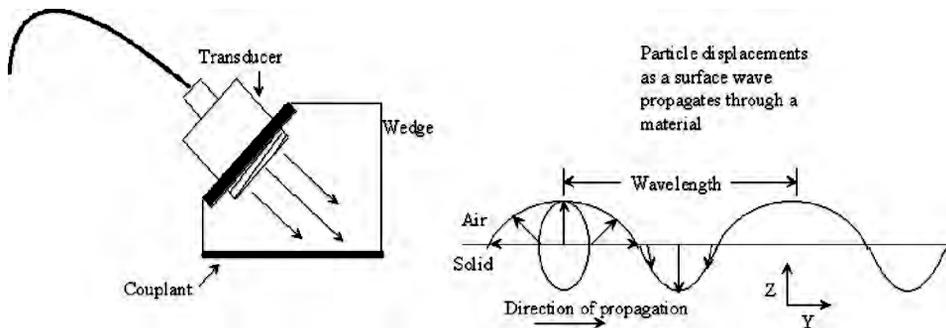

Fig. 18 Generation and propagation of surface waves in a material.

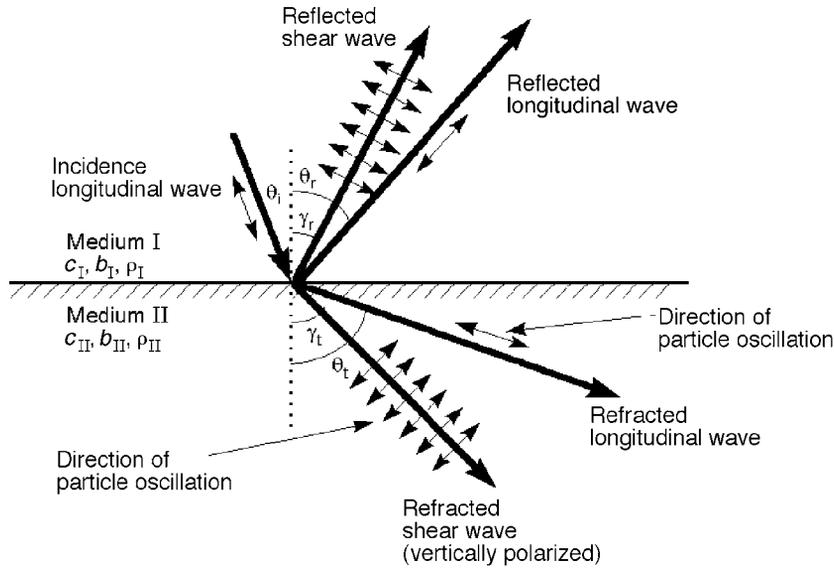

Fig. 19 Representation of Snell's law and mode conversion of longitudinal wave incident on solid–solid interface.

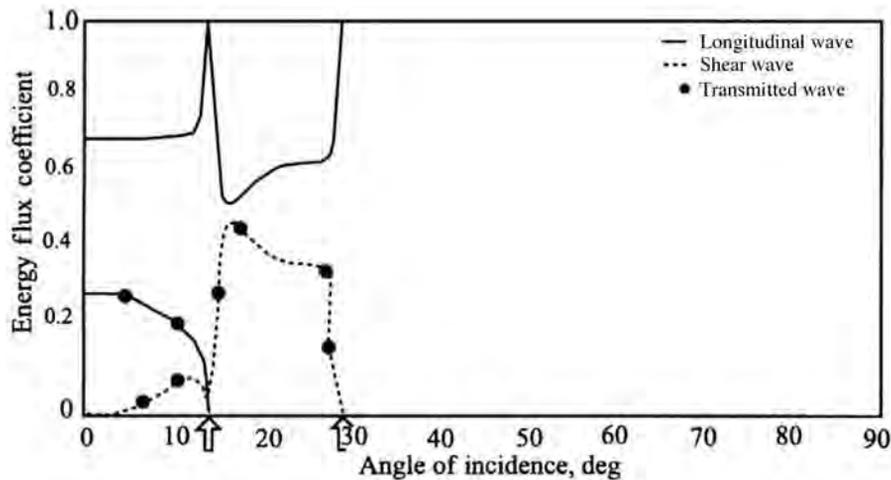

Fig. 20 Amplitude (energy flux) and phase of reflected coefficient and transmitted amplitude versus angle of incidence for longitudinal wave incident on water–steel interface. The arrows indicate the critical angles for the interface.

acoustic waves are generating on the material. The Rayleigh angle can be easily calculated from Snell's law by assuming that the refracted angle is 90° . The Rayleigh angle for steel occurs at 29.5° . In the region between the two critical angles, only the shear wave is generated and is referred to as *shear wave testing*. There are two distinct advantages to inspecting parts with this type of shear wave. First, with only one type of wave present, the ambiguity that would exist

concerning which type of wave is reflected from a defect does not occur. Second, the lower wave speed of the shear wave means that it is easier to resolve distances within the part. For these reasons, shear wave inspection is often chosen for inspection of thin metallic structures such as those in aircraft.

Using the relationships for the reflection and transmission coefficients a great deal of information can be deduced about any ultrasonic inspection situation when

the acoustic wave is incident at 90° to the surface. For other angles of incidence, computer software is often used to analyze the acoustic interactions. Analytic predictions of ultrasonic performance in complex materials such as fiber-reinforced composites require the use of more complex algorithms because more complicated modes of wave propagation can occur. Examples of these include Lamb waves (plate waves), Stoneley waves (interface waves), Love waves (guided in layers of a solid material coated onto another one), and others.

4.4 Inspection Process

Once the type of ultrasonic inspection has been chosen and the optimum experimental parameters determined, one must choose the mode of presentation of the data. If the principal dimension of the flaw is less than the diameter of the transducer, then the A-scan method may be chosen, as shown in Fig. 17. The acquisition of a series of A-scans obtained by scanning the transducer in one direction across the specimen and displaying the data as distance versus depth is referred to as a B scan. This is the mode most often used by medical ultrasound instrumentation. In the A-scan mode, the size of the flaw may be inferred by comparing the amplitude of the defect signal to a set of standard calibration blocks. Each block has a flat bottom hole (FBH) drilled from one end. Calibration blocks have FBH diameters that vary in $\frac{1}{64}$ -in. increments, for example, a number 5 block has a $\frac{5}{64}$ -in. FBH. By comparing the amplitude of the signal from a calibration block with one from a defect, the inspector may specify a defect size as equivalent to a certain size FBH. The equivalent size is meaningful only for smooth flaws that are nearly perpendicular to the path of the ultrasonic beam and is used in many industrial situations where a reference size is required by a UT procedure.

If the flaw size is larger than the transducer diameter, then the C-scan mode is usually selected. In this mode, shown in Fig. 21, the transducer is rastered back

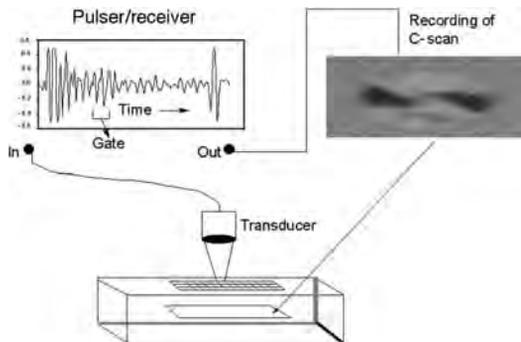

Fig. 21 Representation of ultrasonic data collection. The data are displayed using the C-scan mode. The image shows a defect located at a certain depth in the material.

and forth across the part. In normal operation, a line is traced on a computer monitor or piece of paper. When a flaw signal is detected between the front and back surfaces, the line drawing ceases and a blank place appears on the paper or monitor. Using this mode of presentation, a planar projection of each flaw is presented to the viewer and its positional relationship to other flaws and to the component boundaries is easily ascertained. Unfortunately, the C-scan mode does not show depth information, unless an electronic gate is set to capture only information from within a specific time window or time gate in the part. With current computer capability, it is a rather simple matter to store all of the returning A-scan data and display only the data in a C-scan mode for a specific depth.

Depending on the structural complexity and the attenuation of the signal, cracklike flaws as small as 0.015 in. in diameter may be reliably detected and quantified with this method. An example of a typical C-scan printout of an adhesively bonded test panel is shown in Fig. 22. This panel was fabricated with a void-simulating Teflon implant and the numerous additional white areas indicate the presence of a great deal of porosity in the part.

Through Transmission versus Pulse-Echo

Thus far, the discussion of ultrasonic inspection methods has been concerned with the setup that uses a single transducer to send a signal into the part and to receive any returning echoes. This method is variously referred to as pulse-echo or pitch-catch inspection and is shown schematically in Fig. 23. The other frequently used inspection setup for many structures is called through transmission. With this setup two transducers are used, one to send ultrasonic pulses and the other placed on the opposite side of the part to receive the transmitted signals, as shown schematically in Fig. 24. In Figs. 23 and 24 a large number of reflections occur for the many individual layers in a composite part that can obscure subtle reflections from inclusions whose reflectivity is similar to that of the layered materials. An inclusion with an acoustic impedance very close to that of the part, for example, paper or peel-plys in polymer-based composites, is

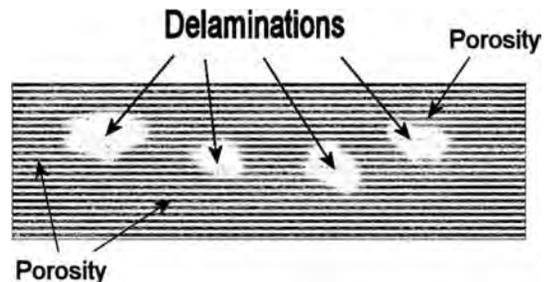

Fig. 22 Typical C-scan image of composite specimen showing delaminations and porosity.

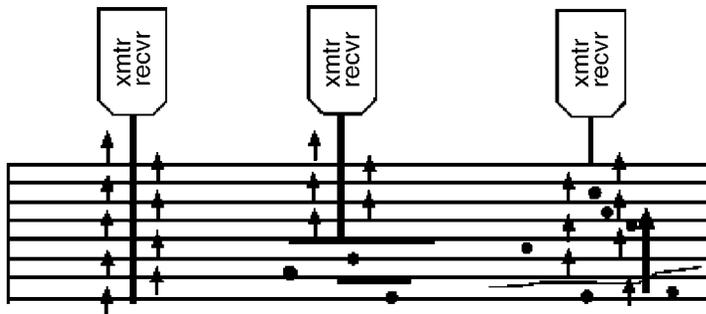

Fig. 23 Representation of pulse-echo mode of ultrasonic inspection.

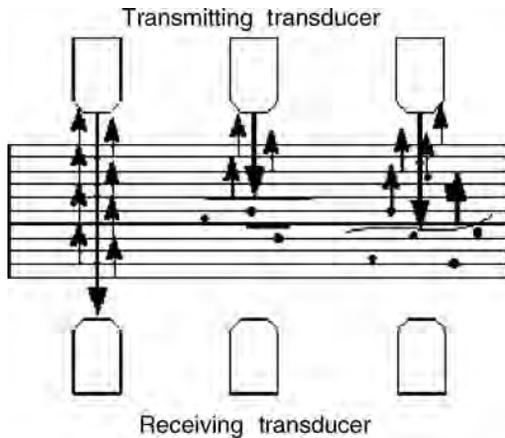

Fig. 24 Representation of through-transmission mode of inspection.

very difficult to detect with the through-transmission mode of inspection. In this case, the pulse-echo inspection mode is often used to detect these flaws. On the other hand, reflection from distributed flaw such as porosity, as shown on the right-hand side of Figs. 23 and 24, can be obscured by the general background noise present in an acoustic signal. Therefore, it is the loss in signal strength of the transmitted signal of the through-transmission method that is most often used to detect this type of flaw. While porosity is detectable in this manner, its location may not be determined. In this situation, the pulse-echo mode is required because the distance from the front or back surface to the flaw can be determined by the relative position of the reflection of the scattered porosity with respect to the surface reflection. Because each method supplies important information about potential flaws and its location, modern ultrasonic instrumentation is frequently equipped to perform both types of inspection nearly simultaneously.^{60,61} In such a setup, two transducers are used to conduct a through-transmission

test and then each is used separately to conduct pulse-echo tests from opposite sides of the part. This method also helps ensure that a large flaw does not shadow a smaller one, as shown in Figs. 23 and 24.

Portable Ultrasonic Systems This ability to image defects on specific levels within a layered component, for example, a composite, is so important that C-scan instrumentation has been miniaturized for usage in the field. An example of one such system developed for aircraft inspection is shown in Fig. 25. The heart of this system is a computer that records the position of a hand-held transducer and the complete A-scan wave train at each point of the scan. Since the equipment tracks the motion of the transducer as it is scanned manually across a structure, the inspector can see which areas have been scanned. If areas are missed, he or she can return to “color them in,” as shown in the image on the monitor. Additionally, computer manipulation of ultrasonic image data allows the inspector to select either one or a small number of layers for evaluation. In this way, an orderly assessment of the flaw in critical structures can be accomplished. This process of selecting flaws on a layer-by-layer basis for evaluation is shown schematically in Fig. 26 for the instrument depicted in Fig. 25.

4.5 Bond Testers

A great deal of the ultrasonic inspection literature is devoted to instruments that test adhesive bonds. There has been a recent resurgence of interest in the inspection of adhesive bonds due to concerns about the viability of bonded patches on our aging aircraft.⁶² For an extensive treatment of most of the currently used instruments, the reader is referred to review articles.⁶³⁻⁶⁷ However, while there may seem to be a large number of instruments, some with exaggerated claims of performance, most operate on the same physical principles.

Bond-testing instruments use a variety of means to excite sonic or low-frequency sound waves into the part. In these methods, a low-frequency acoustic transducer is attached to the structure through a couplant.

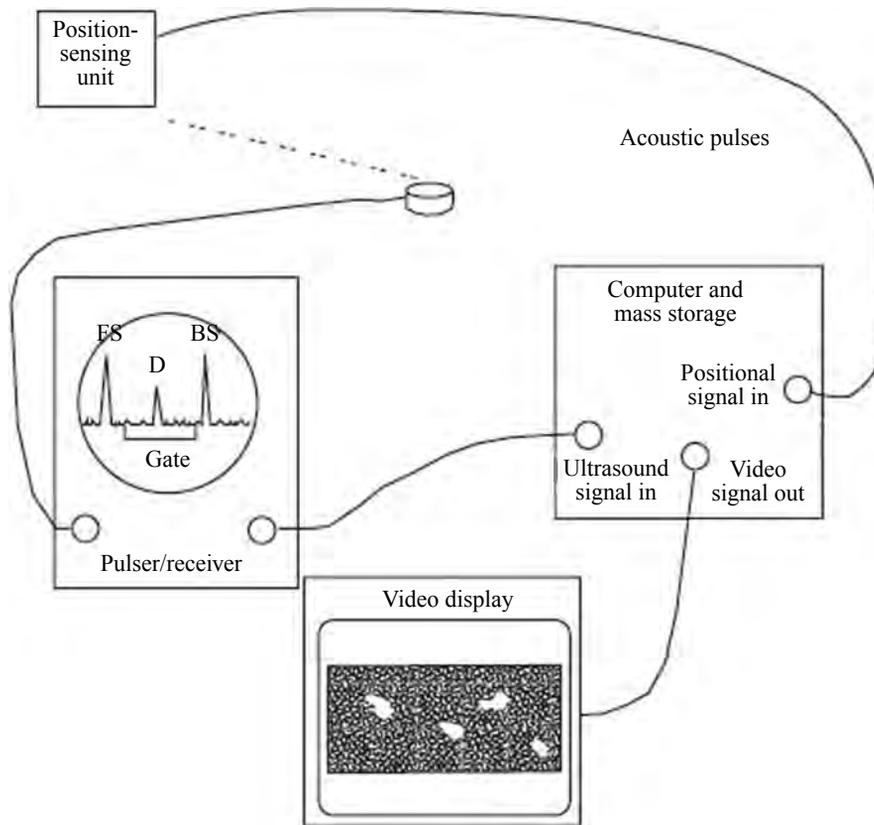

Fig. 25 Field level C-scan instrumentation that is capable of simultaneously tracking the motion of a handheld transducer and recording the ultrasonic information.

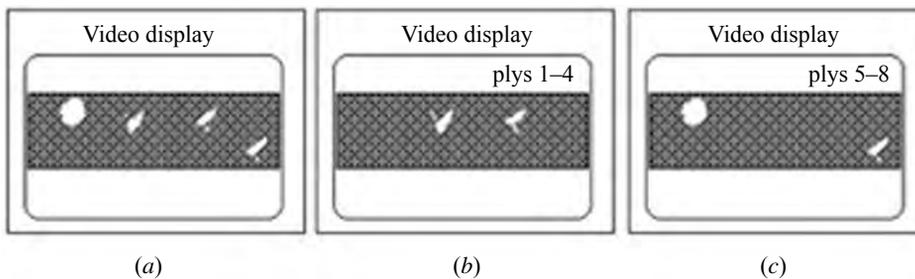

Fig. 26 Three different displays of delaminations in 16-ply composite obtained from field-level C-scan system. (a) Projection of all flaws through specimen. (b, c) Images from selected depths within specimen.

As the driving frequency of the transducer is varied, the amplitude and phase of the transducer oscillations change dramatically as it passes through a resonance. The phase and amplitude of these vibrations change very rapidly and reach a maximum as the driving frequency passes through the resonance frequency of the

transducer. The effect of the structure is to dampen the resonant response of the transducer-block combination because of the transfer of acoustic energy into it. Defects such as delaminations and porosity in the adhesive bond layer increase the stiffness of the structure and lower the resonant frequency of the combination.

The amplitude of the resonance is increased since there is less material to adsorb the sound energy. These changes in the sharpness of the resonant response are easily detectable electronically.

An alternate method of detecting flaws in bonded components is with a low-frequency or sonic instrument that senses the change in the time of flight for sound waves in the layered structure due to the presence of planar delamination. In such instruments, the increased time of traveling from a transmitting to a receiving transducer is detected electronically. Several commercially available bond-testing instruments successfully exploit this principle. A clever adaptation of a commercial version of this instrument has recently been used to successfully test the joints of structures made from sheet molding compounds.⁶⁴

Probably the most often used method of detecting delaminations in laminated structures is with a coin or tap hammer. This simple instrument is surprisingly effective in trained hands at detecting flaws since an exceedingly complex computer interprets the output signal, that is, the human brain. Consider, for a moment, that most parents can easily hear their child playing a musical instrument at a school concert. They can perform this task even though their child may have a minor part to play and all the other instruments are much louder than the one that their child is playing. With this powerful real-time signal-processing capability, inspectors can often detect flaws that cannot be detectable with current instrumentation and computers.

5 MAGNETIC PARTICLE METHOD

The magnetic particle method of nondestructive testing is used to locate surface and subsurface discontinuities in ferromagnetic materials.⁶⁸ An excellent reference for this NDE method is Ref. 21, especially Chapters 10–16. Magnetic particle inspection is based on the principle that magnetic lines of force, when present in a ferromagnetic material, are distorted by changes in material continuity, such as cracks or inclusions, as shown schematically in Fig. 27. If the flaw is open to the surface or close to it, the flux lines escape the surface at the site of the discontinuity. Near-surface flaws such as nonmagnetic inclusions, cause the same bulging of the lines of force above the surface. These distorted fields usually referred to as a leakage field, reveals the presence of the discontinuity when fine magnetic particles are attracted to them during magnetic particle inspection. If these particles are fluorescent, their presence at a flaw will be visible under ultraviolet light, much like penetrant indications.

Fig. 27 Representation of magnetic lines of flux in ferromagnetic metal near a flaw. Small magnetic particles are attracted to the leakage field associated with the flaw.

Magnetic particle inspection is used for steel components because it is fast and easily implemented and has rather simple flow indications. The part is usually magnetized with an electric current and then a solution containing fluorescent particles is applied by flowing it over the part. The particles stick to the part, forming the indication of the flaw

5.1 Magnetizing Field

The magnetizing field may be applied to a component by a number of methods. Its function is to generate a residual magnetic field at the surface of the part. The application of a magnetizing force (H) generates a magnetic flux (B) in the component, as shown schematically in Fig. 28. In this figure the magnetic flux density B has units of newtons per ampere or webers per square meter, and the strength of the magnetic field or magnetic flux intensity H has units of oersteds or amperes per meter. Starting at the origin, a magnetizing force is applied and the magnetic field internal to the part increases in a nonlinear fashion along the path shown by the arrows. If the force is reversed, the magnetic field does not return to zero but follows the arrows around the curve as shown. The reader will note that once the magnetizing force is removed, the flux density does not return to zero but remains at an elevated value called the material's remanence. This is the point at which most magnetic particle inspections are performed. The reader will also note that an appreciable reverse magnetic force H must be applied before the internal field density is again zero. This point is referred to as the coercivity of the material. If the magnetizing force is applied and reversed, the material will respond by continually moving around this hysteresis loop.

Selection of the type of magnetizing current depends primarily on whether the defects are open to the surface or are wholly below it. Alternating-current (ac) magnetization is best for the detection of surface discontinuities because the current is concentrated in the near-surface region of the part. Direct-current (dc) magnetization is best suited for subsurface discontinuities because of its deeper penetration of the part. While dc can be obtained from batteries or dc generators, it is usually produced by half-wave or full-wave rectification of commercial power. Rectified current is classified as half-wave direct current (HWDC) or full-wave direct current (FWDC). Alternating-current fields are usually obtained from conventional power mains, but it is supplied to the part at reduced voltage for

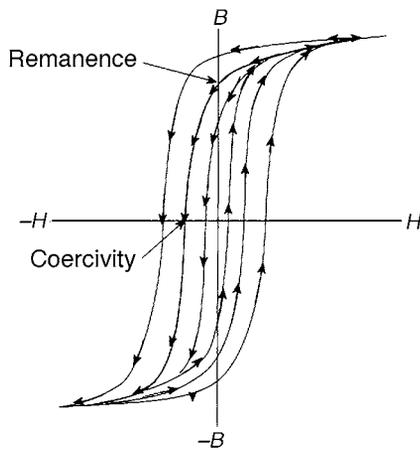

Fig. 28 Magnetic flux intensity H versus magnetic flux density B hysteresis curve for typical steel. Initial magnetization starts at the origin and progresses as shown by the arrows. Demagnetization follows the arrows of the smaller hysteresis loops.

reasons of safety and the high-current requirements of the magnetizing process.

Two general types of magnetic particles are available to highlight flaws. One type is low-carbon steel with high-permeability and low-retentivity particles, which are used dry and consist of different sizes and shapes to respond to leakage fields. The other type of is very fine particles of magnetic iron oxide that are suspended in a liquid (either a petroleum distillate or water). These particles are smaller and have a lower permeability than the dry particles. Their small mass permits them to be held by the weak leakage fields at very fine surface cracks. Magnetic particles are available in several colors to increase their contrast against different surfaces or backgrounds. Dry powders are typically gray, red, yellow, and black, while wet particles are usually red, black, or fluorescent.

5.2 Continuous versus Noncontinuous Fields

Because the field is always stronger while the magnetizing current is on, the continuous magnetizing method is generally preferred. Additionally, for specimens with low retentivity this continuous method is often preferred. In the continuous method, the current can be applied in short pulses, typically 0.5 sec. The magnetic particles are applied to the surface during this interval and are free to move to the site of the leakage fields. Liquid suspended fluorescent particles produces the most sensitive indications. For field inspections, the magnetizing current is often continuously applied during the test to give time for the powder to migrate to the defect site. In the residual method, the particles are applied after the magnetizing current is removed. This method is particularly well suited for production inspection of multiple parts.

The choice of direction of the magnetizing field within the part involves the nature of the flaw and its direction with respect to the surface and the major axis of the part. In circular magnetization, the field runs circumferentially around the part. It is induced into the part by passing current through it between two contacting electrodes. Since flaws perpendicular to the magnetizing lines are readily detectable, circular magnetization is used to detect flaws that are parallel or less than 45° to the surface of the long, circular specimens. Placing the specimen inside a coil to create a field running lengthwise through the part produces longitudinal magnetization. This induction method is used to detect transverse discontinuities to the axis of the part.

5.3 Inspection Process

The surface of the part to be examined should be clean, dry, and free of contaminants such as oil, grease, loose rust, loose sand, loose scale, lint, thick paint, welding flux and weld spatter. Cleaning of the specimen may be accomplished with detergents, organic solvents, or mechanical means, such as scrubbing or grit blasting.

Portable and stationary equipment are available for this inspection process. Selection of the specific type of equipment depends on the nature and location of testing. Portable equipment is available in lightweight units (35–90 lb) that can be readily taken to the inspection site. Generally, these units operate at 115, 230, or 460 V ac and supply current outputs of 750–1500 A in half-wave ac.

5.4 Demagnetizing the Part

Once the inspection process is complete, the part must be demagnetized. This is done by one of several ways depending on the subsequent usage of the component. A simple method of demagnetizing to remove residual magnetism from small tools is to draw it through the loop-shaped coil tip of a soldering iron. This has the effect of retracing the hysteresis loop a large number of times, each time with a smaller magnetizing force. When completely withdrawn, the tool will then have a very small remnant magnetic field which for all practical purposes is zero. This same process is accomplished with an industrial part by slowly reducing and reversing the magnetizing current until it is essentially zero, as shown schematically by the arrows in Fig. 28. Another method of demagnetizing a part is to heat it above its Curie temperature (about 550°C for iron), at which point all residual magnetism disappears. This last process is the best means of removing all residual magnetism, but it requires the expense and time of an elevated heat treatment.

6 THERMAL METHODS

Thermal nondestructive inspection methods involve the detection of infrared energy emitted from the surface of a test object.⁶⁹ This technique is used to detect

the flow of thermal energy either into or out of a specimen and the effect of anomalies have on the surface temperature distribution. The material properties that influence this method are heat capacity, density, thermal conductivity, and emissivity. Defects that are usually detected include porosity, cracks, and delaminations that are parallel to the surface. The sensitivity of any thermal method is greatest for near-surface flaws that impede heat flow and degrades rapidly for deeply buried flaws in high-conductivity materials. Materials with lower thermal conductivity yield better resolution because they allow larger thermal gradients.

6.1 Infrared Cameras

All objects emit infrared (IR) radiation with a temperature above absolute zero. At room temperature, the thermal radiation is predominately IR with a wavelength of approximately $10\ \mu\text{m}$. IR cameras are available that can produce images from this radiation and are capable of viewing large areas by scanning. Since the IR images are usually captured and stored in digital form, image processing is easily performed and the enhanced images are stored on magnetic or optical media. For many applications, an uncalibrated thermal image of a specimen is sufficient to detect flaws. However, if absolute temperatures are required, the IR instrumentation must be calibrated to account for the surface emissivity of the test subject.

The ability of thermography to detect flaws is often affected by the type of flaw and its orientation with respect to the surface of the object. To have a maximum effect on the surface temperature, the flaw must interrupt heat flow to the surface. Since a flaw can occur at any angle to the surface, the important parameter is its projected area to the camera. Subsurface flaws such as cracks parallel to the surface of the object, porosity, and debonding of a surface layer are easily detected. Cracks that are perpendicular to the surface can be very difficult or impossible to detect using thermography.

Most thermal NDE methods do not have good spatial resolution due to spreading of thermal energy as it diffuses to the surface. The greatest advantage of thermography is that it can be a noncontact, remote-viewing technique requiring only line-of-sight access to one side of a test specimen. Large areas can be viewed rapidly, since scan rates for IR cameras run between 16 and 30 frames per second. Temperature differences of 0.02°C or less can be detected in a controlled environment.

6.2 Thermal Paints

A number of contact thermal methods are available for inspection purposes. These usually involve applying a coating to the sample and observing a color change as the specimen is thermally cycled. Several different types of coatings are available that cover a wide temperature ranges. Temperature-sensitive pigments in the form of paints have been made to cover a temperature

range of $40\text{--}1600^\circ\text{C}$. Thermal phosphors emit visible light when exposed to ultraviolet (UV) radiation. (The amount of visible light is inversely proportional to temperature.) Thermochromic compounds and cholesteric liquid crystals change color over large temperature ranges. The advantages of these approaches are the simplicity of application and relatively low cost if only small areas are scanned.

6.3 Thermal Testing

Excellent results may be achieved for thermographic inspections performed in dynamic environments where the transient effects of heat flow in the test object can be monitored. This enhances detection of areas where different heat transfer rates are present. Applications involving steady-state conditions are more limited. Thermography has been successfully used in several different areas of testing. In medicine, it is used to detect subsurface tumors. In aircraft manufacturing and maintenance, it may be used to detect debonding in layered materials and structures. In the electronics industry, it is used to detect poor thermal performance of circuit board components. Recently thermography has been used to detect stress-induced thermal gradients around defects in dynamically loaded test samples. For more information on thermal NDE methods, the reader is referred to Refs. 69–71.

7 EDDY CURRENT METHODS

7.1 Eddy Current Inspection

Eddy current (EC) methods are used to inspect electrically conducting components for flaws. Flaws that cause a change in electrical conductivity or magnetic permeability such as surface-breaking cracks, subsurface cracks, voids, and errors in heat treatment are detectable using EC methods. Thickness measurements and the thickness of nonconducting coatings on metal substrates can also be determined with EC methods.⁷² Quite often, several of these conditions can be monitored simultaneously if instrumentation capable of measuring the phase of the EC signal is used.

This inspection method is based on the principle that eddy currents are induced in a conducting material when a coil (probe) is excited with an alternating or transient electric current that is placed in close proximity to the surface of a conductor. The induced currents create an electromagnetic field that opposes the field of the inducing coil in accordance with Lenz's law. The eddy currents circulate in the part in closed, continuous paths, and their magnitude depends on many variables. These include the magnitude and frequency of the current in the inducing coil, the coil's shape and position relative to the surface of the part, electrical conductivity, magnetic permeability, shape of the part, and presence of discontinuities or inhomogeneities within the material. Therefore, EC inspection is useful for measuring the electrical properties of materials and detecting discontinuities or variations in the geometry of components.

Skin Effect Eddy current inspections are limited to the near-surface region of the conductor by the skin effect. Within the material, the EC density decreases with the depth. The density of the EC field falls off exponentially with depth and diminishes to a value of about 37% of the surface value at a depth referred to as the standard depth of penetration (SDP). The SDP in meters is calculated with the formula

$$SDP = \frac{1}{\sqrt{\pi f \sigma \mu}}$$

where f = test frequency, Hz
 σ = test material's electrical conductivity, mho/m
 μ = permeability, H/m

The latter quantity is the product of the relative permeability of the specimen, 1.0 for nonmagnetic materials, and the permeability of free space, $4\pi \times 10^{-7}$ H/m.

Impedance Plane While the SDP is used to give an indication of the depth from which useful information can be obtained, the choice of the independent variables in most test situations is usually made using the impedance plane diagram suggested by Förster.⁷³ It is theoretically possible to calculate the optimum inspection parameters from numerical codes based on Maxwell's equations, but this is a laborious task that is justified in special situations.

The eddy currents induced at the surface of a material are time varying and have amplitude and phase. The complex impedance of the coil used in the inspection of a specimen is a function of a number of variables. The effect of changes in these variables can be conveniently displayed with the impedance diagram, which shows the variations in amplitude and phase of the coil impedance as functions of the dependent variables specimen conductivity, thickness, and distance between the coil and specimen, or lift-off. For the case of an encircling coil on a solid cylinder, shown schematically in Fig. 29, the complex impedance plane is displayed in Fig. 30. The reader will note that the ordinate and abscissa are normalized by the inductive reactance of the empty coil. This eliminates the effect of the geometry of the coil and specimen. The numerical values shown on the large curve, which are called reference numbers, are used to combine the effects of the conductivity, size of the test specimen, and frequency of the measurement into a single parameter. This yields a diagram that is useful for most test conditions. The reference numbers shown on the outermost curve are obtained with the following relationship for nonmagnetic materials:

$$\text{Reference number} = r\sqrt{2\pi f \mu \sigma}$$

where r = radius of bar, m
 f = frequency of test, Hz
 m = magnetic permeability of free space, $4\pi \times 10^{-7}$ H/m
 σ = conductivity of specimen, mho/m

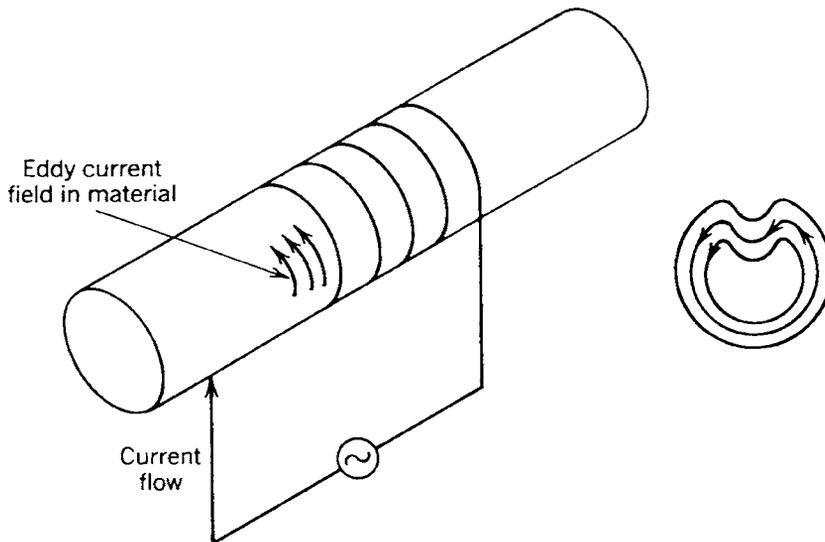

Fig. 29 Representations of eddy current inspection of solid cylinder. Also shown are the eddy current paths within the cross section of the cylinder near the crack.

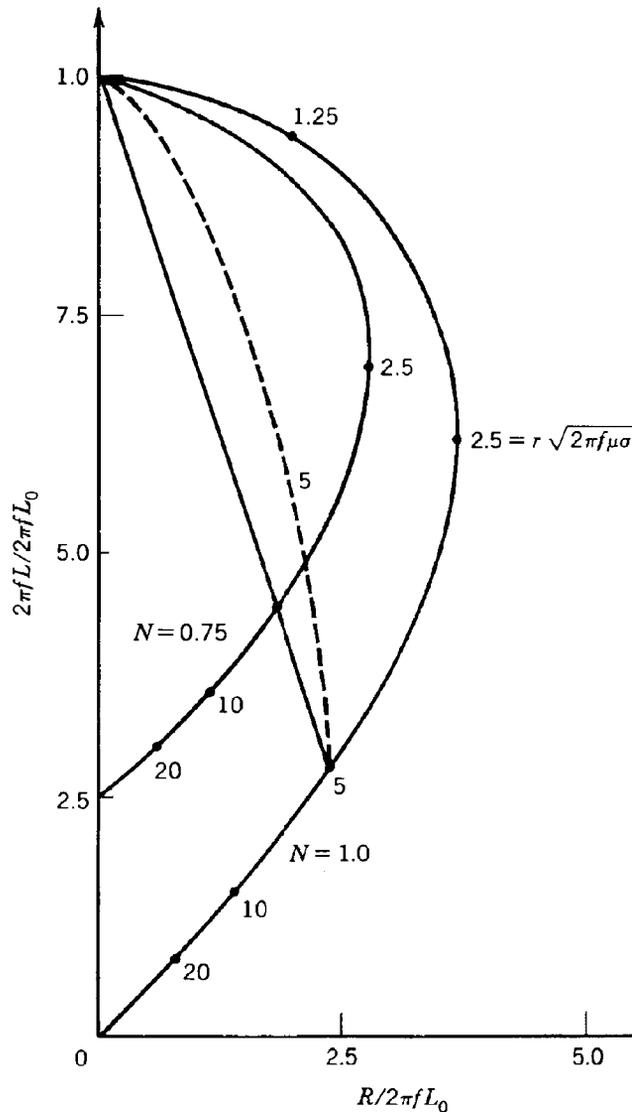

Fig. 30 Normalized impedance diagram for long encircling coil on solid, nonferromagnetic cylinder. For $N = 1$ the coil and cylinder have the same diameter, while for $N = 0.75$ the coil is approximately 1.155 times larger than the cylinder.

The outer curve in Figs. 30 and 31 is useful only for the case where the coil is the same size as the solid cylinder, which can never happen. For those cases where the coil is larger than the test specimen, which is usually the case, a coil-fillin factor is calculated. This is quite easily accomplished with the formula

$$N = \frac{\text{diameter}_{\text{specimen}}}{\text{diameter}_{\text{coil}}}$$

Figure 30 shows the impedance plane with a curve for specimen/coil inspection geometry with a fill factor of 0.75. Note that the reference numbers on the curves representing the different fill factors can be determined by projecting a straight line from point 1.0 on the ordinate to the reference number of interest, as is shown for the reference number 5.0. Both the fill factor and the reference number change when the size of either the specimen or coil changes. Assume that a reference number of 5.0 is appropriate to a specific test with $N = 1.0$; if the coil diameter is changed so that

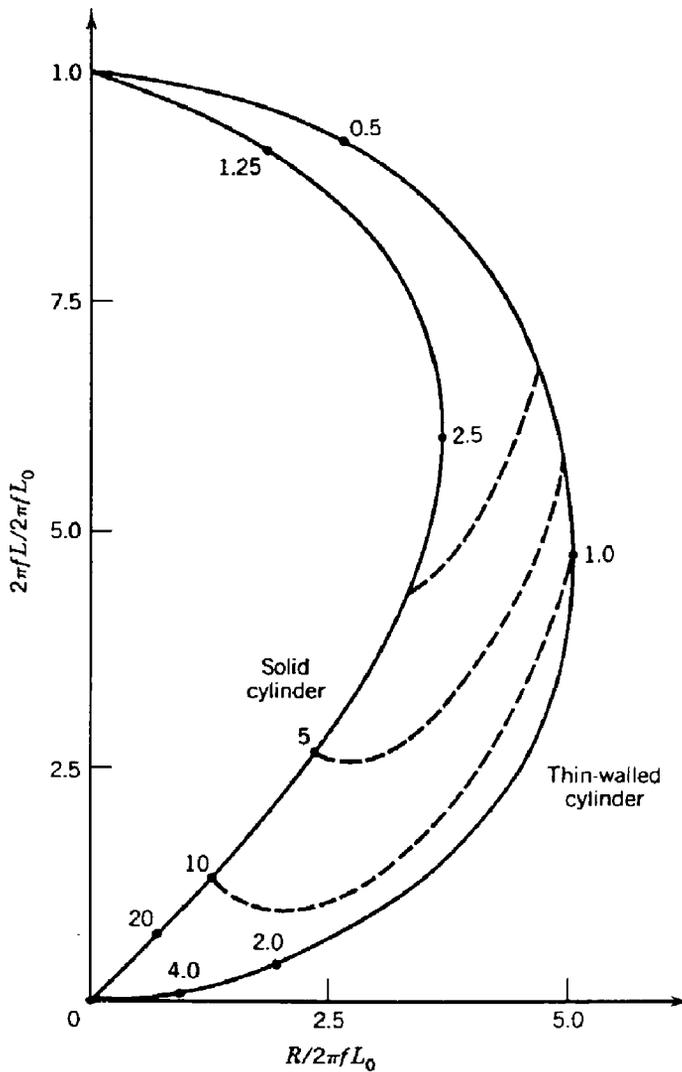

Fig. 31 Normalized impedance diagram for long encircling coil on both solid and thin-walled conductive but nonferromagnetic cylinders. The dashed lines represent the effects of varying wall thicknesses.

the fill factor becomes 0.75, then the new reference number will be equal to approximately 7. While the actual change in reference number for this case follows the path indicated by the dashed line in Fig. 30, we have estimated the change along a straight line. This yields a small error in optimizing the test setup but is sufficient for most purposes. For a more detailed treatment of the impedance plane, the reader is referred to Ref. 72. The inspection geometry discussed thus far has been for a solid cylinder. The other geometry of general interest is the thin-walled tube. In this case the

skin effect limits the thickness of the metal that may be effectively inspected.

For an infinitesimal thin-walled tube, the impedance plane is shown in Fig. 31, which includes the curve for a solid cylinder. The dashed lines that connect these two cases are for thin-walled cylinders of varying thicknesses. The semicircular curve for the thin cylinder is used in the same manner as described above for the solid cylinder.

Lift-off of Inspection Coil from Specimen In most inspection situations, the only independent

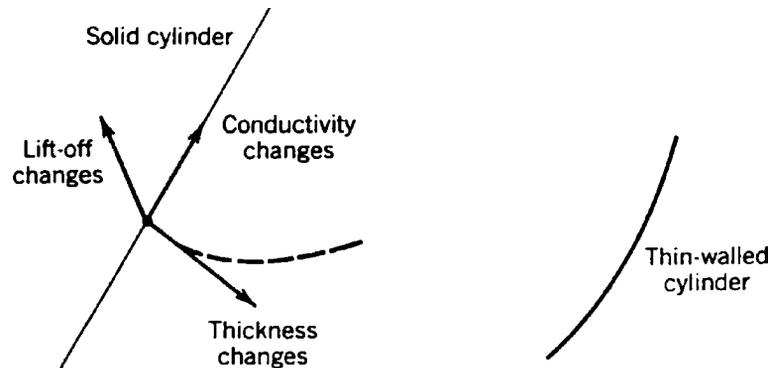

Fig. 32 Effects of various changes in inspection conditions on local signal changes in impedance plane of Figure 31. Phase differentiation is relatively easily accomplished with current instrumentation.

variables are frequency and lift-off. High-frequency excitations are frequently used for detecting defects such as surface-connected cracks or corrosion, while low frequencies are used to detect subsurface flaws. It is also possible to change the coil shape and measurement configuration to enhance detectability, but the discussion of these more complex parameters is beyond the scope of this chapter and the reader is referred to the literature. The relationships discussed so far may be applied by examining Fig. 32, where changes in thickness, lift-off, and conductivity are represented by vectors. These vectors all point in different directions representing the phases of the different possible signals. Instrumentation with phase discrimination circuitry can differentiate between these signals and therefore is often capable of detecting two changes in specimen condition at once. Changes in conductivity can arise from several different conditions. For example, aluminum alloys can have different conductivities depending on their heat treatment. Changes in apparent conductivity are also due to the presence of cracks or voids. A crack decreases the apparent conductivity of the specimen because the eddy currents must travel a longer distance to complete their circuit within the material. Lift-off and wall thinning are also shown in Fig. 32. Thus, two different flaw conditions can be rapidly detected. There are situations where changes in wall thickness and lift-off result in signals that are very nearly out of phase and therefore the net change is not detectable. If this situation is suspected, then inspection at two different frequencies is warranted. There are other inspection situations that cannot be covered in this brief description. These include the inspection of ferromagnetic alloys, plate, and sheet stock and the measurement of film thicknesses on metal substrates. For a treatment of

these and other special applications of EC inspection, the reader is referred to Ref. 72.

7.2 Probes and Sensors

In some situations, it may be advantageous to have a core with a high magnetic permeability inside the coil. Magnetic field will pass through the medium with the highest permeability if possible. Therefore, materials with high permeability can be placed in different geometric configuration to enhance the sensitivity of a probe. One example of this is the cup-core probe where the coil has a ferrite core, shield, and cap.⁷⁴

For low-frequency or transient tests, using the inductive coil as a sensor is not sufficient since it responds to the time change in magnetic field and not the direct magnetic field. It is necessary to induce a magnetic field sensor that responds well at the lower frequencies. Sensors such as the Hall effect sensor and giant magnetoresistive (GMR) sensors have been used to accomplish this.⁷⁵

There are numerous methods of making eddy current NDE measurements. Two of the more common methods are shown schematically in Fig. 33. In the absolute coil arrangement, very accurate measurements can be made of the differences between the two samples. In the differential coil method, it is the differences between the two variables at two slightly different locations that may be detected. For this arrangement, slightly varying changes in dimensions and conductivity are not sensed, while singularities such as cracks or voids are highlighted, even in the presence of other slowly changing variables. Since the specific electronic circuitry used to accomplish this task can vary dramatically, depending on the specific inspection situation, the reader is referred to the current NDE and instrumentation Refs. 73, 76, and 77.

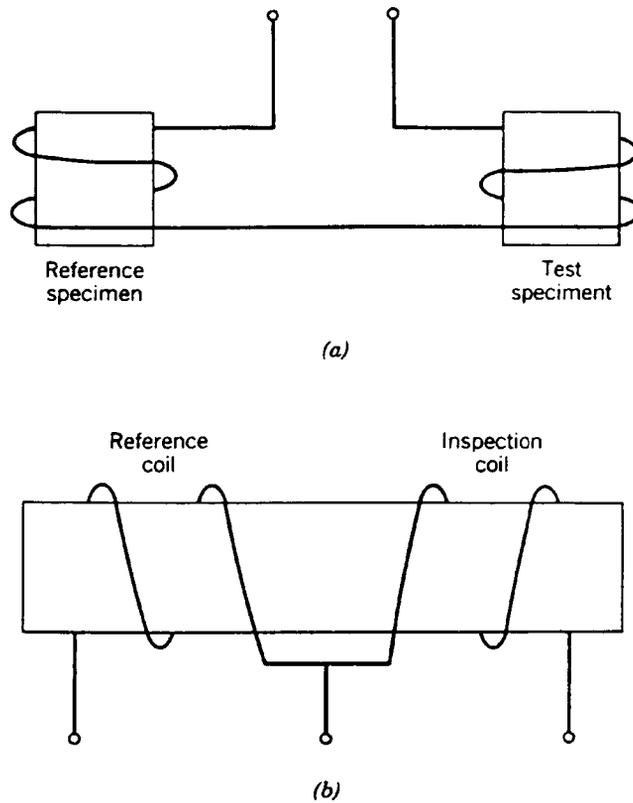

Fig. 33 Representation of (a) absolute versus (b) differential coil configurations used in eddy current testing.

1 INTRODUCTION

We experience and interact with fluids such as air, water, oil, and gas, in many aspects of our daily life. These fluids can be categorized in different ways depending on the level of analysis required. An obvious first categorization is that they can be viewed as liquid or gas; but they can be classified depending on their behavior in a particular application as well. Some common fluid classifications are viscous or inviscid, compressible or incompressible, laminar or turbulent, Newtonian or non-Newtonian, and steady or unsteady. These classifications are sometimes idealizations (approximations) and sometimes exact descriptions. Overall, they offer information on fluid properties and characteristics, the state of the flow field and how to approach an engineering solution to the relevant flow problem. This chapter will cover the basics on many of these classifications but will primarily restrict a bulk of the discussion to the category of Newtonian incompressible fluids.

All substances are compressible to some extent and fluids are no exception. However, in many cases, fluids may be treated as incompressible without introducing unacceptable inaccuracies in either computations or measurements. In the case of liquids, the vast majority of problems may be addressed as incompressible flow problems. Even in situations where pressure changes are significant enough to cause small changes in density (water hammer), incompressible flow techniques are applied to solve problems. For gases where flow velocities are low compared to the local speed of sound (low Mach number) or where density changes in the system are small, incompressible flow theory may be used to good approximation.

1.1 Definition of a Fluid

A *fluid*, which can be a liquid or gas, is defined as a collection of molecules of a substance (or several substances) that cannot support a shearing stress of any size (magnitude) without undergoing permanent and continual angular deformation. Even though the fluid is a collection of molecules, it is generally considered to be a continuous substance without voids, referred to as a continuum (typical liquid has on the order of 10^{21} molecules/mm³). Newtonian fluids are those whose rate of angular deformation is linear with respect to the magnitude of the deforming shear stress. Most common liquids and gases are Newtonian fluids (e.g., air, water, oil). Non-Newtonian fluids are those whose rate of angular deformation bears a nonlinear relationship to the applied shear stress. Examples of non-Newtonian fluids are blood, paints, and suspensions.

1.2 System of Units and Dimension

The scientific world is in the midst of a conversion from various systems of units to SI (Système International d'Unités) units. However, the English FSS

(foot-slug-second) system is still in widespread use throughout the United States. Hence, this work will use both the English system of units as well as the SI equivalent in the text, tables, and numerical examples. Table 1 provides the units used to identify the basic dimensional quantities in each system, and Table 2 gives a conversion table for fluid properties and other commonly used quantities.

2 FLUID PROPERTIES

Properties of fluids generally encountered in engineering practice are presented in tables and figures in this section. Included are the commonly used properties of density, specific gravity, bulk modulus (compressibility), viscosity, surface tension, and vapor pressure.

2.1 Density, Specific Weight, and Specific Gravity

Density is defined as the mass per unit volume ρ . Table 3 provides values for a selection of liquids at standard atmospheric pressure (14.7 lb/in.² or 101325 Pa), and Table 4 provides properties of some common gases. Density varies with temperature and pressure, but for liquids, variation with pressure is generally negligible. Also included in these tables are the specific weight γ , which is the density multiplied by the gravitational acceleration, which produces a measure of weight per unit volume (pounds per cubic foot or newtons per cubic meter).

For a gas, the density depends heavily on the pressure and temperature. Most gases closely follow the ideal gas equation of state

$$\rho = \frac{p}{RT} \quad (1)$$

where p is the absolute pressure, T is the absolute temperature, and R is the specific gas constant. This equation should be used with discretion under conditions of very high temperature or very low pressure or when the gas approaches a liquid. Because all gases at the same temperature and pressure contain the same number of molecules per unit volume (Avogadro's law), the specific gas constant can be calculated to good accuracy by dividing the universal gas constant, 8314 J/mol-K, by the molecular weight of the gas. For example, oxygen has the molecular weight of 32 kg/mol. The specific gas constant of oxygen is calculated as $R = 8314/32 = 259.8$ J/kg-K (compare with Table 4).

Another widely used fluid property is the specific gravity, SG, which is defined as the ratio of the fluid density to the density of water at a specific temperature (typically 39.2°F, or 4°C, which gives a density of water as 1.94 slugs/ft³ or 1000 kg/m³). So the specific gravity can be found from

$$SG = \frac{\rho}{\rho_{\text{water}}} \quad (2)$$

Table 1 Basic Dimensions and Abbreviations in English and SI Units

<i>Abbreviations</i>		
BTU = British thermal unit		m = meter (SI) = mile (FSS)
cfs = cubic feet per second		mb = millibar = 10^{-3} bar
fps. ft/sec = feet per second		mm = millimeter = 10^{-3} meter
ft = foot		mm ² = square millimeter
gpm = gallons per minute		mph = miles per hour
hp = horsepower		mps, m/s = meters per second
hr, h = hour		N = newton
Hz = hertz		Pa = pascal = N/m ²
in. = inch		psi = pounds per square inch
J = joule = N-m		sec, s = second
kg = kilogram = 10^3 grams		W = watt = J/s
lb = pound force		
<i>Units</i>		
Quantity	SI Unit Name (Symbol)	FSS Unit Name (Symbol)
<i>Basic units</i>		
Length	Meter (m)	Foot (ft)
Mass	Kilogram (kg)	Slug (slug)
Time	Second (s)	Second (sec)
Temperature	Kelvin (K) [Celsius (°C)]	Rankine (°R) [Fahrenheit (°F)]
<i>Derived units</i>		
Energy	Joule (J)	Foot-pound (ft-lb)
Force	Newton (N)	Pound (lb)
Frequency	Hertz (Hz)	Hertz (Hz)
Power	Watt (W)	Horsepower (hp)
Pressure	Pascal (Pa)	—

Source: From Ref. 1.

This provides a direct measure of whether the fluid is less dense or more dense than water and by what degree; for example, the specific gravity of mercury is 13.6, so it is 13.6 times denser than water.

2.2 Compressibility

The *compressibility* of fluid is confined to their behavior in the mode of compression. The definition of the bulk modulus of elasticity stems from the relative change in volume and provides a measure of the compressibility of a fluid:

$$E_v = -\frac{\Delta p}{\Delta V/V} \quad (3)$$

where Δp is the pressure increment which causes a relative decrease in volume, $\Delta V/V$. The E_v value has the dimensions of pressure, and it depends on

the pressure and temperature of a liquid. For a gas, the E_v value depends on the thermodynamic process governing the change in volume resulting from the pressure increment. For example, if the process is isentropic, $E_v = kp$, where k is the ratio of the specific heats given in Table 4. If the process is isothermal, $E_v = p$. Values of E_v for a variety of liquids at standard temperature and pressure are given in Table 3.

As expected, the values of E_v for liquids are large, which indicates the fluid can be considered incompressible. Figure 1 is provided to demonstrate the variation of E_v with pressure for pure water. Entrained gas in a liquid can drastically affect the E_v value; Fig. 2 illustrates the effect of entrained air on the compressibility of water for relatively small amounts of air.

One of the common applications of the property of fluid compressibility is in the computation of the acoustic wave speed (speed of sound) in a fluid. The

Table 2 Conversion Factors for English FSS and SI Units

Absolute viscosity: 1 slug/ft-sec = 1 lb-sec/ft ² = 47.88 N-s/m ² = 47.88 kg/m-s = 478.8 P	
Acceleration due to gravity: 32.174 ft/sec ² = 9.80665 m/s ²	
Area: 1 ft ² = 0.0929 m ²	
1 in. ² = 645.2 mm ²	
Density: 1 slug/ft ³ = 515.4 kg/m ³

1 ft = 0.3048 m	
1 mile = 1.609 km	
Mass: 1 slug = 14.59 kg	
Power: 1 ft-lb/sec = 1.356 W = 1.356 J/s	
1 hp = 550 ft-lb/sec = 745.7 W	
Pressure: 1 psi = 6895 N/m ² = 6895 Pa	1 atm = 14.70 psi
1 in. Hg = 25.4 mm Hg = 3386 N/m ²	= 29.92 in. Hg = 760 mm Hg
1 in. H ₂ O = 249.1 N/m ²	= 101.325 kN/m ²
1 lb/ft ² = 47.88 N/m ² = 47.88 Pa = 0.4788 mb	1 bar = 14.504 psi
	= 10 ⁵ N/m ² = 100 kN/m ²
Specific heat, engineering gas constant: 1 ft-lb/slug °R = 0.1672 Nm/kg °K	
Specific weight: 1 lb/ft ³ = 157.1 N/m ³	
Temperature: 1°C = 1 K = 1.8°F = 1.8°R	
Velocity: 1 fps = 0.3048 mps = 0.3048 m/s	
1 mph = 1.609 km/h = 0.447/m/s	
1 knot = 1.152 mph = 1.689 fps = 0.5155 m/s	
Volume: 1 ft ³ = 0.02832 m ³	
1 U.S. gallon = 0.1337 ft ³ = 0.003785 m ³ = 3.785 liters	

Source: From Ref. 1.

equation applicable to both liquids and gases is

$$a = \sqrt{\frac{E_v}{\rho}} \quad (4)$$

where a is the acoustic wave speed. The value of E_v is obtained from a table (e.g., Table 3) or, in the case of gases, computed using the isentropic thermodynamic process. For reference, the speed of sound is much higher in water than in air.

2.3 Viscosity

Viscosity is a fluid's resistance to angular deformation under action of a shearing stress. It is a measure of how easy or difficult a fluid "flows. For example, pancake

syrup has a higher viscosity than water. Viscosity is a property that changes according to the thermodynamic conditions; thus, it strongly depends on temperature but is relatively unaffected by pressure.

In liquids, viscosity depends on the strength of cohesive forces between fluid molecules; hence an increase in temperature results in a decrease in viscosity. For gases, viscosity depends on the momentum exchange between layers of gas moving at different velocities. An increase in temperature provides an increase in molecular activity and an increase in viscosity.

All real fluid have some level of viscosity. However, for certain types of flows or specific regions of the flow field it is sometimes reasonable to assume that the effects of viscosity are negligible. In these cases, the flow is classified as inviscid and the viscosity is set

to zero. If the flow cannot be assumed inviscid, then you must account for the effects of viscosity.

A fundamental device for measuring fluid viscosity leads to the definition of viscosity. Figure 3 illustrates the flow situation occurring when a moving plate, under the action of a shearing force, slides over a fixed plate separated by a fluid. If the movement is sufficiently slow so that the flow between the plates

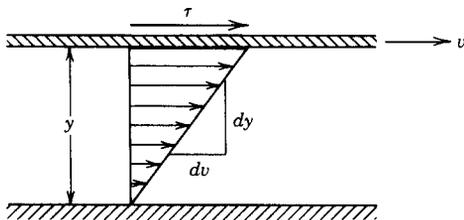

Fig. 3 Definition sketch for absolute viscosity.

is laminar, the shear stress is related to the velocity difference by the equation

$$\tau = \mu \frac{du}{dy} \quad (5)$$

where τ is the shear stress, du/dy is the velocity gradient (or rate of angular strain), and μ is the coefficient of viscosity.

In a more precise sense, μ is known as the absolute (or dynamic) viscosity and has the units pound-seconds per foot squared in the English FSS system. The values of μ for various fluids are listed in Tables 3 and 4. Because the viscosity shows up in many instances divided by the density, the ratio $\nu = \mu/\rho$ is defined as the kinematic viscosity with the English FSS units square feet per second. In the metric system, absolute viscosity is commonly given in poises (dyne-second per square centimeter) where $1 \text{ lb-sec/ft}^2 = 478.8 \text{ P}$. The metric equivalent of kinematic viscosity is the stoke (square centimeters per second) where $1 \text{ ft}^2/\text{sec} = 929 \text{ stokes}$.

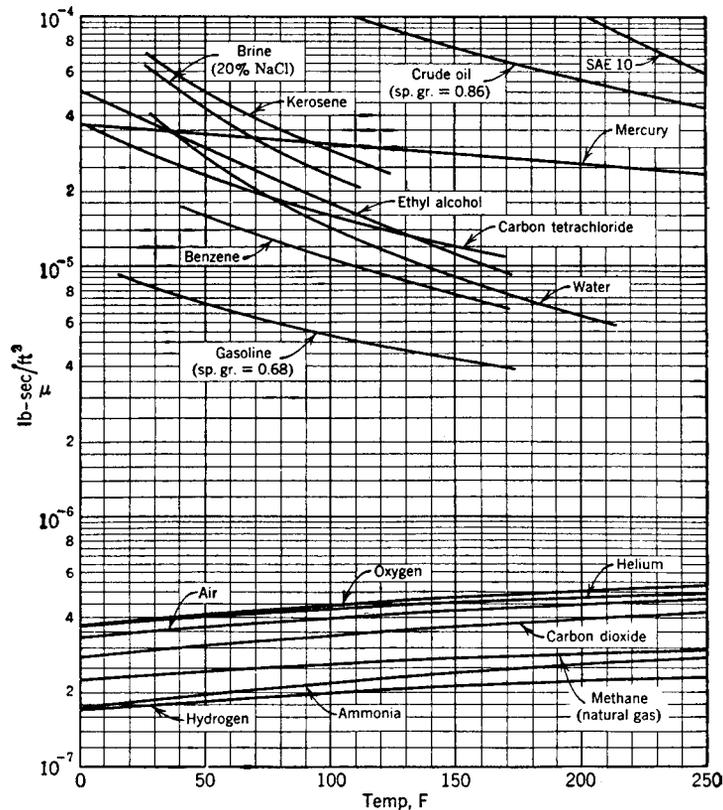

Fig. 4 Dynamic viscosity versus temperature for common gases and liquids. (Courtesy of Hunter Rouse, State University of Iowa, Iowa City.)

Figures 4 and 5 give absolute and kinematic viscosities for a wide range of liquids and gases. The English FSS values may be converted to the SI values using the conversions

$$\mu = 1 \text{ lb-sec/ft}^2 = 47.88 \text{ N-s/m}^2$$

$$\nu = 1 \text{ ft}^2/\text{sec} = 0.0929 \text{ m}^2/\text{s}$$

2.4 Surface Tension and Capillarity

Molecules of a liquid exert a mutual cohesive force that causes those molecules in the interior of a liquid to be in a balanced state of cohesive forces that is attracted equally in all directions. However, liquid molecules at a surface are attracted by the interior molecules but experience no balancing attraction from above the surface. This imbalance of forces causes the liquid surface to behave as though it were covered with an elastic membrane, hence the term *surface tension*. This phenomenon is also apparent at the interface between immiscible liquids. This is why surface tension values for a liquid must always specify

what fluid lies across the interface. As a result of its dependence on molecular cohesion, surface tension σ (in pounds per foot or newtons per meter) decreases with increasing temperature. Table 3 gives values for a variety of liquids.

Surface tension manifests itself in free liquid jets, bubbles, small waves, and capillary action in small conduits. At the interface between two fluids, surface tension can sustain a pressure discontinuity across the interface. The magnitude of the pressure difference is a function of the surface curvature with the higher pressure on the concave side of the interface.

Capillary rise in a circular tube is an important application of surface tension (Fig. 6). The equation for capillary rise h is

$$h = \frac{2\sigma \cos \theta}{\gamma r} \quad (6)$$

The value of h depends heavily on the contact angle Θ , which in turn depends strongly on the liquid and the tube material as well as the cleanliness of the tube

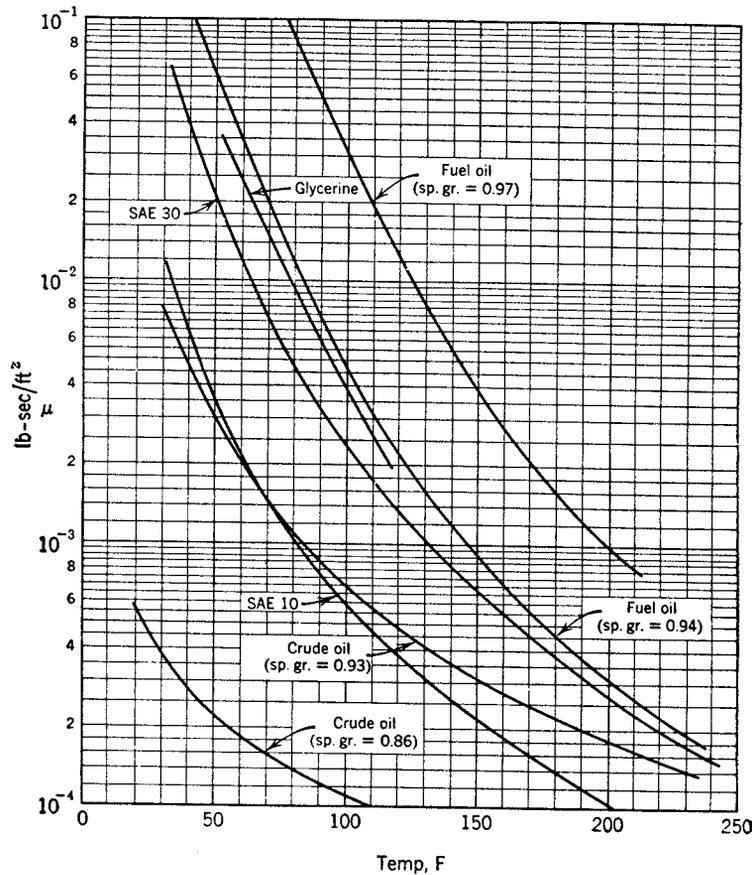

Fig. 5 Dynamic viscosity versus temperature for typical grades of oil. (Courtesy of Hunter Rouse, State University of Iowa, Iowa City.)

surface. This equation should not be used unless the capillary tube is small enough that the liquid surface is approximately spherical in shape (constant curvature).

2.5 Vapor Pressure

A liquid exhibiting a free surface is continually ejecting and absorbing molecules of the liquid across the free surface. Some of the molecules at the surface have enough energy due to local collisions that they can break free of the intermolecular cohesive forces. If more molecules leave than return, the liquid is said to be evaporating. In an equilibrium situation, the number of molecules expelled equals the number returning. The molecules of the liquid in the overlying gaseous fluid exert a force on the liquid surface, in conjunction with the other gas molecules bombarding the surface, to make up the total surface pressure. That portion of the surface pressure generated by the vapor molecules from the liquid is called the partial pressure, or *vapor pressure*, p_v , of the liquid. An alternative view is if you

started with a completely liquid-filled container. You were then able to move one end of the container outward, which increased the volume, but did not allow air to enter the container. The free space between the liquid and the movable end would become filled with a vapor from the liquid and impose a pressure on the liquid surface equal to the vapor pressure of the liquid. Table 3 provides values of the vapor pressure p_v for a variety of liquids.

The higher the liquid temperature, the more vigorous the molecular activity and the larger the fraction of the total pressure contributed by the liquid vapor. When the liquid temperature is elevated to a level where the vapor pressure is equal to the total pressure, boiling occurs (formation of vapor bubbles in liquid). Boiling is also experienced when the total pressure is reduced to the liquid vapor pressure, for example, in liquid cavitation in pumps, valves, and propellers. Therefore, boiling can occur by either raising the temperature to increase the vapor pressure to

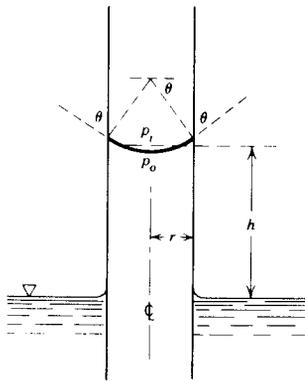

Fig. 6 Capillary rise in a small circular tube. By permission from J. K. Vennard and R. L. Street, *Elementary Fluid Mechanics*, 5th ed., Wiley, New York, 1975.

meet the local pressure or reducing the local pressure to meet the vapor pressure at the current temperature. In fluid mechanics, the latter is the most common phenomenon; flow conditions and geometry contribute to a significant reduction in local pressure. If the pressure is low enough to reach the vapor pressure of the liquid, vapor bubbles will form. In some instances, these vapor bubbles travel downstream and suddenly collapse due to higher pressure regions, which causes cavitation to occur. Cavitation can have enough intensity to cause structural damage to the system.

3 FLUID STATICS

3.1 Pressure Variation in a Fluid at Rest

By definition a Newtonian fluid at rest has no internal shear stresses, only normal stresses. As a consequence, pressure does not vary horizontally in a homogeneous fluid only vertically. The equation describing the vertical variation in pressure is

$$\frac{dp}{dz} = -\rho g = -\gamma \tag{7}$$

where z is measured vertically upward as shown in Fig. 7. If a fluid has variable density, this expression must be integrated to determine differences in pressure. However, for an incompressible fluid (i.e., constant density), the commonly used form of this equation is the hydrostatic pressure variation equation

$$\Delta p = \gamma \Delta h \tag{8}$$

where Δh is the difference in elevation between two points and Δp is the corresponding pressure difference. Note that the pressure is increased linearly with increasing depth; the fluid at a lower level needs to support all the fluid above it so the pressure is higher.

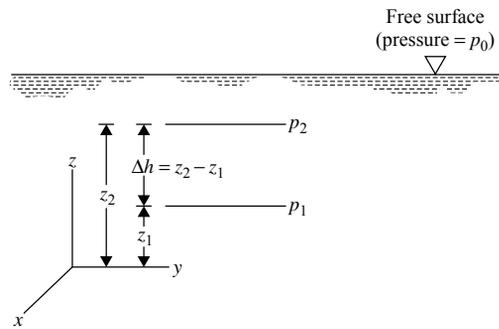

Fig. 7 Notation for pressure variation in a fluid at rest. From Ref. 2.

3.2 Basic Pressure-Measuring Devices

Pressure is generally measured from one of two datum locations—absolute zero or the surrounding environment (gauge). Pressures measured above absolute zero, for example, barometric pressure, are known as absolute pressure. Those measured above the local atmospheric pressure are known as gage pressures. Absolute pressure always equals gage pressure plus atmospheric pressure:

$$p_{\text{absolute}} = p_{\text{gage}} + p_{\text{atmospheric}} \tag{9}$$

It is possible to have negative gage pressure, since it is measured with respect to a datum. But, it is impossible to have negative absolute pressure, since the minimum you can achieve is a perfect vacuum, which is zero absolute pressure.

A fundamental pressure-measuring device, which is based on the hydrostatic pressure variation equation, is the manometer (Fig. 8). Because one end of this manometer is open to the atmosphere, it is known as an open-end manometer. By making use of the fact that pressure does not vary in the horizontal direction for a fluid at rest and making use of the hydrostatic pressure equation at various points, the gage pressure at A is calculated as

$$p_A = \gamma_2 y_2 - \gamma_1 y_1 \tag{10}$$

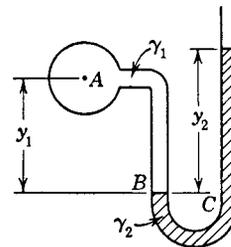

Fig. 8 Simple manometer.

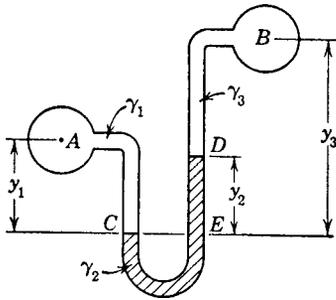

Fig. 9 Differential manometer.

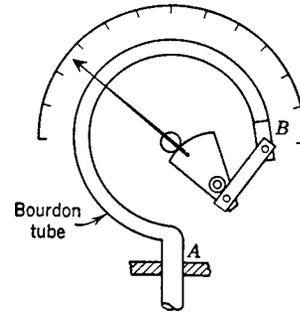

Fig. 10 Essential features of Bourdon gage.

Figure 9 illustrates a differential manometer. The difference in pressure between A and B is calculated as

$$p_B - p_A = \gamma_1 y_1 - \gamma_2 y_2 - \gamma_3 (y_3 - y_2) \quad (11)$$

Another commonly used mechanical device for measuring both gage pressure and absolute pressure is the Bourdon-type gage (Fig. 10).

3.3 Fluid Forces on Plane Surfaces

The magnitude of the total fluid force exerted on a plane (flat surface) can be calculated with the equation (refer to Fig. 11)

$$F_R = p_c A \quad (12)$$

where p_c is the pressure at the centroid of the surface and A is the total area of the surface. Note that pressure always acts normal to the surface.

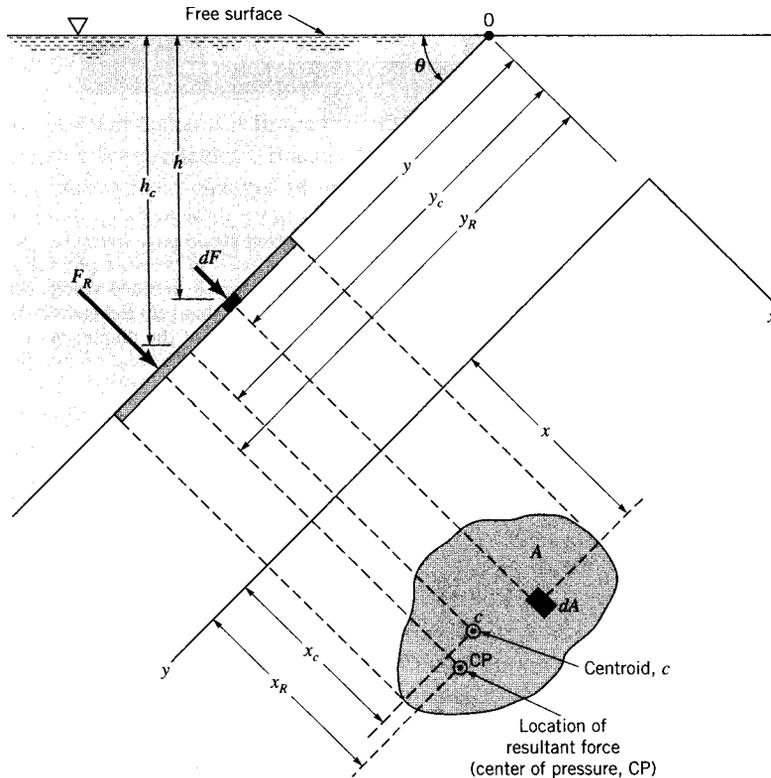

Fig. 11 Notation for pressure force calculation on submerged plane of arbitrary shape. From Ref. 2.

If the fluid is a liquid with a free surface open to the atmosphere,

$$p_c = \gamma h_c \quad (13)$$

where h_c is the distance the centroid lies below the free surface. Locations of centroids of variously shaped areas are shown in Table 5.

The location of the resultant of the pressure forces acting on a plane area is known as the center of pressure. For a plane area lying below a liquid surface, the center-of-pressure location is computed with the equation

$$y_R - y_c = \frac{I_c}{y_c A} \quad (14)$$

where y_R is measured in the plane of the area (slant distance) from the free surface to the center of pressure, y_c is the distance (in the same plane) from the free surface to the centroid of the area, and I_c is the second moment of the area about a horizontal axis through the centroid and in the plane of the area. Values of I_c for common geometric shapes are given in Table 5.

Two special cases of this application are the horizontal-plane and the vertical-plane cases. For a horizontal plane ($\theta = 0^\circ$ of inclination), the centroid of the surface and the center of pressure coincide, since the pressure distribution over the entire surface area is uniform. For the vertical case ($\theta = 90^\circ$ of inclination), the center of pressure will always be below the centroid of the surface since the pressure acting on the surface increases with depth. Note that for deeply submerged plane areas, the center of pressure approaches the centroid of the area regardless of the angle of inclination.

3.4 Fluid Forces on Curved Surfaces

Pressure forces exerted on curved surfaces vary in direction and must usually be divided into horizontal and vertical components to facilitate calculation. The resultants of the horizontal and vertical components of the pressure forces are determined with assistance from the equations developed for plane surfaces. Figure 12 illustrates a common situation. The fluid mass ABC is in equilibrium under the action of pressure forces; hence the vertical component of the resultant of the pressure forces is equal to the weight of the fluid mass plus the force F_{AC} exerted on the upper surface of the fluid mass by the overlying fluid. The horizontal component of the resultant of the pressure forces is equal to the force on a vertical projection of the curved surface. The line of action and point of application (center of pressure) for the resultant force is determined by taking moments of the contributing forces about an axis of convenience. The force F_{BC} is located using the formula for plane surfaces. The weight W_{ABC} is concentrated at the centroid of the area ABC (see Table 5).

3.5 Buoyancy and Stability

An object floatin or submerged in a fluid at rest experiences pressure forces from the surrounding fluid. Consider a square block of material that is submerged in a liquid; due to hydrostatic pressure variation with depth, the pressure on the bottom surface will be greater than on the top surface (pressure on the two sides is equal and opposite). The resultant of these pressure forces is known as the buoyant force, which acts in the upward direction, and is equal in magnitude to the weight of the displaced fluid. The line of action of the buoyant force is vertical through the centroid of the volume of displaced fluid (center of buoyancy). The magnitude of the buoyant force can be found from the following equation:

$$F_B = \gamma \mathcal{V} \quad (15)$$

where \mathcal{V} is the volume of the displaced fluid. If the object is totally submerged in the fluid then the volume of the displaced fluid equals the volume of the object; otherwise, the displaced volume equals only the volume of the submerged portion of the object.

The overturning stability (Fig. 13) of a floating or submerged body is affected by the relative position of the center of gravity of the body and the center of buoyancy. When the center of gravity lies below the center of buoyancy, the body is always *stable*. If the center of buoyancy is below the center of gravity, the body may or may not be stable in terms of overturning. If the geometric shape of the body is such that a rocking motion results in a shift of the buoyancy center that in turn causes a righting action, the body is stable. For example, a 2×4 board floatin on its side would be stable. However, the same board floatin on its edge would be unstable.

3.6 Accelerated Fluid Masses without Relative Motion

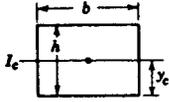

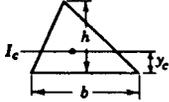

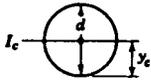

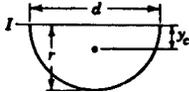

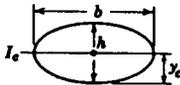

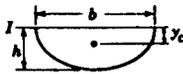

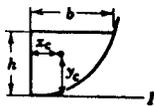

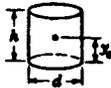

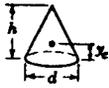

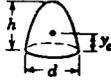

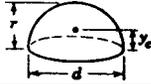

There are situations when a fluid body is accelerated with no relative motion among fluid particles (zero-shear stress). This is true only for constant accelerations. As in a fluid at rest, the pressure will still vary linearly with elevation, but the pressure gradient will generally not equal the specific weight. Further, there will be a variation in pressure in the horizontal plane in this situation.

For horizontal acceleration of a container of liquid (Fig. 14), the free surface will tilt just enough to provide the unbalanced hydrostatic force on the opposite sides of the container required to impart a constant acceleration to the fluid mass. As shown in the figure this will produce lines of constant pressure that are parallel to the tilted free surface. Under these conditions the slope of the free surface is given as

$$\text{Slope} = \frac{a_x}{g} \quad (16)$$

where a_x is the constant horizontal acceleration.

Table 5 Properties of Areas and Volumes

	Sketch	Area or Volume	Location of Centroid	I or I_c
Rectangle		bh	$y_c = \frac{h}{2}$	$I_c = \frac{bh^2}{12}$
Triangle		$\frac{bh}{2}$	$y_c = \frac{h}{3}$	$I_c = \frac{bh^2}{36}$
Circle		$\frac{\pi d^2}{4}$	$y_c = \frac{d}{2}$	$I_c = \frac{\pi d^4}{64}$
Semicircle ^a		$\frac{\pi d^2}{8}$	$y_c = \frac{4r}{3\pi}$	$I = \frac{\pi d^4}{128}$
Ellipse		$\frac{\pi bh}{4}$	$y_c = \frac{h}{2}$	$I_c = \frac{\pi bh^2}{64}$
Semiellipse		$\frac{\pi bh}{4}$	$y_c = \frac{4h}{3\pi}$	$I = \frac{\pi bh^2}{16}$
Parabola		$\frac{2}{3}bh$	$y_c = \frac{3h}{5}$ $x_c = \frac{3b}{8}$	$I = \frac{2bh^2}{7}$
Cylinder		$\frac{\pi d^2 h}{4}$	$y_c = \frac{h}{2}$	
Cone		$\frac{1}{3} \left(\frac{\pi d^2 h}{4} \right)$	$y_c = \frac{h}{4}$	
Paraboloid of revolution		$\frac{1}{2} \left(\frac{\pi d^2 h}{4} \right)$	$y_c = \frac{h}{3}$	
Sphere		$\frac{\pi d^2}{6}$	$y_c = \frac{d}{2}$	
Hemisphere		$\frac{\pi d^2}{12}$	$y_c = \frac{3r}{8}$	

^aFor the quarter-circle, the respective values are $\pi d^2/16$, $4r/3\pi$, and $\pi d^4/256$.

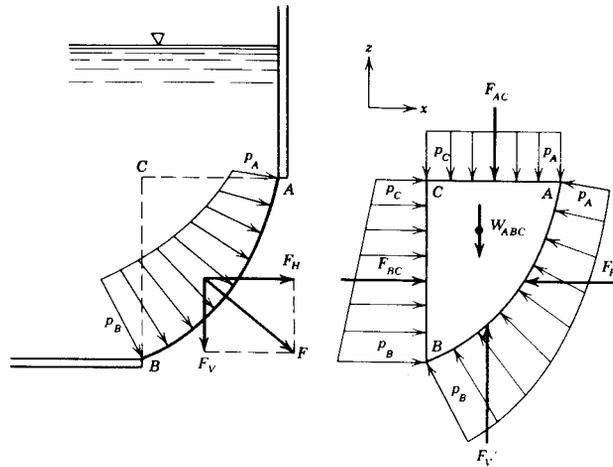

Fig. 12 Forces acting on curved surface. By permission from J. K. Vennard and R. L. Street, *Elementary Fluid Mechanics*, 5th ed., Wiley, New York, 1975.

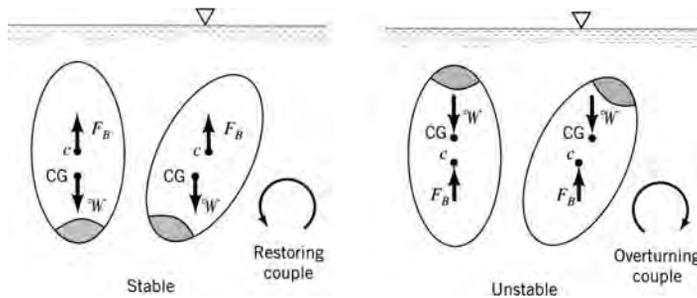

Fig. 13 Stable and unstable settings for totally submerged body. From Ref. 2.

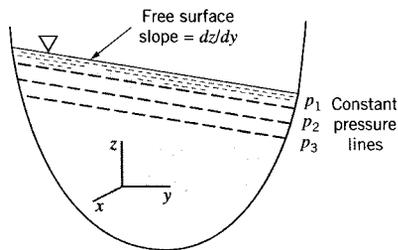

Fig. 14 Horizontal acceleration of liquid with free surface. From Ref. 2.

For vertical acceleration, the free surface remains horizontal, but the pressure variation with depth is given by the equation

$$\frac{dp}{dz} = -\gamma \left(1 + \frac{a_z}{g} \right) \quad (17)$$

Note that if $a_z = -g$ (free fall), the pressure gradient throughout the fluid is zero.

Another situation occurs for a container of liquid undergoing a constant rotational angular velocity (Fig. 15). When the relative motion between fluid particles ceases, the free surface forms the shape of a parabola described by the equation

$$z = \frac{\omega^2}{2g} r^2 \quad (18)$$

where z is the elevation of the free surface at radius r above that at the center of rotation and ω is the angular velocity of rotation of the container. Pressure in the fluid varies parabolically with radius,

$$p = p_o + \frac{\gamma \omega^2}{2g} r^2 \quad (19)$$

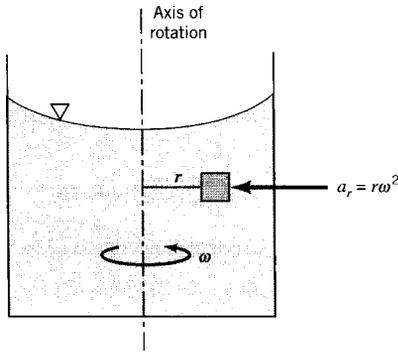

Fig. 15 Rotation of tank filled with liquid. From Ref. 2.

where p is the pressure at radius r in a horizontal plane and p_o is the pressure at the center of rotation in the same horizontal plane. Because there is no vertical acceleration, pressure variation in the vertical direction is the same as if the fluid were at rest.

4 IDEAL (INVISCID) FLUID DYNAMICS

An *ideal fluid* is a hypothetical substance exhibiting all the characteristics of a real fluid except that it is a continuum (no molecular spaces), it has no viscosity (frictionless) or inviscid, and it can accept pressures down to negative infinity. These characteristics greatly simplify the mathematical treatment of fluid flow and, in many cases, give acceptable engineering results for real fluid situations where viscous effects are not significant.

Although not restricted to ideal fluid flow some definitions are common to all flow situations. Steady flow occurs when all conditions in the flow at any point do not change with time. In turbulent flows, this definition is extended to include temporal mean values of all conditions. Uniform flow is defined as the condition where the velocity is everywhere the same at a given time. For one-dimensional flow, this definition refers to the average velocity at any cross section of the flow. In nonuniform flow the velocity varies with position in the flow domain at any given time.

Qualitative aspects of a fluid flow situation can be illustrated effectively through the use of streamlines. For steady flow, *streamlines* are tracks of fluid particles that are everywhere tangent to fluid velocity vectors. As a consequence, flow cannot occur across streamlines; so a collection of streamlines defining a closed surface (a stream tube) would act like a conduit within the flow. Further, regions of flow where streamlines are close together represent locally high velocities (and low pressures). Regions where the streamlines are straight and parallel identify situations where there is no acceleration normal to the flow therefore, the pressure variation normal to the flow is hydrostatic.

4.1 One-Dimensional Flow

Most real flows are three dimensional in nature. However, in order to simplify the analysis and obtain

solutions to engineering problems, some assumptions can be made. Some types of flows have a dominant flow direction, with the remaining two spatial directions only contributing secondary effects. Therefore, making the assumption that the flow is one dimensional can simplify the analysis and provide reasonable results under certain conditions. The introduction of the various conservation laws (mass, momentum, and energy) for fluid flow is also simplified by using a one-dimensional analysis, which is given below.

Conservation of Mass (Continuity) Conservation of mass is an analog of the conservation of energy. It states that in a fluid flow accumulation of mass within a control volume (a volume whose boundaries are specified) is equal to the difference of the net inflow and the net outflow of mass. For steady state, the accumulation, by definition is zero. Consequently, conservation of mass simplifies to a balance of net inflow and net outflow of mass.

For one-dimensional flow, the control volume is generated by the cross-sectional area of the conduit at two specific locations, where the streamlines are essentially straight and parallel to each other and normal to the cross-sectional area, and the walls of the conduit between these two locations (see Fig. 16).

For steady flow, the mass flow rate \dot{m} (slugs per second or kilograms per second) is a constant along the conduit and is written

$$\dot{m} = \rho AV = \rho Q = \text{const} \quad (20)$$

where Q is the volume flow rate (cubic feet per second), A is the cross-sectional area of the conduit, and V is the average velocity, Q/A . In cases where the flow enters the control volume at section 1 and leaves at section 2 (see Fig. 16), conservation of mass states that the mass inflow rate equals mass outflow rate, or

$$\rho_1 A_1 V_1 = \rho_2 A_2 V_2 \quad (21)$$

In the case of incompressible flow, the density will not vary and therefore will drop from the above expression, yielding constant volume flow rate:

$$Q_1 = Q_2 \quad (22)$$

Euler's Equations Application of Newton's second law to a fluid particle gives Euler's equations of motion, assuming inviscid flow. Along a streamline (see Fig. 16)

$$\frac{dp}{\gamma} + \frac{v dv}{g} + dz = 0 \quad (23)$$

where v is the local velocity. Normal to the streamline,

$$\frac{dp}{\gamma} - \frac{v^2}{gr} dr + dz = 0 \quad (24)$$

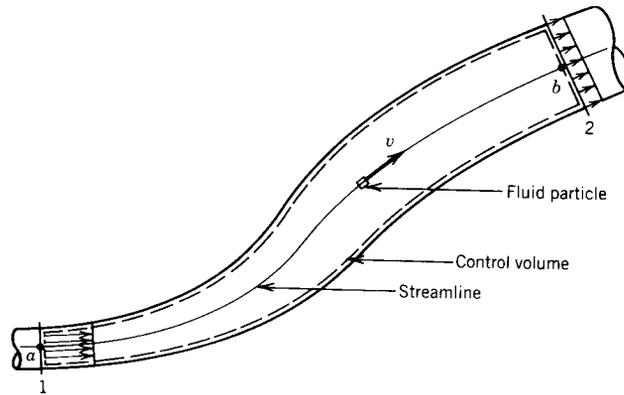

Fig. 16 One-dimensional inviscid flow.

where r is the local radius of curvature of the streamline along which the fluid particle is moving.

Bernoulli Equation Integration of the Euler equation along a streamline for constant density yields the Bernoulli equation

$$\frac{p}{\gamma} + \frac{v^2}{2g} + z = \text{const} \quad (25)$$

If the integration is performed along a streamline between points a and b (Fig. 16), the Bernoulli equation takes the form

$$z_a + \frac{P_a}{\gamma} + \frac{v_a^2}{2g} = z_b + \frac{P_b}{\gamma} + \frac{v_b^2}{2g} \quad (26)$$

Multiplying through by the specific weight, the Bernoulli equation can also be written as

$$p_a + \frac{1}{2}\rho v_a^2 + \gamma z_a = p_b + \frac{1}{2}\rho v_b^2 + \gamma z_b \quad (27)$$

This states that the combination of these three terms remains constant everywhere along the streamline.

The Bernoulli equation can be “expanded” to apply to a full-sized one-dimensional flow (as opposed to a single streamline) if the sections at 1 and 2 (Fig. 16) are regions where the streamlines are essentially straight and parallel and the velocity profile uniform (irrotational flow),

$$p_1 + \frac{1}{2}\rho V_1^2 + \gamma z_1 = p_2 + \frac{1}{2}\rho V_2^2 + \gamma z_2 \quad (28)$$

where V is the average velocity. This is true because at a section where the streamlines are straight and parallel the velocity is constant over the cross section and the pressure variation is hydrostatic ($z + p/\gamma = \text{const}$). Hence the sum of the three terms on each side of the equation is a constant regardless of the streamline

selected. Because 1 and 2 are sections and not points, the quantities z and p/γ (or γz and P) are usually evaluated at some arbitrary point in the cross section, for example, at the centerline for a cylindrical pipe.

A further conclusion extends from the uniform-flow section concept. If the sum of the three terms is the same for all streamlines at the special cross section, the sum is everywhere constant throughout the flow:

$$p_1 + \frac{1}{2}\rho V_1^2 + \gamma z_1 = \text{const throughout flow field for irrotational flow} \quad (29)$$

Work-Energy Equation An equation similar to the Bernoulli equation can be derived from work-energy principles. However, the work-energy equation has broader application because it can include thermal energy and heat transfer. Utilizing the principle that the work done on a fluid system is equal to the change in energy of the system and applying this principle to the fluid in the control volume of Fig. 16,

$$z_1 + \frac{p_1}{\gamma} + \frac{V_1^2}{2g} = z_2 + \frac{p_2}{\gamma} + \frac{V_2^2}{2g} \quad (30)$$

This equation is identical to the Bernoulli equation; however, we have not considered other energies beyond mechanical energies. Further, the terms in the work-energy equation have the following meanings:

- z = potential energy per pound of fluid flowing
- $V^2/(2g)$ = kinetic energy per pound of fluid flowing
- p/γ = “flow work” done on fluid in control volume per pound of fluid flowing (also known as “pressure energy”)

Based on the fact that we can obtain the Bernoulli equation from both Newton’s second law and the

conservation of energy, we can conclude that it is a very powerful equation, which is also witnessed by its numerous applications in nature.

Momentum Equation

Linear Momentum. Newton's second law was applied to a fluid particle moving along a streamline to produce the Euler equations. If the second law is applied to a finite fluid mass within a control volume (e.g., Fig. 16), another set of useful equations are derived. All internal forces cancel so that only external forces due to pressure, shear (for real fluids) and gravity need be considered. The resulting linear momentum equations are vector equations and are written as

$$\sum \mathbf{F}_{\text{ext}} = \sum (Q\rho\mathbf{V})_{\text{out}} - \sum (Q\rho\mathbf{V})_{\text{in}} \quad (31)$$

where \mathbf{F}_{ext} are the external forces acting on the fluid in the control volume and summations are used if there are multiple inlets and outlets. Again, the control volume is generally selected in such a way that the sections where the momentum enters and leaves the control volume are regions where the streamlines are straight and parallel.

In applying the linear momentum equations to a problem, it is customary to use the vector component equations with the orthogonal axes chosen in a convenient orientation. For example, the scalar equation in the x direction would be

$$\sum (F_x)_{\text{ext}} = \sum (Q\rho V_x)_{\text{out}} - \sum (Q\rho V_x)_{\text{in}} \quad (32)$$

It should be noted that this equation can be used to determine the resultant force but not the distribution of that force. Also note that in the calculation of Q the velocity that is normal to the cross section is used [also see explanation for Eq. (20)], whereas the V_x term only refers to the component of that velocity in the x direction. Therefore, when dealing with the y and z component of this equation, the Q term is always calculated with the velocity that is normal to the cross section, and the V_y or V_z is calculated by considering the respective component of velocity in those directions. When considering the component magnitudes, it is also important to pay attention to the sign of the magnitudes as (+) or (-).

Moment of Momentum. In problems involving fluid flow through a conduit, the linear momentum equation provides the necessary force information. However, for some problems the moment of a force, or the torque, is important; for example, fluid flow through a rotary water sprinkler. In these cases, a moment-of-momentum equation is needed that relates torque to angular momentum.

For the derivation of this equation, a similar approach to that which resulted in the linear momentum equation is used; but this time, the moments of

the vectors are used instead. The resultant moment-of-momentum equation is

$$\sum (\mathbf{r} \times \mathbf{F})_{\text{ext}} = \sum [Q\rho(\mathbf{r} \times \mathbf{V})]_{\text{out}} - \sum [Q\rho(\mathbf{r} \times \mathbf{V})]_{\text{in}} \quad (33)$$

where the terms in parentheses are vector cross products.

A more directly usable form of the equation is that applicable in two dimensions,

$$\sum (M_o)_{\text{ext}} = \sum (Q\rho r V_t)_{\text{out}} - \sum (Q\rho r V_t)_{\text{in}} \quad (34)$$

where M_o are moments of the external forces about an axis through o and V_t is the value of the velocity normal to a vector \mathbf{r} extending from the moment center o to the location of the V_t . This equation is vastly used in the design of turbomachinery such as pumps and turbines.

4.2 Two- and Three-Dimensional Flow*

The equations describing two- and three-dimensional ideal fluid flow are derived using a small cubic fluid element or control volume of sides dx , dy , and dz .

Conservation of Mass (Continuity) The continuity equation for an ideal fluid states that under steady-state conditions the net flow rate into any small volume must be zero. In equation form

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} = 0 \quad (35)$$

or in vector notation

$$\nabla \cdot \mathbf{V} = 0 \quad (36)$$

that is, the divergence of the velocity vector \mathbf{V} is everywhere zero (see Chapter 2 for vector analysis).

Euler's Equation of Motion Consideration of body and pressure forces on a fluid element and neglecting the viscous contributions lead to the Euler equations:

$$X - \frac{1}{\rho} \frac{\partial p}{\partial x} = u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} + w \frac{\partial u}{\partial z} + \frac{\partial u}{\partial t} \quad (37)$$

$$Y - \frac{1}{\rho} \frac{\partial p}{\partial y} = u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} + w \frac{\partial v}{\partial z} + \frac{\partial v}{\partial t} \quad (38)$$

$$Z - \frac{1}{\rho} \frac{\partial p}{\partial z} = u \frac{\partial w}{\partial x} + v \frac{\partial w}{\partial y} + w \frac{\partial w}{\partial z} + \frac{\partial w}{\partial t} \quad (39)$$

*Illustrations and material extracted all or in part from the previous edition by Victor L. Streeter.

where X, Y, Z are the components of the body (extraneous) forces per unit mass in the xyz directions, respectively; ρ is the mass density; p is the pressure at a point (independent of direction); and u, v, w are velocity components in the xyz directions at any point x, y, z . The terms on the right-hand side of the equations are acceleration components, the first three of which are known as the *convective* acceleration (account for fluid convecting in space) and the fourth as the *local* acceleration (accounts for local unsteadiness).

Boundary Conditions A kinematic boundary condition must be satisfied at every solid boundary. For real fluid (i.e., with viscosity), the widely known “no-slip” condition states that the fluid particles adjacent to a solid boundary move with the same velocity as the boundary. Therefore, in the case of wind over a stationary flat plate, for example, the air particles adjacent to the plate will not move, while their fellow particles that are further into the air will move with the wind. Therefore, both u and v components of the velocity at the solid boundary are zero according to the no-slip condition for real fluids. However, the Euler equations are derived for inviscid cases, and so, for Euler solutions to flow problems, there will be a slip velocity tangent to the solid boundary. Therefore, the u component of the velocity, in the case of wind over a flat plate, will be equal to the free-stream velocity, whereas the normal component of the velocity, v , of the air particles at the solid boundary will be zero (since there is no suction or blowing from the surface and it is not a porous surface).

Irrotational Flow-Velocity Potential Rotation of a fluid element may be represented by a vector that has a length proportional to the magnitude of the rotation (radians per second) and in a direction parallel to the instantaneous axis of rotation. The right-handed rule is adopted; that is, the positive direction of the vector is the direction a right-handed screw would progress when rotating in the same sense as the element. In vector notation the *curl* of the velocity vector is twice the rotation vector, which is called vorticity ($\boldsymbol{\Omega}$):

$$\nabla \times \mathbf{V} = 2\boldsymbol{\omega} = \boldsymbol{\Omega} \quad (40)$$

Scalar components of the rotation vector $\omega_x, \omega_y, \omega_z$ in the directions of the xyz axes may be used in place of the vector itself. Define a rotation component of an element about an axis as the average angular velocity of two infinitesimal line segments through the point, mutually perpendicular to themselves and the axis,

$$\omega_x = \frac{1}{2} \left(\frac{\partial w}{\partial y} - \frac{\partial v}{\partial z} \right) \quad (41)$$

$$\omega_y = \frac{1}{2} \left(\frac{\partial u}{\partial z} - \frac{\partial w}{\partial x} \right) \quad (42)$$

$$\omega_z = \frac{1}{2} \left(\frac{\partial v}{\partial x} - \frac{\partial u}{\partial y} \right) \quad (43)$$

For an irrotational flow, each of these rotational components must be zero, or

$$\nabla \times \mathbf{V} = 0 \quad (44)$$

Then,

$$\frac{\partial w}{\partial y} = \frac{\partial v}{\partial z} \quad \frac{\partial u}{\partial z} = \frac{\partial w}{\partial x} \quad \frac{\partial v}{\partial x} = \frac{\partial u}{\partial y} \quad (45)$$

A visual concept of irrotational flow may be obtained by considering as a free body a small element of fluid in the form of a sphere. As the fluid is frictionless, no tangential stresses or forces may be applied to its surface. The pressure forces act normal to its surface and hence through its center. Extraneous, or body, forces act through its mass center, which is also its geometric center for constant density. Hence, it is evident that no torque may be applied about any diameter of the sphere. The angular acceleration of the sphere must always be zero. If the sphere is initially at rest, it cannot be set in rotation by any means whatsoever; if it is initially in rotation, there is no means of changing its rotation. As this applies to every point in the fluid, one may visualize the fluid elements as being pushed around by boundary movements but not being rotated if initially at rest. Rotation or lack of rotation of the fluid particles is a property of the fluid itself and not its position in space.

The velocity potential Φ is a scalar function of space such that its rate of change with respect to any direction is the velocity component in that direction. In vector notation

$$\mathbf{V} = \nabla \Phi \quad (46)$$

or in terms of Cartesian coordinates

$$u = \frac{\partial \Phi}{\partial x} \quad v = \frac{\partial \Phi}{\partial y} \quad w = \frac{\partial \Phi}{\partial z} \quad (47)$$

The assumption of irrotational flow is equivalent to the assumption of a velocity potential.

Laplace Equation The Laplace equation results when the continuity equation is written in terms of the velocity potential. By using Eqs. (36) and (46), we get

$$\nabla \cdot \mathbf{V} = \nabla \cdot (\nabla \Phi) = \nabla^2 \Phi = 0 \quad (48)$$

$$\frac{\partial^2 \Phi}{\partial x^2} + \frac{\partial^2 \Phi}{\partial y^2} + \frac{\partial^2 \Phi}{\partial z^2} = 0 \quad (49)$$

For plane polar coordinates (r, θ)

$$\frac{\partial \Phi}{\partial r} + r \frac{\partial^2 \Phi}{\partial r^2} + \frac{1}{r} \frac{\partial^2 \Phi}{\partial \theta^2} = 0 \quad (50)$$

For spherical polar coordinates (r, θ, γ) , where r is the distance from the origin, θ is the polar angle and γ is the meridian angle,

$$\begin{aligned} \frac{\partial}{\partial r} \left(r^2 \frac{\partial \Phi}{\partial r} \right) + \frac{1}{\sin \theta} \frac{\partial}{\partial \theta} \left(\sin \theta \frac{\partial \Phi}{\partial \theta} \right) \\ + \frac{1}{\sin^2 \theta} \frac{\partial^2 \Phi}{\partial \gamma^2} = 0 \end{aligned} \quad (51)$$

Once the velocity field is found by use of the potential function, the pressure distribution may be found by the Bernoulli equation.

Two-Dimensional Flow In two-dimensional flow all lines of motion are parallel to a fixed plane, say the xy plane, and the flow patterns are identical in all planes to this plane. Application of this assumption to the Laplace equation in Cartesian coordinates gives

$$\nabla^2 \Phi = \frac{\partial^2 \Phi}{\partial x^2} + \frac{\partial^2 \Phi}{\partial y^2} = 0 \quad (52)$$

In addition to streamlines as a means of visualizing the flow, equipotential lines are also useful in two dimensions. Equipotential lines are defined as the lines connecting the points in the flow domain where the value of the potential function Φ remains constant. Both the streamlines and the equipotential lines are utilized in the following sections of this chapter.

Stream Function. A streamline is a continuous line drawn through the fluid in such a way that at every point it is tangent to the velocity vector; therefore, there is no flow across a streamline. The stream function ψ is a scalar function of space whose value remains constant along a streamline. The volume rate of flow between two streamlines is given by the difference in values of the stream function along these streamlines, as shown in Fig. 17. So,

$$\psi_2 - \psi_1 = q \quad (53)$$

This notion of the stream function suggests that for the no-slip condition in real fluid the value of the stream function is zero at the stationary solid boundary; as for Euler solutions where viscous effects are neglected, the stream function will have a nonzero value proportional to the slip velocity tangent to the solid boundary. However, the important point is not the actual value used for the stream function at the surface, but rather the difference in stream function values between two streamlines, indicating the flow rate at that location.

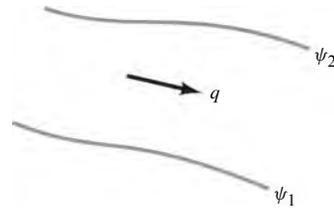

Fig. 17 Flow between two streamlines. From Ref. 2.

The velocity components u, v in the x and y directions, respectively, can be expressed in terms of stream function ψ as

$$u = \frac{\partial \psi}{\partial y} \quad v = -\frac{\partial \psi}{\partial x} \quad (54)$$

From the definition of the stream function, it is subject to addition of an arbitrary constant. Substituting these values of u and v into the continuity equation for two-dimensional flow,

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = \frac{\partial}{\partial x} \left(\frac{\partial \psi}{\partial y} \right) + \frac{\partial}{\partial y} \left(-\frac{\partial \psi}{\partial x} \right) = 0 \quad (55)$$

which exactly satisfies the conservation of mass.

Application of Complex Variables to Irrotational Flow. The idea of combining the stream function and the velocity potential function into a single variable can be realized through the use of complex variables. This method of expression provides simplicity in the formulations.

Let $z = x + iy$ be a complex variable where x and y are real and $i = \sqrt{-1}$. Any function of z

$$w = f(z) = f(x + iy) = \phi + i\psi \quad (56)$$

that is defined throughout a region and that has a derivative throughout the region gives rise to two possible irrotational flow cases, since it may be shown that

$$\nabla^2 w = \nabla^2 \phi + i \nabla^2 \psi = 0 \quad (57)$$

and hence $\nabla^2 \phi = 0$ and $\nabla^2 \psi = 0$. Here, w is termed the complex potential, ϕ is the real part of w , and ψ is the pure imaginary part of w . The complex velocity

$$\frac{dw}{dz} = -u + iv \quad (58)$$

provides a simple method of finding velocity components from the complex potential. Stagnation points

occur at those points in the flow where the velocity is zero, that is,

$$\frac{dw}{dz} = 0 \tag{59}$$

Conformal Mapping. Each of the two complex variables w and z introduced in the preceding paragraphs may be represented by plotting on a graph. The w plane is a graph having ϕ as abscissa and ψ as ordinate, showing values of $\phi = \pm nc, \psi = \pm nc$, where n is every integer and c is a constant. Figure 18 is a flow net of the simplest form showing equipotential and streamlines as series of parallel straight lines. The z plane is a plot of the equipotential and streamlines of the w plane, with x as abscissa and y as ordinate. The particular flow net in the z plane depends entirely on the functional relation between w and z , that is, $w = f(z)$. Since

$$w = f(z) = \phi + i\psi \quad z = x + iy \tag{60}$$

where ϕ, ψ, x, y are real,

$$\phi = \phi(x, y) \quad \psi = \psi(x, y) \tag{61}$$

The values of $\phi = \text{const}$ and $\psi = \text{const}$ can be plotted on the z plane from the functional relations of ϕ and ψ with x, y .

Examples of Two-Dimensional Flow. Since the Laplace equation is linear in ϕ , the sum of two solutions is also a solution, and the product of a

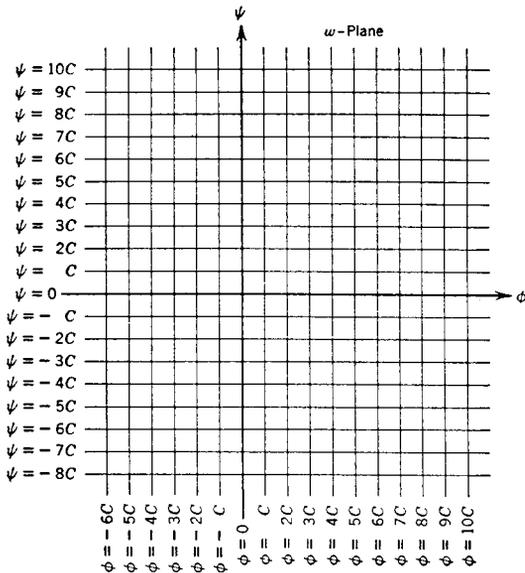

Fig. 18 Flow net in w plane.

solution by a constant is a solution. Several of the important solutions are given.

Rectilinear Flow. Uniform straight-line flow is given by

$$w = Uz - iVz \quad \phi = Ux + Vy \quad \psi = -Vx + Uy \tag{62}$$

where the character of flow is easily seen from the complex velocity

$$\frac{dw}{dz} = u + iv = U + iV \quad u = U \quad v = V \tag{63}$$

and U, V are the $+x, y$ components of the velocity, respectively.

Source or Sink. A source in two-dimensional flow is a point from which fluid flow outward uniformly in all directions. A sink is a negative source; that is, the flow is into the point:

$$\phi = -\mu \ln r \quad \psi = -\theta \tag{64}$$

where $2\pi\mu$ is the outward flow from the line per unit length, known as the *strength*, with r and θ shown in Fig. 19. In this figure streamlines are the radial lines and equipotential lines are the concentric circles. When μ is negative, the equations become those for a sink.

Vortex. A vortex defines a rotation around a point. The relevant equations for a vortex are

$$\phi = -\mu\theta \quad \psi = \mu \ln r \tag{65}$$

Figure 20 is the flow net for a vortex with the radial lines now equipotential lines and the concentric circles streamlines. The vortex causes circulation about itself. Circulation about any closed curve is defined as the line integral of the velocity around the curve. The circulation about the vortex is $\kappa = 2\pi\mu$, considered

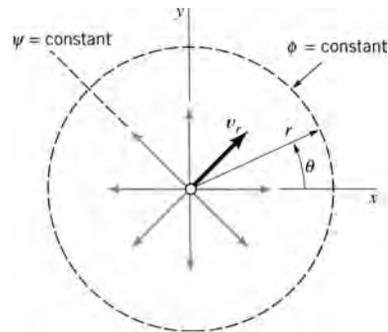

Fig. 19 Streamline pattern for source (or sink). From Ref. 2.

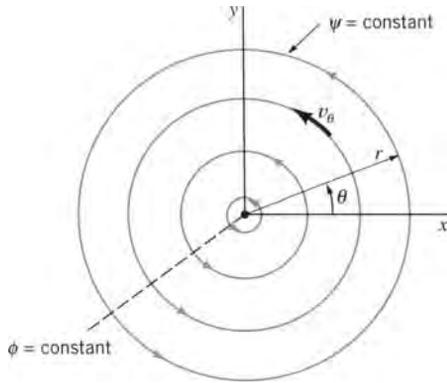

Fig. 20 Flow net for vortex. From Ref. 2.

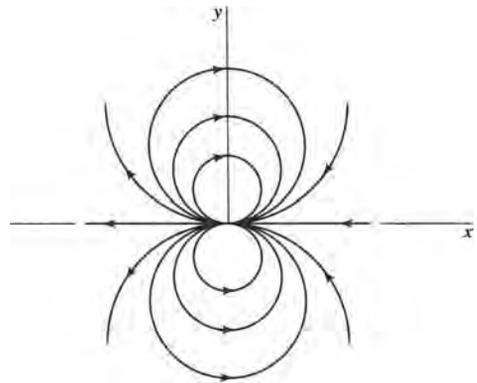

Fig. 22 Streamlines for doublet. From Ref. 2.

positive in the counterclockwise direction around the vortex.

Based on the radial variation of the strength of the rotation, two major types of vortices are assumed: forced vortex and free vortex (Fig. 21). In the forced vortex, which is also known as solid-body rotation, the angular velocity is the same at all points, and the tangential velocity increases linearly with distance from the center of the vortex. In the free vortex, however, both the angular velocity and the tangential velocity decay with distance from the vortex center.

Doublet The doublet is defined as the limiting case of a source and a sink of equal strength that approach each other such that the product of the strength by the distance between them remains a constant. The constant μ is called the strength of the doublet:

$$\phi = \frac{\mu x}{x^2 + y^2} \quad \psi = \frac{\mu y}{x^2 + y^2} \quad (66)$$

Figure 22 shows the flow net. The axis of the doublet is in the direction from sink to source and is parallel to the $+x$ axis as given here. The equipotential lines are circles having their centers on the x axis; the streamlines are circles having centers on the y axis.

Flow around a Circular Cylinder The superposition of a uniform flow in the $-x$ direction on a doublet with axis in the $+x$ direction results in flow around a circular cylinder. Adding the two flows taking $\mu = Ua^2$, where a is the radius of the cylinder,

$$\phi = U \left(r + \frac{a^2}{r} \right) \cos \theta \quad \psi = U \left(r - \frac{a^2}{r} \right) \sin \theta \quad (67)$$

The streamline $\psi = 0$ is given by $\theta = 0, \pi$ and by $r = a$; hence the circle $r = a$ may be taken as a solid boundary and the flow pattern of Fig. 23 is obtained.

Three-Dimensional Flow Three-dimensional flows in general are more difficult to handle than those in two

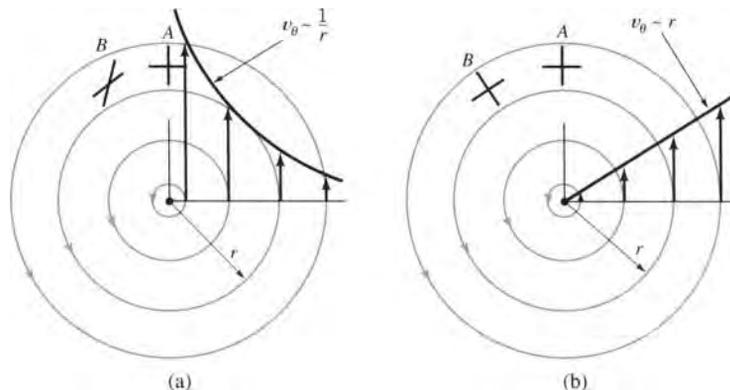

Fig. 21 Depiction for (a) free vortex and (b) forced vortex. From Ref. 2.

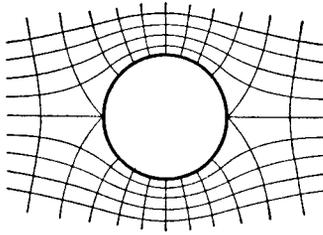

Fig. 23 Flow pattern for uniform flow around circular cylinder without circulation.

dimensions, primarily owing to a lack of methods comparable to the use of complex variables and conformal mapping. A velocity potential must be found that satisfies the Laplace equation and the boundary conditions. When the velocity potential is *single valued*, it may be shown that the solution is unique. For a body moving through an infinite fluid otherwise at rest, a necessary condition is that the solution be such that the fluid at infinity remains at rest. Flow cases are usually found by investigating solutions of the Laplace equation to determine the particular boundary conditions that they satisfy.

Stokes's Stream Function. The Stokes stream function is defined only for those three-dimensional flow cases that have axial symmetry, that is, where the flow is in a series of planes passing through a given line and where the flow pattern is identical in each of these planes. The intersection of these planes is the axis of symmetry.

In any one of these planes through the axis of symmetry select two points A, P such that A is fixed and P is variable. Draw a line connecting AP . The flow through the surface generated by rotating AP about the axis of symmetry is a function of the position of P . Let this function be $2\pi\psi$, x the axis of symmetry, r the distance from the origin, and Θ the angle the radius vector makes with the x axis. The meridian angle is not needed because of axial symmetry. Then

$$v_r = -\frac{1}{r^2 \sin \theta} \frac{\partial \psi}{\partial \theta} \quad v_\theta = \frac{1}{r \sin \theta} \frac{\partial \psi}{\partial r} \quad (68)$$

and

$$\frac{1}{\sin \theta} \frac{\partial \psi}{\partial \theta} = r^2 \frac{\partial \phi}{\partial r} \quad \frac{\partial \psi}{\partial r} = -\sin \theta \frac{\partial \phi}{\partial \theta} \quad (69)$$

The surfaces $\psi = \text{const}$ are stream surfaces. Since A is an arbitrary point, the stream function is always subject to the addition of an arbitrary constant. These equations are useful in dealing with flow about spheres, ellipsoids, and discs and through apertures. Stokes's stream function has the dimensions *volume per unit time*.

Examples of Three-Dimensional Flow. Two examples of three-dimensional flow with axial symmetry follow.

Source in a Uniform Stream. A point source is a point from which fluid issues at a uniform rate in all directions. Its strength m is the flow rate from the point, and the velocity potential and stream function for a source at the origin are

$$\phi = \frac{m}{4\pi r} \quad \psi = \frac{Ur^2}{2} \sin^2 \theta \quad (70)$$

The flow net is shown in Fig. 24. Superposing a uniform flow on a point source results in a *half body*, with the flow equations

$$\phi = \frac{m}{4\pi r} + Ur \cos \theta \quad \psi = \frac{m}{4\pi} \cos \theta + \frac{Ur^2}{2} \sin^2 \theta \quad (71)$$

The resulting flow net is shown in Fig. 25. The body extends to infinity in the downstream direction and has the asymptotic cylinder whose radius is

$$R_{\text{asympt}} = \sqrt{\frac{m}{\pi U}} \quad (72)$$

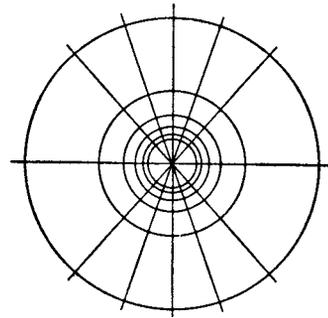

Fig. 24 Streamlines and equipotential lines for source.

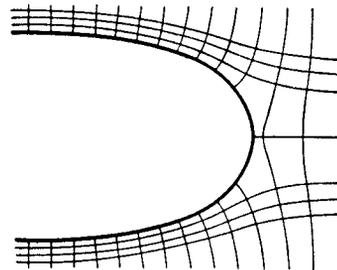

Fig. 25 Streamlines and equipotential lines for half body.

The equation of the half body is

$$r = \frac{1}{2} \sqrt{\frac{m}{\pi U}} \sec \frac{\theta}{2} \quad (73)$$

The pressure on the half body is given by

$$p = \frac{\rho}{2} U^2 \left(\frac{3m^2}{16\pi^2 r^4 U^2} - \frac{m}{2\pi r^2 U} \right) \quad (74)$$

showing that the dynamic pressure drops to zero at great distances downstream along the body.

Flow around a Sphere. A doublet is defined as the limiting case as a source and sink approach each other such that the product of their strength by the distance between them remains a constant. The doublet has directional properties. Its axis is positive from the sink toward the source. For a doublet at the origin with axis in the $+x$ direction

$$\phi = \frac{\mu}{r^2} \cos \theta \quad \psi = -\frac{\mu}{r} \sin^2 \theta \quad (75)$$

where μ is the strength of the doublet.

Superposing a uniform flow $u = -U$, on the doublet results in flow around a sphere,

$$\begin{aligned} \phi &= \frac{Ua^3}{2r^2} \cos \theta + Ur \cos \theta \\ \psi &= -\frac{Ua^3}{2r} \sin^2 \theta + \frac{Ur^2}{2} \sin^2 \theta \end{aligned} \quad (76)$$

where $\mu = Ua^3/2$. This is shown to be the case, since the streamline $\psi = 0$ is satisfied by $\Theta = 0, \pi$ and $r = a$.

The flow net is shown in Fig. 26,

5 VISCOUS FLUID DYNAMICS

The additional consideration of viscosity in the flow of fluid greatly complicates analysis and understanding of flow situations. In the fundamental sense, viscosity only introduces the possibility of shear stress into the flow process. However, the effects are far-reaching and for many years have caused researchers and designers

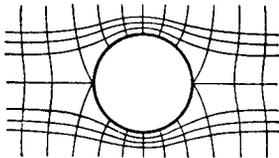

Fig. 26 Streamlines and equipotential lines for uniform flow about sphere at rest.

to rely heavily on experimental techniques. In recent years the wide availability of supercomputers has led to an increasing use of numerical analysis to predict the behavior of fluid flows (known as computational fluid dynamics, or CFD).

Viscous flow are typically classified as laminar or turbulent, although in any given flow there may be regions of both laminar and turbulent flow. In laminar flow fluid particles slide smoothly over one another with no mixing except that which normally occurs as a result of molecular activity. Shear stress τ in laminar flow depends directly on the local velocity gradient and the fluid viscosity,

$$\tau = \mu \frac{du}{dy} \quad (77)$$

Shear stress is not affected by boundary roughness in laminar flow so long as the boundary roughness is small in comparison to the flow cross section.

In turbulent flow, a great deal of mixing occurs with random motion of fluid masses of various sizes occurring. Shear stress in turbulent flow depends strongly on the momentum exchange occurring as the result of turbulent mixing. An equivalent expression for shear stress in turbulent flow is

$$\tau = \varepsilon \frac{du}{dy} \quad (78)$$

where ε is the eddy viscosity, which is a function of both fluid viscosity and the local structure of the turbulent flow. This expression was unsatisfactory because it was impossible to quantify ε . An analysis of the turbulent momentum exchange process by Reynolds yielded a shear stress equation directly related to the flow turbulence:

$$\tau = -\rho \overline{u'v'} \quad (79)$$

where u', v' are the turbulent velocity fluctuation about the mean values and $\overline{u'v'}$ is the time average of the product of the fluctuation in the x and y directions. This expression is also not very useful in a practical sense. Research eventually led to the Prandtl-von Karman equation for shear stress:

$$\tau = \rho \kappa^2 \frac{(dv/dy)^4}{(d^2v/dy^2)^2} \quad (80)$$

where κ is a dimensionless turbulence constant. This practical form of the shear stress equation can be integrated to generate velocity profiles

5.1 Internal Flows

Flow in pipes and ducts under the action of viscosity requires some changes in basic concepts as well as in the equations for one-dimensional flow. Specifically

the velocity is no longer uniform in the cross section where the streamlines are straight and parallel. The velocity will be zero at the wall due to the “no-slip” condition, and increase to a maximum near the center of the conduit. This nonuniform velocity profile requires correction coefficients in the work–energy and momentum equations.

In addition to the need for compensating for the nonuniform velocity profile in one-dimensional flow, it is necessary to account for the energy converted to heat through the frictional processes caused by viscosity. If heat transfer is of no interest or concern, then energy conversion to heat is considered a loss in usable energy. The amount of useful energy converted to heat per pound of fluid flowing is designated by h_L , or the head loss. The one-dimensional work–energy equation now has the form

$$\frac{P_2}{\gamma} + \alpha_2 \frac{\bar{V}_2^2}{2g} + z_2 = \frac{P_1}{\gamma} + \alpha_1 \frac{\bar{V}_1^2}{2g} + z_1 - h_{L1-2} \quad (81)$$

where α_1, α_2 are the correction factors for a nonuniform velocity profile ($\alpha \geq 1$ with $\alpha = 1$ for uniform profile and \bar{V} is an average velocity. Looking at Fig. 16, this equation states that the frictional effects reduce the amount of incoming available energy [i.e., $P_1/\gamma + \alpha_1 \bar{V}_1^2/(2g) + z_1$] by an amount h_L , resulting in a reduced amount of available energy in the fluid leaving the control volume. In actuality, the h_L term reveals itself in an increase in internal energy (temperature) of the fluid or a heat transfer from the fluid. It should be noted that the Bernoulli equation (same as above except for the h_L term) is a statement that the amount of incoming and outgoing available energy are equal since a primary assumption is inviscid flow or no frictional losses.

Another phenomenon stemming directly from the effect of friction is flow separation. Separation occurs when the fluid is forced to decelerate too rapidly or change direction too quickly. The result is regions of reversed flow, formation of wakes and eddies, poor pressure recovery, and excessive friction losses (see Fig. 27a).

The nonuniform velocity profile occurring in viscous flow also causes vortices and cross currents to occur at certain locations. Vortices form in corners and at abrupt changes in cross section or flow direction. Cross currents or secondary flows occur at bends in the conduit. These secondary flows are the consequence of equal pressure gradients in the bend acting on fluid particles moving at different speeds in the flow cross section. The result is a spiral flow (superposed on the main flow) (Fig. 27b). Both vortices and secondary flow generate additional head losses and may cause some additional problems in hydraulic machinery.

5.2 External Flows

External flow are generally associated with lift and drag on solid bodies in a fluid of large extent. Although for ideal fluid there is no drag, this is not the case for real fluids. Frictional effects on the surface of the body create skin friction drag. That is, the no-slip fluid condition at the body surface creates a velocity profile and the resulting shear stress at the surface to occur. The frictional effects are confined to the “boundary layer” near the body where the flow may be laminar, turbulent, or both. Theoretical analysis of skin friction drag has been relatively successful. Some specific on lift and drag are presented in a subsequent section.

Separation in external flows is also caused by “adverse” pressure gradients that are forcing the flow to decelerate faster than it can and still remain “attached” to the boundary. Separation manifests itself as a turbulent wake behind the body (see Fig. 28), which creates considerable drag on the body largely resulting from the pressure difference between the front and rear. Smooth bodies with gradually changed form tend to generate less separation and lower drag than blunt or sharp-cornered objects.

5.3 Navier–Stokes Equations*

Application of Newton’s second law to an incompressible small fluid particle of dimension dx, dy, dz

*Illustrations and material extracted all or in part from the previous edition by Victor L. Streeter.

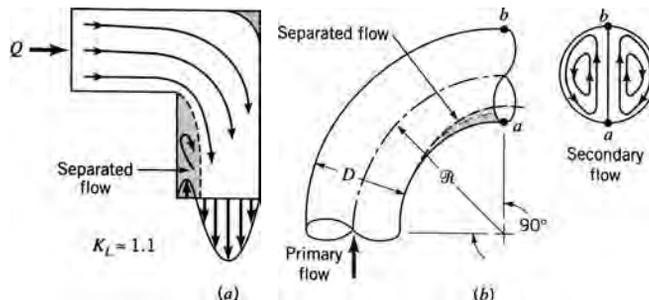

Fig. 27 Character of flow in 90°-turn elbow and subsequent viscous phenomena: (a) separated flow; (b) secondary flow. From Ref. 2.

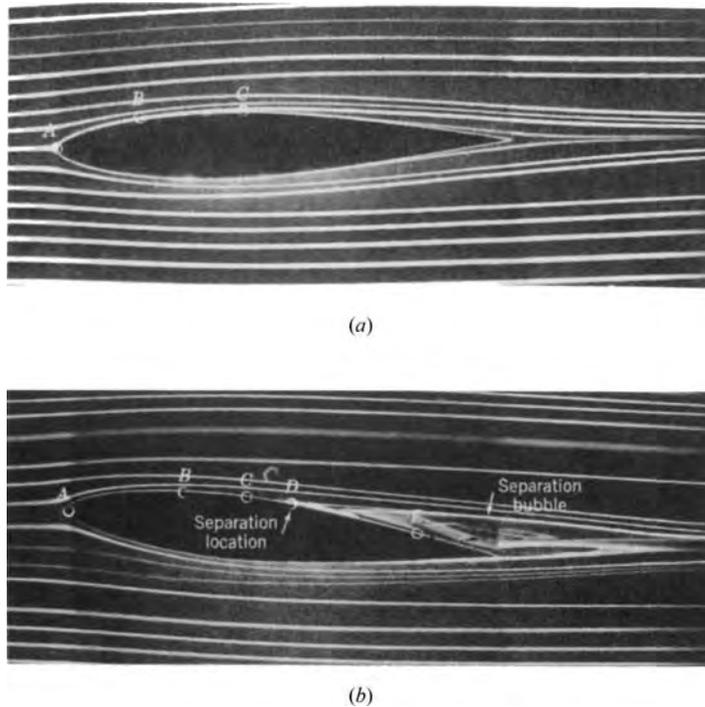

Fig. 28 Flow visualization past an airfoil at (a) 0° angle of attack with no flow separation and (b) 5° angle of attack with flow separation. From Ref. 2.

yields a set of equations comparable to the Euler equation previously derived, but now viscous effects are included. The equations are referred to as the Navier–Stokes equations, and they take the following form for laminar flow

$$\begin{aligned}
 X - \frac{1}{\rho} \frac{\partial p}{\partial x} + \nu \left(\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} + \frac{\partial^2 u}{\partial z^2} \right) \\
 = u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} + w \frac{\partial u}{\partial z} + \frac{\partial u}{\partial t} \quad (82)
 \end{aligned}$$

$$\begin{aligned}
 Y - \frac{1}{\rho} \frac{\partial p}{\partial y} + \nu \left(\frac{\partial^2 v}{\partial x^2} + \frac{\partial^2 v}{\partial y^2} + \frac{\partial^2 v}{\partial z^2} \right) \\
 = u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} + w \frac{\partial v}{\partial z} + \frac{\partial v}{\partial t} \quad (83)
 \end{aligned}$$

$$\begin{aligned}
 Z - \frac{1}{\rho} \frac{\partial p}{\partial z} + \nu \left(\frac{\partial^2 w}{\partial x^2} + \frac{\partial^2 w}{\partial y^2} + \frac{\partial^2 w}{\partial z^2} \right) \\
 = u \frac{\partial w}{\partial x} + v \frac{\partial w}{\partial y} + w \frac{\partial w}{\partial z} + \frac{\partial w}{\partial t} \quad (84)
 \end{aligned}$$

where X , Y , Z are external force components per unit mass in the xyz directions, respectively; ρ is the mass

density, considered constant for incompressible flow; p is the average pressure at a point; ν is the kinematic viscosity; and u , v , w are the velocity components in the xyz directions.

These simultaneous, nonlinear, differential equations cannot be integrated except for extremely simple flow cases where many of the terms are neglected. They contain the basic assumption that the stresses on a particle may be expressed as the most general linear function of the velocity gradients.

Boundary Conditions A real fluid in contact with a solid boundary must have a velocity exactly equal to the velocity of the boundary; this is much more restrictive than for an inviscid fluid where no restrictions are placed on tangential velocity components at a boundary.

When two fluids are flowing side by side, a dynamical boundary condition arises at the interface. Applying the equation of motion to a thin layer of fluid enclosing a small portion of the interface shows that the terms containing mass are of higher order of smallness than the surface stress intensities and hence that the stresses must be continuous through the surface.

In general, the viscous boundary conditions at a solid surface give rise to rotational flow. Although the Navier–Stokes equations are satisfied by a velocity

potential, since the viscous terms drop out, the viscous boundary conditions cannot be satisfied

Continuity The continuity equation must hold, as in the case of inviscid flow. It is

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} = 0 \quad (85)$$

Several examples of flow at low Reynolds numbers are given. It is assumed that in each case any turbulent fluctuation are completely damped out by viscous action, and the dominant flow is one dimensional with incompressible conditions.

Flow between Parallel Boundaries: Pressure-Driven Flow. For steady flow between fixed parallel boundaries at low Reynolds numbers, the Navier–Stokes equations can be greatly reduced. Taking the coordinates as shown in Fig. 29 and assuming a pressure gradient exists in the x direction which drives the flow, the differential equations reduce to

$$\frac{\partial}{\partial x}(p + \gamma h) = \mu \frac{\partial^2 u}{\partial z^2} \quad (86)$$

where h is measured vertically upward and γ is the specific weight of the fluid.

Integrating and introducing the boundary conditions $u = 0$ for $z = \pm b$, which are the no-slip conditions for this pressure-driven flow,

$$u = \frac{z^2 - b^2}{2\mu} \frac{\partial}{\partial x}(p + \gamma h) \quad (87)$$

As the z^2 term implies, and as is shown in Fig. 29, such a velocity profile is a parabolic one. It has the maximum value at the center of the pipe—hence maximum velocity. Given a linear pressure gradient, which is an acceptable assumption for such a laminar flow, the derivative term becomes a constant, and the velocity profile becomes only a function of radial distance from the center; thus it remains the same along the length of the pipe (assuming the pipe does not change in direction, diameter, or makeup). Keep in

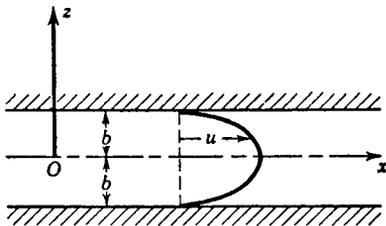

Fig. 29 Viscous flow between fixed parallel boundaries.

mind that the sustainability of laminar flow in a pipe is subject to various conditions. Therefore, once the flow characteristics change (e.g., transition to turbulence, development of secondary flows) this formula is no longer applicable.

Although the velocity potential function is essentially for irrotational flows (i.e., inviscid cases), for this special case, it is possible to express the parabolic velocity profile in terms of a velocity potential

$$\begin{aligned} u &= \frac{z^2 - b^2}{2\mu} \frac{\partial}{\partial x}(p + \gamma h) \\ &= \frac{\partial}{\partial x} \left[(p + \gamma h) \left(\frac{z^2 - b^2}{2\mu} \right) \right] = \frac{\partial \phi}{\partial x} \end{aligned} \quad (88)$$

where ϕ , the velocity potential, is the quantity in brackets.

Flow between Parallel Boundaries: Shear-Driven Flow. A similar approach can be used for flow between parallel plates, one of which is moving with a constant speed U in the x direction. In this case, the motion of the fluid is due to the viscous force between the moving plate and the adjacent fluid layer. Thus, despite the absence of a pressure gradient, there will be a flow. Without the pressure gradient, the simplified version of the Navier–Stokes equations further simplify to

$$\frac{d^2 u}{dz^2} = 0 \quad (89)$$

The relevant boundary conditions for this case are $u = 0$ for $z = -b$ and $u = U$ for $z = +b$. Again integrating and using the boundary conditions, the velocity profile becomes

$$u = \frac{U}{2} \left(1 + \frac{z}{b} \right) \quad (90)$$

This results in a linear velocity profile between the plates.

Flow between Parallel Boundaries: Combined Effects of Pressure Gradient and Shear. One can also have the effect of both pressure gradient and shear for flow between parallel plates. For that case, the simplified version of the Navier–Stokes equations is the same as that for the pressure-driven flow, but the boundary conditions are those for the shear driven flow. The resultant velocity profile is

$$u = \frac{U}{2} \left(1 + \frac{z}{b} \right) + \frac{z^2 - b^2}{2\mu} \frac{\partial}{\partial x}(p + \gamma h) \quad (91)$$

This is still a parabolic velocity profile but now the maximum velocity has been displaced from the middle plane.

Theory of Lubrication The equations for two-dimensional viscous flow are applicable to the case of a slider bearing and can be applied to journal bearings. The simple case of a bearing of unit width is developed here, under the assumption that there is no flow out of the sides of the block, that is, normal to the plane of Fig. 30, where the clearance b is shown to a greatly exaggerated scale. The motion of a bearing block sliding over a plane surface, inclined slightly so that fluid is crowded between the two surfaces, develops large supporting forces normal to the surfaces. The angle of inclination is very small; therefore the differential equations of the preceding example apply. Since elevation changes also are very small and flow is in the x direction only, the equations reduce to

$$\frac{\partial p}{\partial x} = \mu \frac{\partial^2 u}{\partial z^2} \quad \frac{\partial p}{\partial z} = 0 \quad (92)$$

Considering the inclined block stationary and the plane surface in motion and taking the pressure at the two ends of the block as zero, the boundary conditions become $x = 0, x = L, p = 0; z = 0, u = U; z = b, u = 0$. Integrating the equations and considering unit width normal to the figure the discharge Q and pressure distribution are determined:

$$Q = \frac{U b_1 b_2}{b_1 + b_2} \quad p = \frac{6\mu U x (b - b_2)}{b^2 (b_1 + b_2)} \quad (93)$$

The last relation shows that b must be greater than b_2 for positive pressure buildup in the bearing. The point of maximum pressure and its value are

$$x|_{p_{\max}} = \frac{b_1 L}{b_1 + b_2} \quad p_{\max} = \frac{3}{2} \frac{\mu U L}{b_1 b_2} \frac{b_1 - b_2}{b_1 + b_2} \quad (94)$$

The force P which the bearing will sustain is

$$P = \int_0^L p \, dx = \frac{6\mu U L^2}{b^2 (k - 1)^2} \left[\ln k - \frac{2(k - 1)}{k + 1} \right] \quad (95)$$

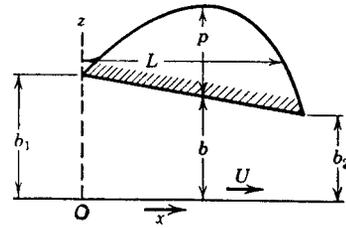

Fig. 30 Slider bearing.

The maximum bearing load is obtained for $k = 2.2$, yielding

$$P = 0.16\mu \frac{UL^2}{b_2^2} \quad D = 0.75\mu \frac{UL}{b_2} \quad (96)$$

The ratio

$$\frac{P}{D} = 0.21 \frac{L}{b_2} \quad (97)$$

can be made very large since b_2 is small. For $k = 2.2$, the line of action of the bearing load is at $x = 0.58L$. In general the line of action is given by

$$\bar{x} = \frac{L}{2} \left[\frac{2k}{k - 1} - \frac{k^2 - 1 - 2k \ln k}{(k^2 - 1) \ln k - 2(k - 1)^2} \right] \quad (98)$$

Journal bearings are computed in an analogous manner. In general the clearances are so small compared with the radius of curvature of the bearing surface that the equations for plane motion can be applied.

Flow through Circular Tubes For steady flow through circular tubes with values of the Reynolds number, $UD\rho/\mu$, less than 2000, the motion is laminar. Equilibrium conditions on a cylindrical element concentric with the tube axis (Fig. 31) show that the shear stress varies linearly from zero at the pipe axis to a maximum $\Delta p r_0 / 2\Delta L$ at the wall, where $\Delta p / \Delta L$ is the drop in pressure per unit length of tube. In one-dimensional laminar flow the relation between shear

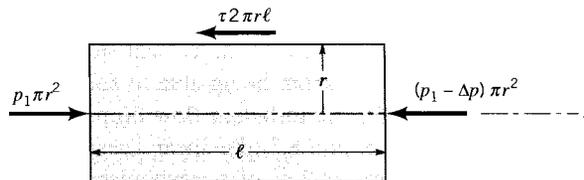

Fig. 31 Free-body diagram of cylinder of fluid in steady laminar flow through circular pipe. From Ref. 2.

stress and the velocity gradient is given by Newton's law of viscosity,

$$\tau = -\mu \frac{du}{dr} \quad (99)$$

Using this relation for the value of shear stress, the velocity distribution is found to be

$$u = \frac{\Delta p}{\Delta L} \frac{r_0^2 - r^2}{4\mu} \quad (100)$$

where r is the distance from the tube axis. The maximum velocity is at the axis:

$$u_{\max} = \frac{\Delta p r_0^2}{\Delta L 4\mu} \quad (101)$$

The average velocity is half the maximum velocity:

$$V = \left(\frac{\Delta p}{\Delta L} \right) \left(\frac{r_0^2}{8\mu} \right) \quad (102)$$

The discharge, obtained by multiplying average velocity by cross-sectional area, is

$$Q = \left(\frac{\Delta p}{\Delta L} \right) \left(\frac{\pi D^4}{128\mu} \right) \quad (103)$$

which is the *Hagen–Poiseuille* law. The preceding equations are independent of the surface condition in the tube, and they therefore hold for either rough or smooth tubes as long as the flow is laminar.

Viscous Flow around a Sphere: Stokes's Law

The flow of an infinitesimal viscous fluid around a sphere at very low Reynolds numbers ($Re \ll 1$, which states that viscous forces are dominant compared to inertial forces) has been solved by Stokes.³ The Navier–Stokes equations with the acceleration terms omitted must be satisfied as well as continuity and the boundary condition that the velocity vanish at the surface of the sphere. Stokes's solution is

$$u = U \left[\frac{3}{4} \frac{ax^3}{r^3} \left(\frac{a^2}{r^2} - 1 \right) + 1 - \frac{1}{4} \frac{a}{r} \left(3 + \frac{a^2}{r^2} \right) \right] \quad (104)$$

$$v = U \frac{3}{4} \frac{axy}{r^3} \left(\frac{a^2}{r^2} - 1 \right) \quad (105)$$

$$w = U \frac{3}{4} \frac{axz}{r^3} \left(\frac{a^2}{r^2} - 1 \right) \quad (106)$$

$$p = -\frac{3}{2} \frac{\mu U a x}{r^3} \quad (107)$$

The radius of a sphere is a ; the undisturbed velocity is in the x direction, $u = U$; and p is the average dynamic pressure at a point. The drag on a sphere is made up from the pressure difference over the surface of the sphere and from the shear stress. The viscous drag due to shear stress is twice as great as that due to the pressure difference. The total drag is

$$D = 6\pi a\mu U \quad (108)$$

This is known as *Stokes's law*.

The settling velocity of small spheres may be obtained by writing the equation for drag, weight of particle, and buoyant force. Solving for the settling velocity,

$$U = \frac{2}{9} \frac{a^2}{\mu} (\gamma_s - \gamma) \quad (109)$$

where γ_s is the specific weight of the solid particle. Stokes's law has been found by experiment to hold for Reynolds numbers below 1, that is,

$$\frac{2a\rho U}{\mu} < 1 \quad (110)$$

6 SIMILITUDE AND DIMENSIONAL ANALYSIS

Similitude and dimensional analysis are inextricably tied to experimental testing and the analysis of experimental data. Principles of similitude permit the prediction of prototype behavior based on the performance of models. Techniques of dimensional analysis permit the efficient and logical presentation of test data in dimensionless form. Even in recent times when CFD techniques are supplementing laboratory work at an increasing pace (note: CFD will never totally replace experiments), many flow phenomena are so complex as to warrant experimental investigation.

6.1 Similitude

For complete similitude the model and the prototype must be geometrically, kinematically, and dynamically similar. In this context, the prototype is the physical system for which you are trying to predict the behavior, while the model (typically a scaled version of the prototype) is the device used for testing in the laboratory. Geometric similarity exists when the model is a photographic reduction (or enlargement) of the prototype. Kinematic similarity occurs when the streamline pattern in the model is a photographic reduction (or enlargement) of that of the prototype. Also ratios of velocity vectors at corresponding points are constant. Dynamic similarity requires that the ratios of similar forces at all corresponding points in the flow be constant. In general, if geometric similarity and dynamic similarity exist, then kinematic similarity is guaranteed.

Quantitative relationships for dynamic similarity are obtained by considering the contributing forces acting on a fluid particle. Potential contributing forces include viscosity (shear), pressure, gravity, elasticity, and surface tension. These forces all contribute to the acceleration of the fluid particle in the prototype flow

$$\mathbf{F}_v + \mathbf{F}_p + \mathbf{F}_g + \mathbf{F}_e + \mathbf{F}_s = m\mathbf{a} \\ = -\mathbf{F}_I \quad (\text{inertial force}) \quad (111)$$

Dividing by the inertial force and considering the prototype (P),

$$\left(\frac{\mathbf{F}_v}{\mathbf{F}_I}\right)_P + \left(\frac{\mathbf{F}_p}{\mathbf{F}_I}\right)_P + \left(\frac{\mathbf{F}_g}{\mathbf{F}_I}\right)_P + \left(\frac{\mathbf{F}_e}{\mathbf{F}_I}\right)_P \\ + \left(\frac{\mathbf{F}_s}{\mathbf{F}_I}\right)_P = -1 \quad (112a)$$

If the same process is followed in the model (m),

$$\left(\frac{\mathbf{F}_v}{\mathbf{F}_I}\right)_m + \left(\frac{\mathbf{F}_p}{\mathbf{F}_I}\right)_m + \left(\frac{\mathbf{F}_g}{\mathbf{F}_I}\right)_m + \left(\frac{\mathbf{F}_e}{\mathbf{F}_I}\right)_m \\ + \left(\frac{\mathbf{F}_s}{\mathbf{F}_I}\right)_m = -1 \quad (112b)$$

This scaling procedure renders the force polygons at the corresponding points in the model and prototype as congruent provided the force ratios for each source of force are the same in the model and prototype. In fact, the scaled polygons are congruent if *all but one* of the force ratios are equal. This relationship can be summarized as follows:

Viscous Forces:

$$\left(\frac{\rho V l}{\mu}\right)_m = \left(\frac{\rho V l}{\mu}\right)_P \quad (113)$$

where $\rho V l / \mu = \text{Reynolds number, } \text{Re} = \text{inertia force/viscous force.}$

Pressure Forces:

$$\left(\frac{P}{\rho V^2}\right)_m = \left(\frac{P}{\rho V^2}\right)_P \quad (114)$$

where $P / \rho V^2 = \text{Euler number, } E = \text{pressure force/inertia force.}$

Gravity Forces:

$$\left(\frac{V^2}{g l}\right)_m = \left(\frac{V^2}{g l}\right)_P \quad (115)$$

where $V / \sqrt{g l} = \text{Froude number, } F = \text{inertia force/gravitational force.}$

Elastic Forces:

$$\left(\frac{V}{a}\right)_m = \left(\frac{V}{a}\right)_P \quad (116)$$

where a is the speed of sound and $V/a = \text{Mach number, } M = \text{inertia force/compression force.}$

Surface Tension Forces:

$$\left(\frac{\rho V^2 l}{\sigma}\right)_m = \left(\frac{\rho V^2 l}{\sigma}\right)_P \quad (117)$$

where $\rho V^2 l / \sigma = \text{Weber number, } W = \text{inertia force/surface tension force.}$

In most fluid problems, some of these forces are negligible and can be ignored in model-prototype relationships. For example, if there is no free surface and flows are well below the sonic velocity, then only viscous and pressure forces are important. In this case, equality of Reynolds numbers would guarantee similarity. Typically, pressure forces are always in existence and the Euler number is the force ratio omitted in specifying similarity (as noted earlier).

Example 1. Model testing of a new submarine is to be conducted in a wind tunnel using standard air at sea level conditions. Due to the limitations on the test section size, the model needs to be a one-twentieth-scale version of the prototype. If the actual submarine will have a velocity of $V_p = 0.5$ ft/sec in sea water at 20°C , what must the air velocity be in the wind tunnel for the model to achieve dynamic similarity?

For dynamic similarity, $\text{Re}_p = \text{Re}_m$, or $(\rho V l / \mu)_m = (\rho V l / \mu)_P$. Solving for model velocity V_m yields

$$V_m = \frac{l_P}{l_m} \frac{\rho_P}{\rho_m} \frac{\mu_m}{\mu_P} V_P$$

The necessary values are found as follows:

$$\rho_m = 0.00238 \text{ slug/ft}^3 \quad \mu_m = 3.74 \times 10^{-7} \text{ lb-sec/ft}^2$$

$$\rho_P = 2.0 \text{ slugs/ft}^3 \quad \mu_P = 2.23 \times 10^{-5} \text{ lb-sec/ft}^2$$

So, the required wind tunnel velocity is found from

$$V_m = \left(\frac{20}{1}\right) \left(\frac{2.0}{0.00238}\right) \left(\frac{3.74 \times 10^{-7}}{2.23 \times 10^{-5}}\right) (0.5) \\ = 141 \text{ ft/sec}$$

There are situations where complete similarity cannot be practically achieved. For example, in the modeling of ship hulls, if water is used as the modeling fluid the model must be as large as the prototype. This is true because viscous and gravity forces predominate

and both Reynolds and Froude numbers must be equal to guarantee similarity. In this case, to get around the problem, the model–prototype relation is determined by the Froude number equality and the viscous effects on hull drag are determined through other means. This situation is known as incomplete similarity or distorted model.

In other flow situations such as rivers and harbors, the lateral dimensions are so large compared to the vertical dimensions that geometric scaling would make the model so shallow as to be under strong surface tension effects. Also the boundary roughness would be reduced to supersmoothness. In these situations, two different model scales are used: one for horizontal dimensions, another for vertical dimensions. These models generally have to be adjusted for “scale effects” by employing artificial roughness to properly represent prototype behavior.

6.2 Dimensional Analysis

Dimensional analysis is based on the principle that meaningful physical relationships between quantities must be dimensionally homogeneous; that is, both sides of an equation must have the same dimensions. The four basic dimensions used in fluid mechanics are force (F), mass (M), length (L), and time (T). In fact, the dimension of force is related to the dimensions of mass, length, and time through Newton’s second law:

$$F = M \frac{L}{T^2} \quad (118)$$

The units of force are said to be *equivalent* to the units of mass \times length/time squared.

The principle of dimensional homogeneity can be used to develop a formal procedure for establishing relations between physical quantities and, most importantly, dimensionless groups. Dimensionless groups of quantities are extremely valuable in the analysis and presentation of experimental data. Their use permits large amounts of data to be presented on simple graphs, graphs with parametric relationships, or in some more complex cases multicorrelational graphs.

For example, consider the case of the drag force on a sphere falling at constant velocity in a very viscous liquid. Drag (D) is a function of velocity (V), size (d), and viscosity (μ):

$$D = f(V, d, \mu)$$

In basic dimensions,

$$F = f' \left(\frac{L}{T}, L, \frac{FT}{L^2} \right)$$

The only combination of quantities on the right-hand side that will make the relationship dimensionally correct is

$$D = KVd\mu \quad (119)$$

where K is a dimensionless constant. Thus, by dimensional reasoning alone, Stokes’s law has been deduced. Sometimes the relationship does not fall out so easily, quantities may need to have positive or negative exponents to create a combination that is dimensionally correct.

However, formal dimensional analysis does not always offer a unique approach to generating the desired dimensionless groups. A more modern and intuitive method, called the Buckingham Π theorem, is more useful. This theorem informs the user as to how many dimensionless groups may be formed and leaves the configuration of each group up to the user. This freedom, coupled with knowledge of the important similarity principles, permits the user to make a good choice of the proper groups.

According to the Buckingham Π theorem, a problem described by k variables can be expressed in terms of $k - r$ nondimensional Π terms, where r is the minimum number of reference dimensions involved in the problem. For example, when establishing the quantities affecting the drag on a ship’s hull, the list includes

$$D(\text{drag}) = f(l, V, \mu, \rho, g) \quad (120)$$

or

$$f'(D, l, V, \mu, \rho, g) = 0 \quad (121)$$

The Π theorem allows the formation of three dimensionless groups ($k - r = 6 - 3$). Knowing that viscous and gravitational effects are most significant in affecting drag, the dimensionless groups of Reynolds number and Froude number are selected. Then the drag force D is combined into a third group. The final relationship states that the nondimensional drag (i.e., drag coefficient) is a function of the Reynolds and Froude numbers:

$$\frac{D}{\rho l^2 V^2} = \phi \left(\frac{\rho V l}{\mu}, \frac{V^2}{g l} \right) \quad (122)$$

or

$$C_D = \phi(\text{Re}, F^2) \quad (123)$$

The use of this kind of nondimensional expression allows the experimenter to make use of scale-size models and can perform experiments more easily and affordably by reducing the number of parameters that need to be varied. Once the experiments are performed on the model, the experimenter can plot all data on one graph using the nondimensional values; for example, $D/\rho l^2 V^2$ as the ordinate, Re as the abscissa, and F as the parametric variable.

7 FLOW IN CLOSED CONDUITS

Flow through a conduit may be steady or unsteady, uniform or nonuniform, and laminar or turbulent. Steady flow refers to flow at constant rate, uniform

flow to prismatic sections of conduit, and laminar flow to those cases where viscous forces predominate and the losses are a linear function of the velocity; whereas for turbulent flow the losses vary as the velocity to some power (1.7–2.0), depending in part upon the Reynolds number.

The classical methods of hydrodynamics applying to an ideal fluid are of little value in solving flow problems in conduits, although they are extremely useful in connection with flow around immersed bodies (see Section 9). The nature of turbulent flow, on the other hand, is not sufficiently well understood to permit computation of the energy losses for given boundary conditions and rates of flow and hence recourse must generally be taken to experimentation.

The work–energy equation is of first importance in solving flow problems. Momentum relationships are of use in certain cases in which the forces acting on the fluid are known or are desired. In special situations where both the energy and momentum equations are applicable, the energy loss may be computed without recourse to experimentation. The continuity equation in steady flow usually states that the flow past every cross section is the same. When the fluid is compressible, this is a statement of mass or weight flow but for liquids it is sufficient to deal with volume rates only. The three types of equations (energy, momentum, and continuity), together with the experimentally determined loss relationships, provide the general framework for solving closed-conduit problems.

7.1 Velocity Distribution*

The velocity distribution for established laminar flow through round tubes and between parallel plates has been discussed under laminar fluid motion, Section 5.

Development of Flow The velocity distribution for fully developed uniform flow in a closed conduit is determined by the relationship between the radial velocity gradient and the shear stress. In turbulent flow the velocity distribution cannot be derived exactly, although much has been accomplished in recent years in the analytical approach to rational velocity–distribution equations.

Downstream from any change in cross section or direction, there is a length over which the velocity distribution regains its characteristic form (entrance region), depending on the shape of cross section, the wall roughness, and the Reynolds number. For example (follow the description from Fig. 32), when the flow passes from a reservoir through a rounded entrance into a conduit, the velocity is practically constant over the section at the upstream end of the conduit. Such flow during the initial stages is therefore practically irrotational, since the boundary layer is very thin. The effect of boundary resistance, however, is to retard the fluid in the wall vicinity, resulting, through lateral transmission of shear, in a continuous growth of the boundary layer with distance from the inlet. Since the mean velocity must nevertheless remain constant, the central portion of the fluid is simultaneously accelerated until the forces of shear and pressure gradient reach equilibrium as the velocity distribution of uniform flow becomes fully developed some distance downstream. If the flow experiences a change in cross section or direction, it will undergo another developing flow region until fully developed flow is once again achieved (see Fig. 32).

For laminar flow experiments by Nikuradse give the entrance length l for development of flow as

$$\frac{l_e}{D} = 0.06 \text{ Re} \quad (124)$$

where D is the pipe diameter and the Reynolds number is based on average velocity and diameter.

*Illustrations and material extracted all or in part from previous edition by Victor L. Streeter.

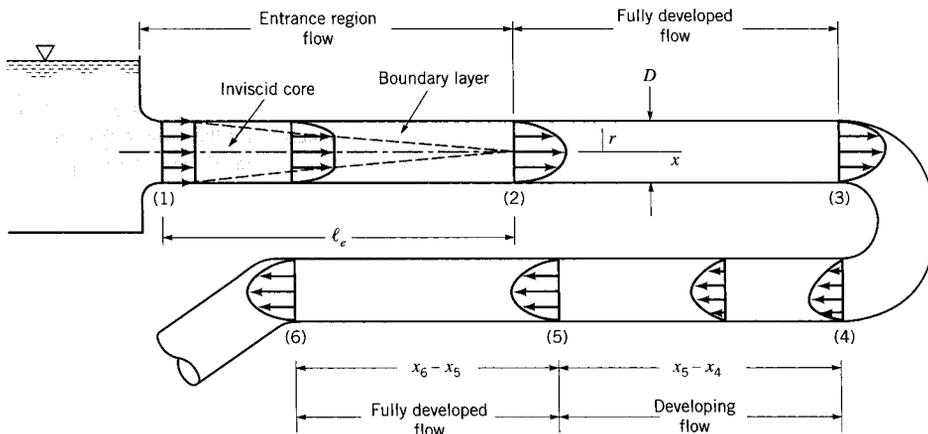

Fig. 32 Entrance region, developing flow, and fully developed flow in pipe system. From Ref. 2.

In turbulent flow, the transition to the established velocity distribution is effected in a much shorter reach, because of the pronounced mixing action that then prevails. Nikuradse's experiments indicate that a distance of 25–40 diameters is sufficient and that the length is not so dependent on the Reynolds number.

Rational Formulas for Fully Developed Turbulent Flow In turbulent flow, the ratio of shear stress to velocity gradient depends not only on the physical properties of the fluid but also on the characteristics of the flow.

Stanton first stated that the turbulent velocity distribution in the central portions of a conduit has a form that is independent of the wall roughness and viscous effects provided that the wall shear remains the same. In equation form

$$\frac{v_{\max} - v}{\sqrt{\tau_o/\rho}} = F\left(\frac{r}{r_o}\right) \tag{125}$$

where v_{\max} is the velocity at the pipe axis, v is the velocity at the distance r from the axis, r_o is the pipe radius, τ_o is the wall shear, ρ is the mass density of fluid and F is an unknown function. The proof is evident by an inspection of the Nikuradse data on smooth and sand-roughened pipes, given in Fig. 33; k is the diameter of sand grains cemented to the pipe walls.

Based on the preceding, von Karman⁴ obtained the formula for smooth pipes,

$$\frac{v}{\sqrt{\tau_o/\rho}} = C_1 + \frac{1}{\kappa} \ln\left(\sqrt{\frac{\tau_o}{\rho}} \frac{y}{\nu}\right) \tag{126}$$

where κ is a universal constant having the value 0.40 and ν is the kinematic viscosity. Figure 34, based on Nikuradse's tests, shows the value of C_1 to be 5.5 for best agreement with the data. In the immediate vicinity of the pipe wall, through a film called the *laminar sublayer*, the velocity is given closely by $v = y\tau_o/\mu$. This may be written as

$$\frac{v}{\sqrt{\tau_o/\rho}} = \sqrt{\frac{\tau_o}{\rho}} \frac{y}{\nu} \tag{127}$$

and is plotted in Fig. 34. The intersection of the two curves may be taken arbitrarily as the border between the two types of flow, although actually there is a transition phase from the laminar to the turbulent zone. From the figure, the laminar film has the thickness

$$\delta = \frac{11.6\nu}{\sqrt{\tau_o/\rho}} \tag{128}$$

For rough pipes von Karman obtained the formula

$$\frac{v}{\sqrt{\tau_o/\rho}} = C_2 + \frac{1}{\kappa} \ln\left(\frac{y}{k}\right) \tag{129}$$

Figure 35 shows the Nikuradse sand-roughened pipe tests. From these data, $C_2 = 8.5$.

The two logarithmic equations do not give a zero slope of the velocity distribution curve at the center line. This is a defect in the formulas that, nevertheless, has little significance from a practical viewpoint. The equations actually portray the true velocity distribution in the central region of the flow very well, although they were derived for the region near the wall.

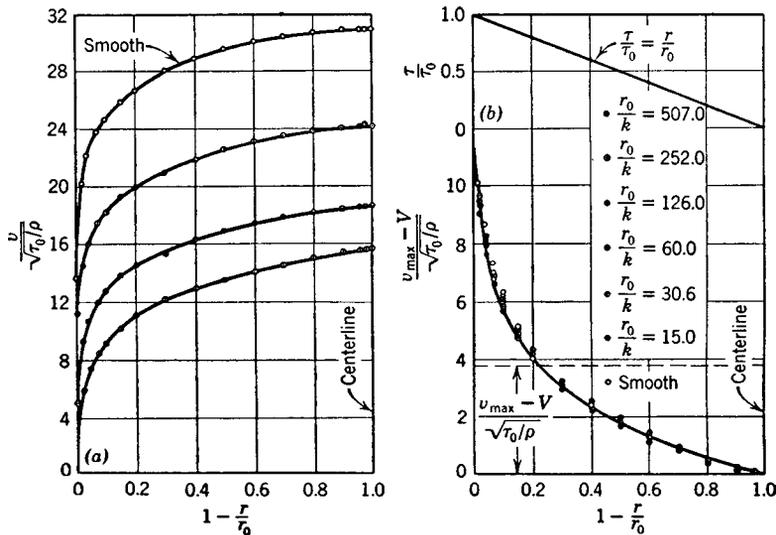

Fig. 33 Generalized plot of velocity distribution for smooth and rough pipes.

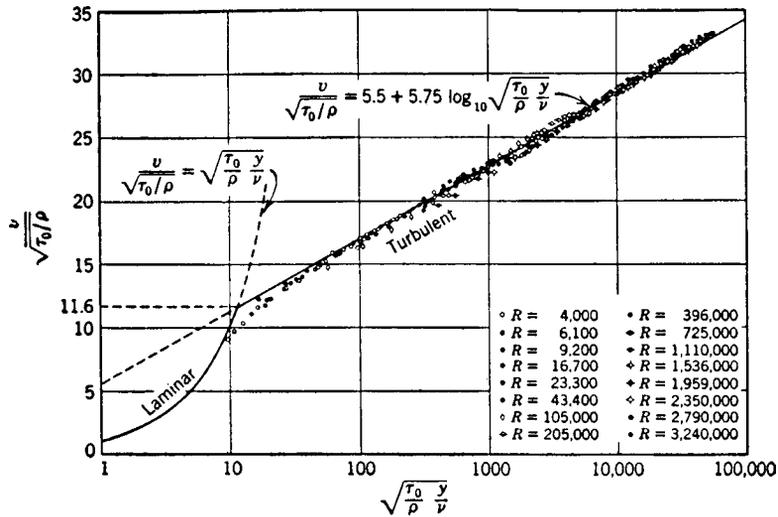

Fig. 34 Universal velocity distribution for smooth pipes.

Energy and Momentum Correction Factors In writing the work-energy equation between two cross sections of a conduit, it is usually satisfactory to express the mean kinetic energy per unit weight simply as $V^2/2g$, where V is the average velocity at a section. As discussed earlier, however, this is strictly true only when the velocity is constant over both cross sections. For laminar flow, the correction α by which $V^2/2g$ must be multiplied to give the true mean value is 2.0, and for sections where there is back flow the factor may be even larger. Values of α and β based on Prandtl-Karman turbulent velocity distribution equations are given in Fig. 36.

7.2 Pipe Friction*

A general equation for solving one-dimensional pipe flow problems is the work-energy equation

$$\frac{P_1}{\gamma} + \alpha_1 \frac{V_1^2}{2g} + z_1 = \frac{P_2}{\gamma} + \alpha_2 \frac{V_2^2}{2g} + z_2 + \sum h_{L1-2} \tag{130}$$

*Material and illustrations used by permission from G. Z. Watters, *Analysis and Control of Unsteady Flow in Pipelines* Butterworth, Stoneham, MA, 1984.

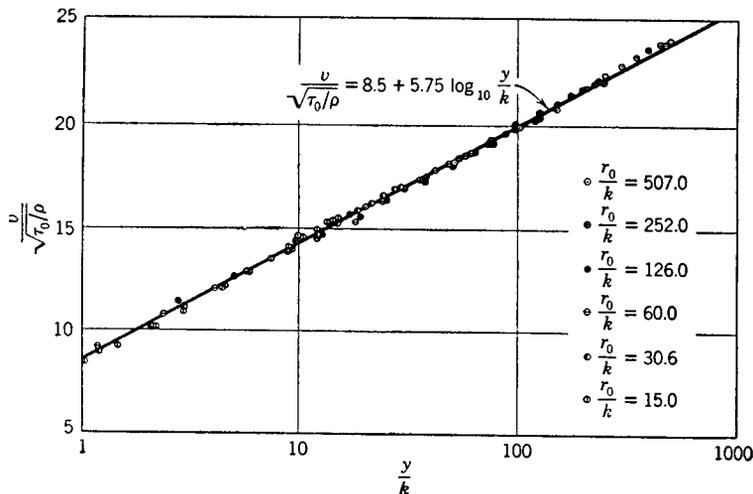

Fig. 35 Universal velocity distribution for rough pipes.

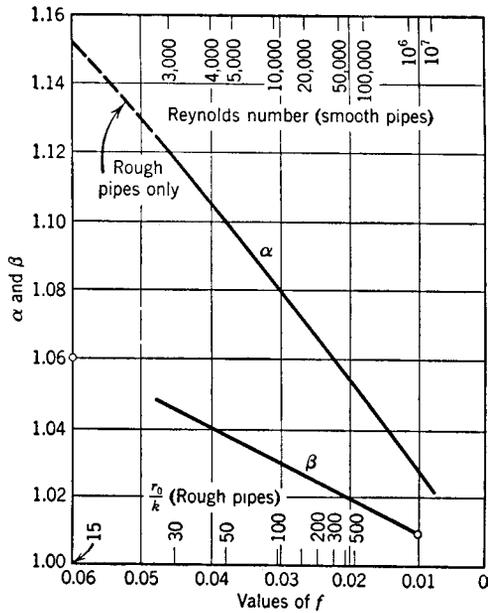

Fig. 36 Energy and momentum correction factors for smooth and rough pipes.

where $\sum h_{L_{1-2}}$ is the total of all the friction losses between cross sections 1 and 2. These losses can be divided into two general categories: pipe friction and minor losses. Pipe friction losses are those caused by the continuing viscous action along the conduit. Minor losses are the result of the additional friction losses over and above the pipe friction. These losses are caused by flow separation, eddies, and wakes that are generated by changes in flow direction or cross section and pipe components such as a valve. This section deals with pipe friction.

Pipe friction losses for circular cylindrical pipes depend on the flow velocity, pipe size, fluid viscosity, and wall roughness. In regard to wall roughness, friction loss specifically depends on relative roughness, that is, the absolute roughness compared with the pipe

diameter. The various formulas for pipe friction loss differ in how they incorporate wall roughness into the head loss equation. The formulas in most common use today are the following:

$$h_f = f \frac{L}{D} \frac{V^2}{2g} \quad \text{(Darcy-Weisbach)} \quad (131)$$

$$V = 0.55 C D^{0.63} S^{0.54} \quad \text{(Hazen-Williams)} \quad (132)$$

$$V = \frac{0.59}{n} D^{2/3} S^{1/2} \quad \text{(Manning)} \quad (133)$$

where f , C , n are friction coefficients; S is head loss per unit length of pipe, D is inside pipe diameter, and L is pipe length. The Darcy-Weisbach formula, commonly referred to as the Darcy formula, is the most general in application. It can be used for a variety of liquids and gases, for laminar and turbulent flow, and for rough or smooth pipes. Its main disadvantage is the fact that the friction factor f is often dependent on one of the design unknowns (pipe diameter or discharge) and an iterative solution results. However, engineers are increasingly using this formula because of its breadth of application.

The Hazen-Williams formula was developed for the computation of friction losses for water flowing in distribution system pipes. It works well for moderately smooth pipes (such as cast iron), but it is not accurate for rough pipes, small pipes, or laminar flow.

The main task is to find the friction factor f . The value depends on two parameters: Reynolds number and relative roughness. The Reynolds number measures the effect of viscosity on f and is defined as

$$Re = \frac{VD}{\nu} \quad (134)$$

where ν is the kinematic viscosity of the fluid. The relative roughness measures the roughness of the pipe wall relative to the pipe diameter and is expressed as k/D , where k is a measure of pipe wall roughness.

For convenience, Table 6 was compiled from several sources to provide assistance in selecting roughness values for various pipe materials. It should be

Table 6 Roughness Values for Commercial Pipes

Pipe Material	k (in.)	C (Hazen-Williams)	n (Manning)
Riveted steel	0.036-0.36	110	0.013-0.017
Concrete	0.012-0.12	120-140	0.011-0.014
Cast iron (new)	0.010	130	0.013
Cast iron (old)	—	100	0.015-0.035
Galvanized iron	0.0060	—	0.016
Asphalted iron	0.0048	—	0.013
Welded steel	0.0018	120	0.012
Asbestos cement	—	140	0.011
Copper, aluminum tube	Smooth	150	0.010
PVC, plastic	Smooth	150	0.009

noted that, typically, there are several inconsistencies between the roughness values given in Table 6 for the different formulas and those generated using the following equations.

The Reynolds number and the relative roughness are used in conjunction with the Moody diagram (Fig. 37) to find the f value. The use of the Moody diagram can best be shown by example.

Example 2. Compute the friction factor f for the flow of 1500 gpm of water at normal temperature in a 10-in. cast-iron pipe.

$$V = \frac{1500}{449 \frac{\pi}{4} \left(\frac{10}{12}\right)^2}$$

$$= 6.13 \text{ ft/sec}$$

From Table 6

$$\frac{k}{D} = \frac{0.01}{10} = 0.001$$

Using $\nu = 1.22 \times 10^{-5} \text{ ft}^2/\text{sec}$, from Eq. (133)

$$\text{Re} = \frac{6.13 \times (10/12)}{1.22 \times 10^{-5}}$$

$$= 418,000$$

From Fig. 37, $f = 0.020$.

Both the Hazen-Williams and Manning formulas can be manipulated into the same form as the Darcy formula. The resulting f expressions may be compared

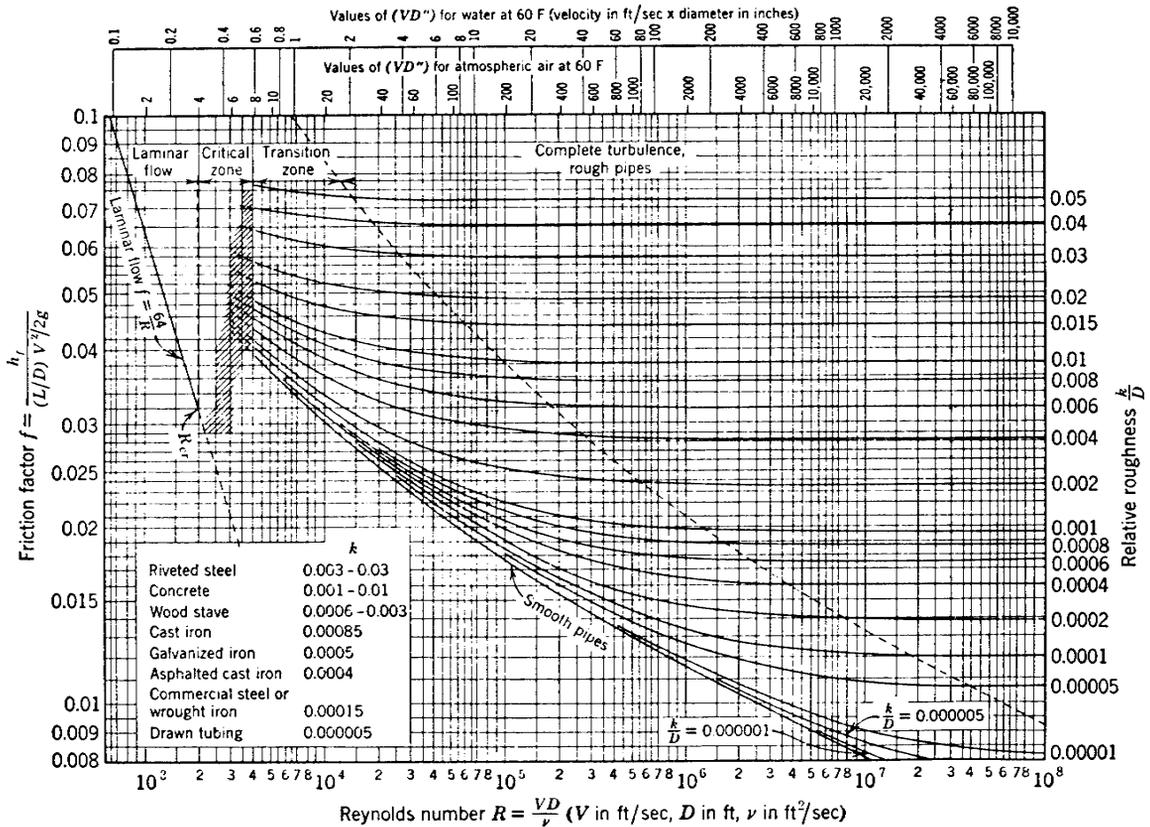

Fig. 37 Resistance diagram. Reproduced with permission from L. F. Moodes, "Friction Factor for Pipe Flow," *Transactions ASME*, November 1944, Princeton, NJ.

with the Darcy f value to deduce the situations where these formulas may be confidently applied:

$$h_f = \left(\frac{1090}{C^{1.85} \text{Re}^{0.15}} \right) \frac{L}{D} \frac{V^2}{2g} \quad (\text{Hazen-Williams}) \quad (135)$$

$$h_f = \left(\frac{185n^2}{D^{1/3}} \right) \frac{L}{D} \frac{V^2}{2g} \quad (\text{Manning}) \quad (136)$$

Both C and n are roughness values that can be obtained from tables such as Table 6. For additional information on C values, see Davis and Sorensen⁵ for n values, see Chow.⁶

The areas of applicability of the three head loss formulas can be deduced. It is clear that the Manning formula is indeed a rough pipe formula because the Reynolds number does not appear. On the other hand, the Hazen-Williams formula is a relatively smooth pipe formula because the head loss varies with discharge in the same manner as smooth pipes. Their use should be strictly limited to these specific hydraulic conditions. However, in actual design use of the formulas, the results are not quite so dramatic. Consider the following example.

Example 3. Select a pipe to convey 20 ft³/sec of water between two reservoirs 5 miles apart and 200 ft different in elevation. Use welded steel pipe.

Hazen-Williams: From Table 6, $C = 120$. From Eq. (131),

$$Q = AV = \frac{1}{4} \pi D^2 \times 0.55 C D^{0.63} S^{0.54}$$

$$20 = \frac{1}{4} \pi D^2 \times 0.55 \times 120$$

$$\times D^{0.63} \left(\frac{200}{5 \times 5280} \right)^{0.54}$$

$$D = 1.90 \text{ ft or } 22.8 \text{ in.} \quad \text{Design } D = 24 \text{ in.}$$

$$\text{Equivalent } f \text{ value} = 0.019$$

Manning: From Table 6, $n = 0.012$. From Eq. (132),

$$Q = AV = \frac{1}{4} \pi D^2 \times \frac{0.59}{n} D^{2/3} S^{1/2}$$

$$20 = \frac{1}{4} \pi D^2 \times \frac{0.59}{0.012} D^{2/3} \left(\frac{200}{5 \times 5280} \right)^{1/2}$$

$$D = 1.95 \text{ ft or } 23.4 \text{ in.} \quad \text{Design } D = 24 \text{ in.}$$

$$\text{Equivalent } f \text{ value} = 0.021$$

Darcy-Weisbach: This is an iterative solution because the Reynolds number and relative roughness cannot be found unless the diameter is known. Because

we know roughly what the diameter is from the previous solution, we will use that as an estimate. From an estimated $D \approx 24$ in., from Table 6, $k/D = 0.000075$. Then

$$V = \frac{20}{(\pi/4)2^2} = 6.4 \text{ ft/sec}$$

$$\text{Re} = \frac{6.4 \times 2}{1.2 \times 10^{-5}} = 1.07 \times 10^6$$

From Fig. 37,

$$f = 0.0135$$

$$D = 1.85 \text{ ft or } 22 \text{ in.} \quad \text{Design } D = 22 \text{ in.}$$

Even though there is a rather dramatic variance in the f value (variation of almost 50%), the resulting effect on the design pipe diameter is quite a lot less. This is a consequence of the fact that diameter varies at about the $\frac{1}{5}$ power of the f value; so, dramatic differences in f value have greatly reduced impact.

For purposes of computer application, it is advantageous to express the information on the Moody diagram in algebraic form. This is most commonly done with the equations of Colebrook⁷:

$$\frac{1}{\sqrt{f}} = -2 \log_{10} \left(\frac{2.51}{\text{Re} \sqrt{f}} \right) \quad (\text{smooth}) \quad (137)$$

$$\frac{1}{\sqrt{f}} = 1.74 - 2 \log_{10} \left(2 \frac{k}{D} + \frac{18.7}{\text{Re} \sqrt{f}} \right) \quad (\text{transition}) \quad (138)$$

$$\frac{1}{\sqrt{f}} = -2 \log_{10} \left(0.266 \frac{k}{D} \right) \quad (\text{rough}) \quad (139)$$
