These equations can then be solved iteratively by computer to determine f for a given Re value and k/D value.

Effects of Aging* The values of k given for the various pipe materials of Fig. 37 and Table 6 are for new, clean pipes. In general, pipes become increasingly rough with age, owing to deposition or corrosion. Colebrook and White have determined an approximately linear increase in absolute roughness with time, which may be expressed as

$$k = k_0 + \alpha t \quad (140)$$

where k_0 is the absolute roughness of the new material, α is a constant, and k is the absolute roughness at time t .

*Material extracted from third edition by Victor L. Streeter.

Example 4. After 10 years of service, a 10-in cast-iron pipe line in water service has a drop of 3.13 psi per 1000 ft for a flow of 1000 gpm. What is the estimated pressure drop for 1200 gpm after 20 years of service?

$$V = \frac{1000}{7.48 \times 60 \frac{\pi}{4} \left(\frac{5}{6}\right)^2} = 4.1 \text{ ft/sec} \quad \frac{V^2}{2g} = 0.262 \text{ ft}$$

$$h_f = \frac{3.13 \times 144}{62.4} = f \frac{1000}{5/6} 0.262 \quad f = 0.023$$

Taking $\nu = 1.2 \times 10^{-5} \text{ ft}^2/\text{sec}$,

$$\text{Re} = \frac{4.1 \times 5}{6 \times 1.2 \times 10^{-5}} = 285,000$$

From Fig. 37, for the above calculated values of f and Re , we get $k/D = 0.0017$ and $k = 0.00142 \text{ ft}$. For new cast iron take $k_0 = 0.001 \text{ ft}$; hence for 10 years,

$$0.00142 = 0.001 + 10\alpha \quad \alpha = 0.000042 \text{ ft/yr}$$

and for 20 years,

$$k = 0.001 + 20 \times 0.000042 = 0.00184 \text{ ft}$$

$$\frac{k}{D} = 0.0022 \quad V = \frac{1200}{1000} \times 4.1 = 4.92 \text{ ft/sec}$$

$$\text{Re} = \frac{4.92}{1.2} \times 285,000 = 342,000$$

From Fig. 37, $f = 0.025$; then

$$h_f = 0.025 \times \frac{1000 \times 4.92^2}{5/6 \times 64.4} = 11.3 \text{ ft}$$

$$\Delta p = \frac{11.3 \times 62.4}{144} = 4.9 \text{ psi}$$

Conduits of Noncircular Cross Section The Darcy-Weisbach equation may also be applied to noncircular conduits if the diameter D is replaced by some equivalent linear measure of the cross section. The hydraulic radius R , widely used in open-channel equations, can be related to D for the circular cross section; this relationship is usually assumed to be a valid replacement of D in the pipe formula. The hydraulic radius is defined as the ratio of the cross-sectional area to the wetted perimeter. For a circular cross section

$$R = \frac{\pi D^2/4}{\pi D} = \frac{D}{4} \quad (141)$$

Hence the diameter may be replaced by four times the hydraulic radius in the Reynolds number, the relative

roughness, and the resistance equation; the resistance equation becomes

$$h_f = f \frac{L}{4R} \frac{V^2}{2g} \quad (142)$$

Although satisfactory for conduits which are reasonably comparable to pipes in cross-sectional form, this equation cannot be expected to give accurate results for cross sections that are at great variance therefrom.

Example 5. Find the head loss per 1000 ft for a flow of 200 gpm of water through a clear cast-iron conduit of rectangular cross section 3 in. by 6 in.

$$R = \frac{3 \times 6}{12 + 6} = 1 \text{ in.} = \frac{1}{2} \text{ ft}$$

$$Q = \frac{200}{7.48 \times 60} = 0.446 \text{ ft}^3/\text{sec}$$

$$V = \frac{0.446}{18} \times 144 = 3.57 \text{ ft/sec}$$

Taking $\nu = 1.2 \times 10^{-5} \text{ ft}^2/\text{sec}$

$$\text{Re} = \frac{V 4R}{\nu} \approx 99,000$$

$$\frac{k}{D} = \frac{k}{4R} = \frac{0.00085}{4/12} = 0.00255$$

From Fig. 37, $f = 0.025$; hence

$$h_f = f \frac{L}{4R} \frac{V^2}{2g} = \frac{0.025 \times 1000}{4 \times \frac{1}{2}} \frac{3.57^2}{64.4} = 14.88 \text{ ft}$$

7.3 Minor Losses

Minor losses are the second type of friction losses and are caused by flow separation, eddies, and excessive turbulence beyond that occurring as a result of normal pipe friction. While the losses occur over a finite length of pipe, they are usually assumed to be concentrated at the location of the causative valve, fitting, and so on. This definition is depicted in Fig. 38.

The formula for minor losses of all kinds is generally of the form

$$h_m = K_L \frac{V^2}{2g} \quad (143)$$

where h_m is the minor head loss, K_L is the loss coefficient whose value depends on the device causing the loss, and V is the velocity of flow in the smaller pipe. Virtually all hydraulics or fluid mechanics textbooks have tables of loss coefficient for various types of devices. In addition, Davis and Sorensen⁵ list several tables of K_L values. The reference book published by

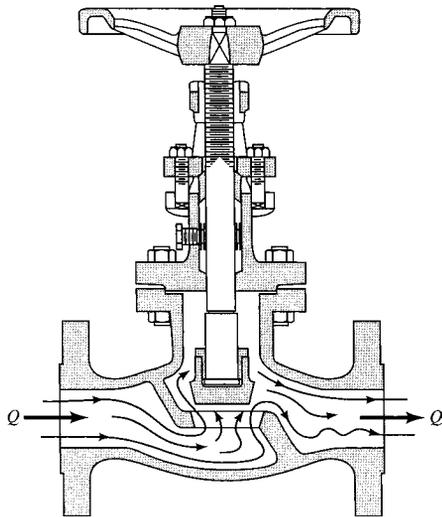

Fig. 38 Depiction of flow through valve illustrating causes of minor losses. From Ref. 2.

the Crane Company⁸ is also a good source for loss coefficients and a selection of K_L values for common situations has been presented in Tables 7 and 8. For an exhaustive collection of loss coefficients, see Idelchik.⁹

To demonstrate the use of the tables and a complete friction loss situation in pipeline analysis, the following example is presented.

Example 6. A series of pipes connecting two reservoirs composed of 150-ft-long 12-in. pipeline and 8-ft-long 6-in. pipeline conveys water at 50°F between two reservoirs. The pipes are asphalted cast iron and the entrance to the pipe is sharp edged. Compute the discharge in the pipeline.

Before starting the solution to the problem, it is useful to classify the various losses that are going to be acting on the flow

- $h_{m_{en}}$ = minor loss at sharp-edged entry to pipeline
- $h_{f_{12}}$ = friction loss in 12-in. pipe
- h_{m_c} = minor loss at connection between 12- and 6-in. pipes
- h_{f_6} = friction loss in 6-in. pipe
- $h_{m_{ex}}$ = minor loss at exit from pipeline

When the discharge is unknown, a flow velocity must be estimated to permit calculating Re and finding an f value.

Assume the velocity in the 12-in. pipe is 7 ft/sec. From Table 6

$$v = 1.41 \times 10^{-5} \text{ ft}^2/\text{sec}$$

$$Re_{12} = \frac{VD}{\nu} = \frac{7 \times 1.0}{1.41 \times 10^{-5}} = 496,000$$

$$Re_6 = \frac{28 \times 0.5}{1.41 \times 10^{-5}} = 993,000$$

^b f is friction factor for pipe.

From Table 6

$$k = 0.0048 \text{ in.}$$

$$\left(\frac{k}{D}\right)_{12} = \frac{0.0048}{12} = 0.0004$$

$$\left(\frac{k}{D}\right)_6 = \frac{0.0048}{6} = 0.0008$$

From Fig. 36

$$f_{12} = 0.017 \quad f_6 = 0.019$$

From the work-energy equation,

$$z_1 + \frac{p_1}{\gamma} + \frac{V_1^2}{2g} = z_2 + \frac{p_2}{\gamma} + \frac{V_2^2}{2g} + \sum h_{L_{1-2}}$$

$$4230 + 0 + 0 = 4200 + 0 + 0 + \sum h_{L_{1-2}}$$

$$\sum h_{L_{1-2}} = 30$$

Summarizing frictional head losses,

$$\sum h_{L_{1-2}} = h_{men} + h_{f_{12}} + h_{m_c} + h_{f_6} + h_{m_{ex}}$$

From Table 7

$$h_{men} = 0.5 \frac{V_{12}^2}{2g} \quad h_{m_r} = 0.34 \frac{V_6^2}{2g}$$

$$h_{m_{ex}} = 1.0 \frac{V_6^2}{2g}$$

$$\sum h_{L_{1-2}} = 0.5 \frac{V_{12}^2}{2g} + 0.017 \times \frac{150}{1.0} \frac{V_{12}^2}{2g} + 0.34 \frac{V_6^2}{2g}$$

$$+ 0.019 \times \frac{8}{6/12} \frac{V_6^2}{2g} + 1.0 \frac{V_6^2}{2g}$$

From continuity considerations,

$$V_6 = 4V_{12}$$

$$\sum h_{L_{1-2}} = (0.5 + 2.55 + 5.44 + 4.86 + 16.0) \frac{V_{12}^2}{2g}$$

Solving for V_{12} ,

$$29.35 \frac{V_{12}^2}{2g} = 30$$

$$V_{12} = 8.11 \text{ fps} \quad V_6 = 32.45 \text{ fps} \quad Q = 6.37 \text{ cfs}$$

Now a check must be made on the accuracy of the initial assumption used to find the f values:

$$\text{Re}_{12} = 575,000 \quad f_{12} = 0.0169$$

$$\text{Re}_6 = 1,150,000 \quad f_6 = 0.0190$$

Because these values are as close to the initial estimates as one could reasonably expect, we will consider the first estimates as the final values.

Another form of expressing minor losses is often used by the manufacturers of valves. This formula is

$$Q = C_v \sqrt{\Delta p} \quad (144)$$

where C_v is the flow coefficient for the valve in question and Δp and Q are expressed in psi (pounds per square inch) and gpm (gallons per minute), respectively. Of course C_v and K_L measure the same thing. They are approximately related by the equation

$$K_L = \frac{890}{C_v^2} D^4 \quad (145)$$

for the units already described with diameter expressed in inches.

Transitions are sections of conduit that connect one prismatic portion to another by a gradual change in cross section. Since, owing to the inherent stability of accelerated flow losses are small in gradual contractions, transition design is usually determined by factors other than energy loss. For example, it is often important that the pressure decrease continuously to that of the reduced section, so that the sections will be both *separation proof* and *cavitation proof*.

In expanding transitions or diffusers, wherein kinetic energy is converted into potential energy, it is even more essential that separation be avoided. The slowly moving fluid near the wall, which is retarded by surface resistance, is also retarded by the adverse pressure gradient due to the flow expansion. If the adverse pressure gradient acts over a sufficient length, it is certain to result in boundary layer separation. Once separation occurs, with the backflow and eddies that accompany it, the losses become high. A series of experiments was conducted by Gibson¹⁰ on conical diffusers, the results of which are shown in Fig. 39.

7.4 Steady-State Pipeline Analysis

The design situation in pipelines is generally that of selecting a pipe diameter that will convey a prescribed amount of discharge between two locations of known elevation with specific reservoir surface elevations or pressure requirements. The attractiveness of the Hazen-Williams and Manning formulas is immediately clear because, if minor losses are neglected, both formulas lead to direct solutions for the required diameter. Use of the Darcy formula requires several iterations beginning with an assumed diameter and ending with a final check on f , Re , and k/D to ensure all are consistent in the final solution. Techniques and skills can be developed to streamline this Darcy equation to determine head loss in a variety of systems with the purpose of refamiliarizing the reader with the techniques.

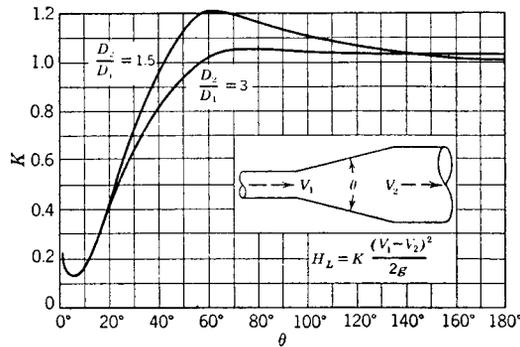

Fig. 39 Loss coefficients for conical diffusers.

Single Pipelines Single-pipeline problems are solved by applying the work–energy equation between two points of known energy levels. An example best illustrates the procedure.

Example 7 An 18-in. welded steel pipeline 1200 ft long connects two reservoirs differing in elevation by 20 ft (see Fig. 40). The pipe has a sharp-edged entrance and a wide-open globe valve at the downstream end near the location where it enters the lower reservoir. Find the flow rate in the pipe. From the work–energy equation,

$$z_1 + \frac{p_1}{\gamma} + \frac{V_1^2}{2g} = z_2 + \frac{p_2}{\gamma} + \frac{V_2^2}{2g} + \sum h_{L1-2}$$

Using the lower reservoir surface as a datum,

$$20 + 0 + 0 = 0 + 0 + 0 + \sum h_{L1-2}$$

where $\sum h_{L1-2}$ = (entrance + friction + valve + exit) losses. From Tables 7 and 8,

$$\begin{aligned} \sum h_{L1-2} &= 0.5 \frac{V_2^2}{2g} + f \frac{L}{D} \frac{V^2}{2g} + 340f \frac{V^2}{2g} + \frac{V^2}{2g} \\ &= \left(0.5 + f \frac{L}{D} + 340f + 1.0\right) \frac{V^2}{2g} \end{aligned}$$

From Table 6,

$$k = 0.0018 \quad \frac{k}{D} = 0.0001$$

From Table 3

$$V \approx 8 \text{ ft/sec} \quad \text{Re} = \frac{8 \times 1.5}{1.2 \times 10^{-5}} = 1 \times 10^6$$

From Fig. 36, $f = 0.0135$. Substituting into the preceding work–energy equation,

$$\begin{aligned} 20 &= 0 + \left(0.5 + 0.0135 \times \frac{1200}{1.5} + 340 \right. \\ &\quad \left. \times 0.0135 + 1.0\right) \frac{V^2}{2g} \\ &= (0.5 + 10.8 + 4.6 + 1.0) \frac{V^2}{2g} \\ &= 16.9 \frac{V^2}{2g} \end{aligned}$$

$$V = 8.73 \text{ ft/sec}$$

Checking on initial assumptions,

$$\text{Re} = \frac{8.73 \times 1.5}{1.2 \times 10^{-5}} = 1.1 \times 10^6$$

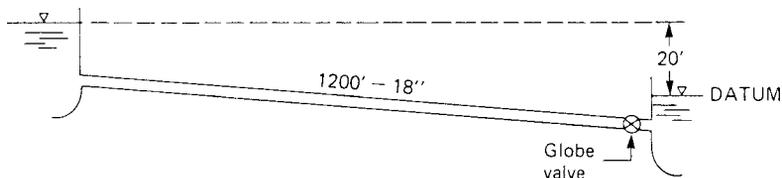

Fig. 40 Diagram for Example 7. By permission from G. Z. Watters, *Analysis and Control of Unsteady Flow in Pipelines*, Stoneham, MA, 1984.

$f = 0.0135$, so solution is acceptable

$$Q = AV = 0.7854 \times 1.5^2 \times 8.73$$

$$Q = 15.4 \text{ ft}^3/\text{sec or } 6927 \text{ gpm}$$

Series pipelines, that is, pipelines of different diameters connected end to end, are handled in a manner similar to the previous example. It is only required that the single pipe friction term be replaced by a summation of the pipe friction losses in each of the pipes, including the additional minor losses between pipes.

Single Pipelines with Pumps The pumped pipeline is a common design situation with which engineers are confronted. Pumps occur at the upstream end of pipelines (source pumps) and at intermediate locations in the pipeline (booster pumps). In each case, the discharge through the pump and the head increase across the pump are affected by the pipe system in which the pump is installed.

To analyze pumped pipelines, the work-energy equation must be modified to include the energy added by the pump:

$$z_1 + \frac{p_1}{\gamma} + \frac{V_1^2}{2g} + H_p = z_2 + \frac{p_2}{\gamma} + \frac{V_2^2}{2g} + \sum h_{L1-2} \quad (146)$$

where H_p is the energy added to each pound of liquid passing through the pump. In the case of series or

multistaged pumps, H_p is the sum of the head increases across each pump or stage.

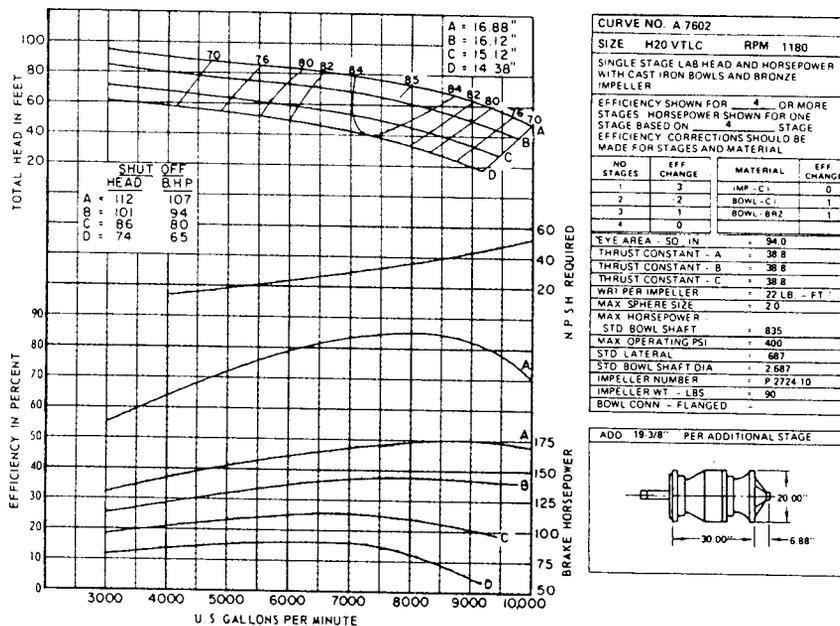

The head increase across a pump is a function of discharge through the pump and is determined experimentally by the manufacturer. The information is presented graphically on a diagram known as the characteristic diagram. Information on the power requirements and pump efficiencies at varying discharges is also included. An example of a typical pump characteristic diagram is shown in Fig. 41.

Because power requirements for a pumping situation are of interest, it is important to establish the relation between energy added (H_p) and brake horsepower required. The power added to the liquid by the pump can be expressed as

$$\text{WHP} = \frac{Q\gamma H_p}{550} \quad (147)$$

where WHP is the horsepower added to the water. Of course, a greater amount of power must be added to the pump shaft because of friction and other losses in the pumping process. The power that must be supplied to a pump shaft (brake horsepower, BHP) in order to provide a given WHP is related to the hydraulic parameters by the equation

$$\text{BHP} = \frac{Q\gamma H_p}{550\eta} \quad (148)$$

where η is the overall pump efficiency. Both overall pump efficiency and brake horsepower are displayed on the pump characteristic diagram in Fig. 41.

Two examples follow that demonstrate the use of the characteristic diagrams in pipeline analysis.

Example 8. A single-stage pump with the characteristics shown in Fig. 41 (curve A) is used to pump water from a reservoir of elevation 1350 ft to another reservoir at elevation 1400 ft. The line is 6000 ft long and 24 in. in diameter with an f value of 0.021.

Neglecting minor losses, compute the discharge in the pipeline. From the work–energy equation

$$z_1 + \frac{p_1}{\gamma} + \frac{V_1^2}{2g} + H_p = z_2 + \frac{p_2}{\gamma} + \frac{V_2^2}{2g} + \sum h_{L_{1-2}}$$

$$1350 + 0 + 0 + H_p = 1400 + 0 + 0 + f \frac{L}{D} \frac{V^2}{2g}$$

$$H_p = 50 + 0.021 \times \frac{6000}{2} \frac{V^2}{2g}$$

$$= 50 + 63.0 \frac{V^2}{2g}$$

This equation must be solved by trial in conjunction with the head-versus-discharge characteristic for the pump given in Fig. 41. In the solution process we neglect losses in the pump discharge column and head, which would normally be included in an analysis.

The solution is best approached using a trial solution table:

Assume Q (gpm)	V (ft/sec)	$\frac{V^2}{2g}$	$63 \frac{V^2}{2g}$	RHS ^a	H_p (ft) ^a
8000	5.67	0.50	31.5	81.5	73
7000	4.96	0.38	24.1	74.1	79
7500	5.32	0.44	27.7	77.7	76
7400	5.25	0.43	26.9	76.9	77

^aRight-hand side $(50 + 63.0V^2/2g)$.

The solution is $Q = 7400$ gpm.

Example 9. Solve the problem of Example 8 if two three-stage parallel pumps with curve C characteristics were employed.

The pipeline analysis would remain the same:

$$H_p = 50 + 63.0 \frac{V^2}{2g}$$

However, H_p is now the total head put out by the three stages in each pump. Also the pipeline discharge must

be halved to obtain the amount passing through each pump.

The resulting trial solution table is as follows:

Assume Pump Q (gpm)	Q_{pipe}	V (ft/sec)	$\frac{V^2}{2g}$	RHS	H_p / stage	H_p (ft)
7000	14,000	9.93	1.53	146	54	159
7500	15,000	10.63	1.76	161	50	150
7250	14,500	10.28	1.64	153	51	153

The solution is $Q = 7250$ gpm.

7.5 Pipe Network Analysis

The steady-state analysis of flows in pipe networks can be a very complex problem. Devices such as pressure-reducing valves, minor losses, booster pumps, and supply pumps, as well as reservoirs, all serve to complicate the analysis. The subject is covered comprehensively by Jeppson¹¹ and the reader is referred to that text for detailed information. The presentation here will be introductory and will apply only to relatively simple systems. However, we shall discuss all three of the most popular analysis methods—the Hardy Cross method, the linear theory method, and the Newton—Raphson method. In addition, a good summary of the application of these three methods is given by Wood and Rayes.¹²

Hardy Cross Method Because of its simplicity of application, its easily understood theory, and its amenability to hand calculation, the Hardy Cross method has enjoyed (and still enjoys) considerable popularity among practicing engineers.

The first step is to estimate flow rates in all the pipes in a network so that continuity is satisfied at each junction (node). Of course it is unlikely that the energy line (EL) and hydraulic grade line (HGL) are continuous throughout the network because the original estimates of the flow rates are always erroneous to some degree. This method assumes that there can be found a unique flow rate adjustment that can be applied to each loop in the network that will cause the EL–HGL to be continuous around each loop. In hydraulic terms this continuity is expressed as

$$\sum_{i=1}^N h_{L_i} = 0 \tag{149}$$

around each loop where i is the pipe number and N is the number of pipes in the loop. Assuming that the head loss can be written in the form

$$h_{L_i} = K_i Q_i^n \tag{150}$$

and assuming a correction ΔQ is being added to each pipe flow in the loop to satisfy the requirement that

the sum of the head loss equals zero, this equation becomes

$$\sum_{i=1}^N K_i(Q_1 + \Delta Q)^n = 0 \quad (151)$$

where Q_i is the most recent estimate for the discharge in each pipe in the loop. It remains only to solve for ΔQ .

Because n is generally a noninteger, the preceding is generally expanded by the binomial theorem to yield an equation for ΔQ . Retaining only the first two terms of the binomial expansion, the following equation for ΔQ is derived:

$$\Delta Q = \frac{\sum_{i=1}^N K_i Q_i^n}{-n \sum_{i=1}^N K_i Q_i^{n-1}} \quad (152)$$

To produce the proper sign on ΔQ , the denominator is kept negative and the terms in the summation in the numerator are positive or negative, depending on whether one moves with or against the flow while proceeding clockwise around the loop.

Once the ΔQ is computed for each loop, it is added (or subtracted) from the flow rates in each member of the loop to get a better estimate of the true flow rate. Because the decomposition of $(Q_i + \Delta Q)^n$ with the binomial theorem was not exact and because pipes that are common to more than one loop have multiple ΔQ corrections, the calculated ΔQ 's will not be correct. Therefore, the process is iterative and must be continued until the error is acceptably small (or no convergence to a solution occurs).

Although this numerical method is not so sophisticated as the other methods, the results are just as valid, provided convergence is obtained. Actually, a more careful investigation would reveal that Hardy Cross analysis is a decoupled Newton–Raphson analysis.

Linear Theory Method The linear theory method is a technique for solving a set of network equations, some of which are nonlinear, for the unknown flow rates in the pipes. The equations are generated by writing continuity equations for flow into and out of each junction and by specifying that the algebraic sum of the head losses around each loop is zero. Solving a set of nonlinear equations is an iterative process and there are many techniques for doing this. In the linear theory approach the nonlinear equations for the sum of the head losses around each loop are linearized. Then the complete set of linear equations (the continuity equations are already linear) is solved.

To understand how the procedure works, look at the equations involved. For each loop in the network the following equation is valid:

$$\sum_{i=1}^N h_{L_i} = \sum_{i=1}^N K_i Q_i^n = 0 \quad (153)$$

where N is the number of pipes in the loop. To linearize this equation, Q_i^n is decomposed into two parts so that this equation becomes

$$\sum_{i=1}^N (K_i Q_i^{n-1}) Q_i = \sum_{i=1}^N K_i' Q_i = 0 \quad (154)$$

Of course K_i' is now a function of Q_i so the process is still iterative.

As the set of linear-plus-linearized equations is successively solved, the estimate of K_i' is revised after each solution. After several iterations the values of Q_i and K_i' should converge to their final values. The mathematical form of the iteration equation is

$$\sum_{i=1}^N K_i [Q_i^{(j-1)}]^{n-1} Q_i^j = 0 \quad (155)$$

where j is the iteration number. For example, if we are making the eighth iteration ($j = 8$), then we would calculate K_i' 's from the results of the seventh iteration.

Experience with the linear theory has shown that the numerical solution tends to oscillate around the final values. To damp out this numerical oscillation, the iteration equation is altered to include the last two iterations for Q_i in computing K_i' :

$$\sum_{i=1}^N K_i \left[\frac{Q_i^{(j-1)} + Q_i^{(j-2)}}{2} \right]^{n-1} Q_i^{(j)} = 0 \quad (156)$$

When starting an analysis, only the direction of flow (not the quantity) has to be specified. This is a substantial savings in effort over the Hardy Cross approach. For the first iteration $K_i^{(1)}$ is assumed to be equal to K_i . For the second iteration $K_i^{(2)}$ will equal $K_i [Q_i^{(1)}]^{n-1}$. Thereafter, Eq. (156) will be used for each loop.

Newton–Raphson Method The Newton–Raphson technique has the same conceptual basis as the Hardy Cross method. Flow rates in each pipe are assumed that satisfy continuity, and these flow rates are corrected so that the sum of the head losses around each loop approaches zero. In the Hardy Cross method the flow rates in each pipe are corrected after each ΔQ computation. In the Newton–Raphson method the equations containing ΔQ are written for each loop; then this nonlinear set of equations is solved successively for the final value of ΔQ in each loop. When the solution is complete, only then are the initial flow rates in each pipe adjusted to their final value.

The method gets its name from the technique used to solve the nonlinear set of equations. The Newton–Raphson technique is a frequently used, powerful method of numerical analysis. In operation, it adjusts

successive approximations to the solution by computing the way the solution is moving with respect to each variable and then, based on that computation, calculates new trial values for the unknowns.

The Newton–Raphson technique in two or more dimensions (two or more equations with two or more unknowns) is most conveniently expressed in matrix form,

$$\{F^{(j-1)}\} + [\mathbf{J}^{(j-1)}]\{x^{(j)} - x^{(j-1)}\} = \{0\} \quad (157)$$

where \mathbf{J} is a $K \times K$ matrix of $\partial F^{(j-1)}/\partial x_k$ known as the Jacobian. Converting this to another form,

$$\{x^{(j)}\} = \{x^{(j-1)}\} - [\mathbf{J}^{(j-1)}]^{-1}\{F^{(j-1)}\} \quad (158)$$

Because all the F_k can be differentiated, the Jacobian can be evaluated at each new approximation for x_i and the inverse computed. However, this is a very large computational task for large systems of equations; hence, a slightly different approach is employed when working with hydraulic networks.

In hydraulic networks,

$$F_k = \sum_{i=1}^N K_i Q_i^n = 0 \quad (159)$$

However, because the Q_i 's are unknown, a value in each pipe must be estimated and a search for ΔQ 's, which will correct the Q_0 's to the proper value, must be made. The loop equations now are of the form

$$F_k = \sum_{i=1}^N K_{L_i} \left[Q_{0i} + \sum_{l=1}^K \Delta Q_l \right]^n = 0 \quad k = 1, K \quad (160)$$

because any pipe in a given loop may be a member of other loops and their ΔQ 's must be included. Then, in general,

$$F_k(\Delta Q_1, \Delta Q_2, \dots, \Delta Q_k) = 0 \quad k = 1, K \quad (161)$$

If $\Delta Q^{(j)} - \Delta Q^{(j-1)}$ is now represented as $\delta Q^{(j)}$ in each loop, then

$$[\mathbf{J}^{(j-1)}]\{\delta Q^{(j)}\} = -\{F^{(j-1)}\} \quad (162)$$

This equation is now solved for $\{\delta Q^{(j)}\}$ and

$$\{\Delta Q^{(j)}\} = \{\Delta Q^{(j-1)}\} + \{\delta Q^{(j)}\} \quad (163)$$

after each iteration. When the δQ 's become small enough, an acceptable solution has been obtained.

It should be noted here that this method only requires the solution to a set of equations equal in number to the number of loops. The linear theory must solve a set of equations equal in number to the number of unknown flow rates. Consequently, the

Newton–Raphson technique may require substantially less storage space for solution.

7.6 Unsteady Flow in Pipe Systems

Unsteady flow in pipe systems is important because it can result in serious problems. Some of these are:

1. Pipe rupture
2. Pipe collapse
3. Vibration
4. Excessive pipe displacements
5. Pipe fitting and support deformation or failure
6. Vapor cavity formation (cavitation, column separation)

Some of the primary causes of unsteady flow are:

1. Valve closure (or opening)
2. Flow demand changes
3. Pump shutdown (or power failure to the pump)
4. Pump startup
5. Air venting from lines
6. Failure of flow or pressure regulators
7. Pipe rupture

Unsteady flow analysis in pipe systems is generally divided into two categories:

1. Rigid water column theory (surge theory) where the fluid and pipe are inelastic, pressure changes propagate instantaneously, and the differential equation of motion is “ordinary”
2. Elastic theory (water hammer) where the elasticity of fluid and pipe affect pressure changes, pressure changes propagate with wave speed \mathbf{a} (1000–4700 ft/sec), and the differential equations of motion are partial and nonlinear

A simple problem is used to demonstrate phenomena and introduce concepts. A steady flow situation is shown in Fig. 42 where velocity V is caused by head H in reservoir. Friction is neglected and the EL and HGL are coincident because water hammer pressures are large compared to velocity head.

The valve is closed suddenly causing a pressure head to propagate upstream at speed \mathbf{a} . The sequence of events shown in Fig. 42 are as follows:

1. Pressure head increase ΔH reaches reservoir at L/\mathbf{a} seconds. Velocity = 0 and pressure head = $H + \Delta H$ throughout pipe. Pipe is stretched. Water is compressed.
2. High pressure in pipe ejects water into reservoir. At $2L/\mathbf{a}$ seconds, velocity = $-V$, pressure head = H throughout pipe.

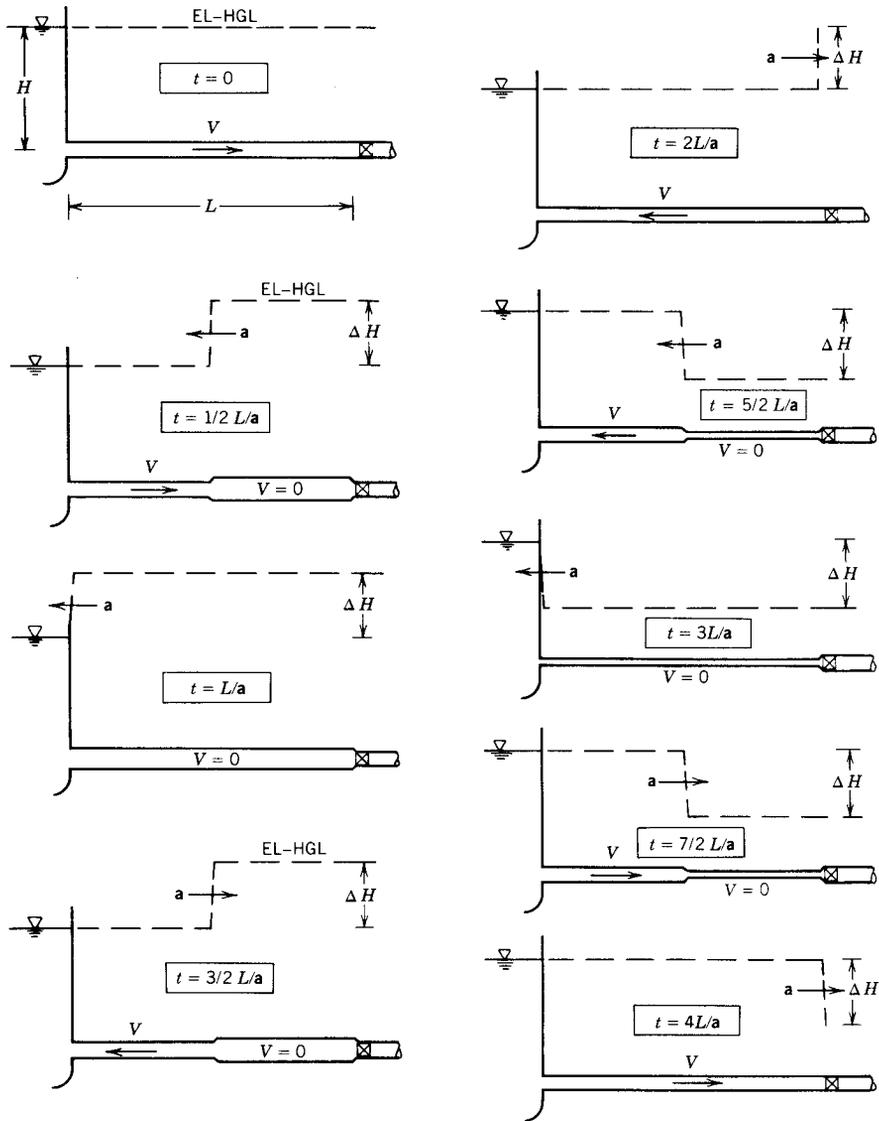

Fig. 42 Pressure wave propagation in simple pipe system. By permission from G. Z. Watters, *Analysis and Control of Unsteady Flow in Pipelines*, Butterworth, Stoneham, MA, 1984.

3. Upstream flow suddenly stopped at valve. Negative wave propagates upstream. At $3 L/a$ seconds, velocity = 0, pressure head = $H - \Delta H$ throughout pipe.
4. High pressure in reservoir forces water into pipe giving downstream flow. At $4 L/a$, velocity = V , pressure = H , and wave period is complete.
5. As long as valve remains closed, these cycles repeat. Any friction in system would cause damping of ΔH until it eventually disappears.

The following are important ideas:

1. L/a is an important time parameter in water hammer situations.
2. Pressure head at the valve reaches its maximum if the valve is closed in any time less than $2 L/a$ seconds. Valve need not be suddenly closed to create maximum water hammer pressures.

Column Separation When pressure change is severe enough to drop pressure in the pipe to the

vapor pressure of water, “column separation” occurs. Dissolved gases come out of solution, water vapor cavities occur, and liquid columns “separate.” Eventually cavity closure causes water hammer pressure “shocks” of a magnitude difficult to calculate and potentially destructive.

Column separation could be caused by simple valve closure. In Fig. 42, if ΔH were large enough, column separation would occur on both sides of the valve, although at different times.

Rigid Water Column Theory This analysis uses Newton’s second law, $F = ma$. For unsteady flow the equation is

$$\frac{p_1}{\gamma} - \frac{p_2}{\gamma} - \frac{fL}{2gD} V^2 = \frac{L}{g} \frac{dV}{dt} \quad (164)$$

where p = pressure, f = Darcy–Weisbach friction factor, L = pipe length, γ = specific weight of water, D = pipe diameter, V = flow velocity, g = acceleration of gravity, and dV/dt = liquid acceleration.

Example 10 Flow establishment in a pipe. The physical situation is shown in Fig. 43 with free discharge at the valve.

The equation applied to this problem is

$$H_0 - \frac{fL}{2gD} V^2 = \frac{L}{g} \frac{dV}{dt}$$

This expression can be integrated in closed form. The time to reach steady flow is infinite. To reach 99% of V ,

$$t_{99} = 2.65 \frac{LV_0}{gH_0}$$

Pipe systems may not be single, constant-diameter pipes. The equivalent pipe technique may be used to reduce complex pipe systems to single pipes. Criteria

for equivalence is friction loss equality and similar dynamic behavior. For series pipes

$$\left[\frac{fL}{D^5} \right]_{eq} = \sum_{i=1}^N \left[\frac{f_i L_i}{D_i^5} \right] \quad (165)$$

$$\left[\frac{L}{D^2} \right]_{eq} = \sum_{i=1}^N \left[\frac{L_i}{D_i^2} \right] \quad (166)$$

For parallel pipes:

$$\left[\frac{D_{eq}^5}{f_{eq} L_{eq}} \right]^{1/2} = \sum_{i=1}^N \left[\frac{D_i^5}{f_i L_i} \right]^{1/2} \quad (167)$$

$$\left[\frac{D_{eq}^2}{L_{eq}} \right] = \sum_{i=1}^N \left[\frac{D_i^2}{L_i} \right] \quad (168)$$

Example 11 A three-unit pumped storage facility is shown in Fig. 44. Flow through the turbines is shut down so that penstock velocities decrease from 60 ft/sec to zero linearly in 30 sec. Compute p_{max} if the f value is the same for all pipes.

Using the parallel-pipe equations,

$$\frac{D_{eq}^2}{L_{eq}} = 3 \left(\frac{8^2}{800} \right) = 0.240 \quad \left[\frac{D_{eq}^5}{L_{eq}} \right]^{1/2} = 3 \left[\frac{8^5}{800} \right]^{1/2} = 19.20$$

The parallel pipes can be replaced by a single pipe $D = 11.54$ ft and $L = 555$ ft:

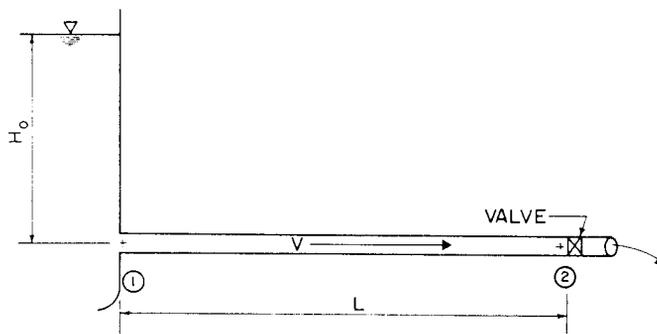

Fig. 43 Simple system for applying rigid water column theory. By permission from G. Z. Watters, *Analysis and Control of Unsteady Flow in Pipelines*, Butterworth, Stoneham, MA, 1984.

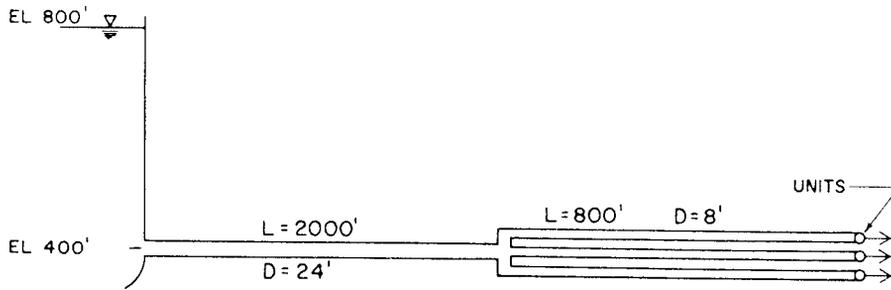

Fig. 44 Schematic sketch of a pumped storage facility. By permission from G. Z. Watters, *Analysis and Control of Unsteady Flow in Pipelines*, Butterworth, Stoneham, Mass., 1984.

Using the series-pipe equation,

$$\frac{L_{eq}}{D_{eq}^2} = \frac{2000}{24^2} + \frac{555}{11.54^2} = 7.64$$

$$\frac{L_{eq}}{D_{eq}^5} = \frac{2000}{24^5} + \frac{555}{11.54^5} = 0.00296$$

This series pipe is replaced by the single pipe $D = 13.71$ ft and $L = 1437$ ft. Steady flow velocity in the equivalent pipe is

$$V_{eq} = \frac{Q}{A_{eq}} = 61.3 \text{ ft/sec}$$

From the unsteady flow equation,

$$400 - \frac{p_2}{\gamma} - \frac{fLV^2}{2gD} = \left(\frac{1437}{32.2} \right) \frac{0 - 61.3}{30}$$

$$\frac{p_2}{\gamma} = 400 + 91.2 - \frac{fLV^2}{2gD}$$

A maximum pressure head of 491 ft occurs at the instant the valve is completely closed.

Elastic Theory Elastic theory includes the effect of water and pipe elasticity on pressures and velocities. The impulse-momentum equation and the conservation-of-mass equation are used.

The impulse-momentum equation is used to develop the equation for ΔH . The x component of the equation is

$$\left(\sum \mathbf{F}_{ext} \right)_x = Q\rho(V_{out} - V_{in}) \quad (169)$$

where the x direction is along the pipe, F_x are forces in the x direction, and Q is discharge.

To make the unsteady case steady, the coordinate system is moved along the pipe at the wave speed so

the wave appears to be standing still. The resulting analysis gives

$$\Delta H = \frac{a}{g} \Delta V \quad (170)$$

It is clear that ΔH depends on the wave speed a . Conservation of mass is used to find an equation for wave speed. The result for thin-walled pipes is

$$a = \frac{[K/\rho]^{1/2}}{\left[1 + \frac{K}{E} \frac{D}{e} (C) \right]^{1/2}} \quad (171)$$

where K = bulk modulus of elasticity of liquid, E = modulus of elasticity of pipe, D = pipe diameter, e = pipe wall thickness, and C = restraint coefficient:

$C = \frac{5}{4} - \mu$ if pipe is free to stretch in longitudinal direction as a pressure vessel.

$C = 1 - \mu^2$ if no longitudinal stretching occurs.

$C = 1.0$ if functioning expansion joints occur, where μ is Poisson's ratio.

Thin-walled pipes have D/e greater than about 40. Suggested values of E and μ are shown in Table 9.

For water $[K/\rho]^{1/2} = 4720$ ft/sec. Most buried-pipe situations are close to $C = 1 - \mu^2$; however, for $\mu \approx 0.3$, the result is about the same regardless of restraint.

Example 12 A 10,000-ft pipe has $V = 10$ ft/sec and a wave speed of 3220 ft/sec. Compute head increase at a valve for sudden valve closure:

$$\Delta H = \frac{a}{g} \Delta V = \frac{3220}{32.2} 10 = 1000 \text{ or } 433 \text{ psi}$$

Note that $L/a = 3.1$ sec. If the valve is closed in less than 6 sec, full water hammer pressure is developed.

Table 9 E and μ Values for Common Pipe Materials

Steel	$E = 30 \times 10^6$ psi	$\mu \approx 0.30$
Ductile cast iron	$E = 24 \times 10^6$ psi	$\mu \approx 0.28$
Copper	$E = 16 \times 10^6$ psi	$\mu \approx 0.36$
Brass	$E = 15 \times 10^6$ psi	$\mu \approx 0.34$
Aluminum	$E = 10.5 \times 10^6$ psi	$\mu \approx 0.33$
PVC	$E = 4 \times 10^5$ psi	$\mu \approx 0.45$
Fiberglass-reinforced plastic (FRP)	$E_2 = 4.0 \times 10^6$ psi	$\mu_2 = 0.27 - 0.30$
	$E_1 = 1.3 \times 10^6$ psi	$\mu_1 = 0.20 - 0.24$
Asbestos cement	$E \approx 3.4 \times 10^6$ psi	$\mu \approx 0.30$
Concrete	$E = 57,000\sqrt{f'_c}$ ^a	$\mu \approx 0.24$ (dynamically)

^a Where f'_c = 28-day strength.

The previous C values for thin-walled pipes must be modified when D/e is less than 40. For homogeneous pipes,

$$\text{Case (a): } C = \frac{1}{1 + e/D} \left[\left(\frac{5}{4} - \mu \right) + 2 \frac{e}{D} (1 + \mu) \left(1 + \frac{e}{D} \right) \right] \quad (172)$$

$$\text{Case (b): } C = \frac{1}{1 + e/D} \left[(1 - \mu^2) + 2 \frac{e}{D} (1 + \mu) \left(1 + \frac{e}{D} \right) \right] \quad (173)$$

$$\text{Case (c): } C = \frac{1}{1 + e/D} \times \left[1 + 2 \frac{e}{D} (1 + \mu) \left(1 + \frac{e}{D} \right) \right] \quad (174)$$

These C values are used in the wave speed equation to compute wave speed.

When air or other dissolved gases come out of solution and form small bubbles, wave speed is affected dramatically. This occurs because:

1. Low pressure at pipeline summit allows air release.
2. Pump sump is aerated by improper inflow design.

If the fraction of the air volume is known, the wave speed can be estimated from the following equation:

$$\mathbf{a} = \frac{\sqrt{K_l / \rho_{ave}}}{\sqrt{1 + \frac{K_l D}{E e} C + (\text{void fraction}) \frac{K_l}{K_a}}} \quad (175)$$

Amounts of air as low as 0.5% can reduce wave velocity to 25% of its unaerated value.

The previous approach permits calculation of pressure head increase at a point where velocity changes suddenly. Generally, it is necessary to find head H and velocity V at any section of pipe system at any time t .

To accomplish this Newton's second law and conservation of mass are applied to a differential length of pipe through which the water hammer wave is passing. The result is two partial differential equations,

$$\frac{dV}{dt} + g \frac{\partial H}{\partial s} + \frac{1}{2} \frac{F}{D} V|V| = 0 \quad (176)$$

$$\frac{\mathbf{a}^2}{g} \frac{\partial V}{\partial s} + V \left[\frac{\partial H}{\partial s} - \frac{\partial z}{\partial s} \right] + \frac{\partial H}{\partial t} = 0 \quad (177)$$

where s = location along pipe and z = elevation above datum.

This type of equation can be solved using the "method of characteristics." First, the equations are simplified by replacing dV/dt with $\partial V/\partial t$ and deleting $\partial H/\partial s$ in Eqs. (176) and (177). This approximation had been shown to have negligible effects on accuracy. If independent variables s and t follow certain relationship in Eqs. (176) and (177), namely

$$\frac{ds}{dt} = \pm \mathbf{a} \quad (178)$$

Then *partial* differential equations can be written as *total* differential equations:

$$C^+ : \frac{dV}{dt} + \frac{g}{\mathbf{a}} \frac{dH}{dt} + \frac{f}{2D} V|V| = 0 \quad (179)$$

if

$$\frac{ds}{dt} = \mathbf{a} \quad (180)$$

and

$$C^- : \frac{dV}{dt} = \frac{g}{\mathbf{a}} \frac{dH}{dt} + \frac{f}{2D} V|V| = 0 \quad (181)$$

if

$$\frac{ds}{dt} = -\mathbf{a} \quad (182)$$

Equations (180) and (182) called the characteristics of the C^+ and C^- equations, respectively.

The physical meaning of C^+ , C^- and characteristic equations is that changes in pressure caused by disturbances (valve closing) propagate at wave speeds upstream and downstream in the pipe ($ds/dt = \pm a$). If this rule is followed, the partial differential equations become total differential equations. The equations are solved numerically as described in Watters,¹³ Wylie and Streeter,¹⁴ and Chaudhry.¹⁵

8 FLOW IN OPEN CHANNELS*

Flow in open channels is similar to that in pipes in that flow can be laminar or turbulent, can have smooth or rough boundaries, and be uniform or nonuniform. Open-channel flow has the one unique characteristic that the pressure is zero on the free surface. Laminar flow is quite rare and will not be addressed here. This work will consider primarily uniform and nonuniform flow in the turbulent rough boundary mode.

8.1 Uniform Flow

In steady uniform flow the slope of channel bottom, free surface (hydraulic grade line), and energy grade line are the same ($\tan \theta$, Fig. 45). For very wide channels, the shear stress varies linearly with distance from the free surface y , given by $\tau = y\gamma \sin \theta$. For other channels, the average shear stress τ_0 at the solid boundary is $\tau_0 = \gamma R \sin \theta$, where R is the hydraulic radius, which is defined as the ratio of area of cross section A to wetted perimeter P . The liquid velocity at the solid boundary is zero; it increases generally with distance from a boundary. The maximum velocity is usually below the free surface.

The *Manning formula* is the most commonly used open-channel formula,

$$V = \frac{1.49}{n} R^{2/3} S^{1/2} \quad (183)$$

where V is the average velocity, R is the hydraulic radius, $S = \sin \theta$ (Fig. 45), and n is an absolute rough-

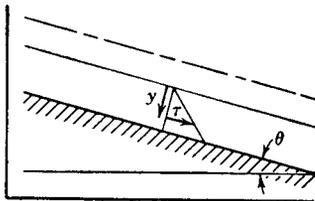

Fig. 45 Uniform flow.

ness factor, having the dimensions $L^{1/6}$, whose values for different surfaces are determined experimentally. Table 10 lists many of these values. Since the constant in the Manning formula is not dimensionless, it is necessary to use the foot-pound-second system of units:

Multiplying the formula by A ,

$$Q = \frac{1.49}{n} A R^{2/3} S^{1/2} \quad (184)$$

When the cross section is known, the equation may be solved directly for any one of the other quantities that is unknown. For determination of depth of flow in a given section, with Q , n , S given, the solution is effected by trial.

Example 13 Find the depth of flow in a trapezoidal channel of roughness 0.012, bottom width 10 ft, and side slopes 1 : 1 for 650 ft³/sec. The channel slope is 0.0009.

Writing

$$A R^{2/3} = \frac{A^{5/3}}{P^{2/3}}$$

from the Manning formula

$$\frac{Qn}{1.49S^{1/2}} = \frac{A^{5/3}}{P^{2/3}} = \frac{650 \times 0.012}{1.49 \times 0.03} = 174.7$$

$A = 10D + D^2, P = 10 + 2\sqrt{2} D$; hence

$$f(D) = \frac{(100 + D^2)^{5/3}}{(10 + 2\sqrt{2}D)^{2/3}} = 174.7$$

Trying $D = 5, f(D) = 160$; hence D must be larger. Trying $D = 5.5, f(D) = 191$. By straight-line interpolation, $D = 5.24, f(D) = 174$, which is a satisfactory check. Hence $D = 5.24$ ft is the answer sought.

The cross section having the least perimeter for given conditions is called the *most efficient* cross section. The semicircular section is the most efficient of all cross sections since it has the least perimeter for a given area. The most efficient *rectangular* channel has a bottom width twice the depth. The most efficient *trapezoidal* channel is half of a hexagon.

Specific Energy – Critical Depth The mechanical energy per unit weight, with elevation datum taken as the bottom of the channel, is called *specific energy*. It is simply the sum of depth of flow and velocity head. In steady uniform flow when all cross sections are identical, the specific energy is constant along the channel.

Referring to Fig. 46, the specific energy is

$$E = y + \frac{V^2}{2g} \tag{185}$$

assuming uniform distribution of velocity over the cross section. For a given discharge Q , the specific energy varies with the depth of flow. Substituting $V = Q/A$, where A is the cross-sectional area and a function of y ,

$$E = y + \frac{Q^2}{2gA^2} \tag{186}$$

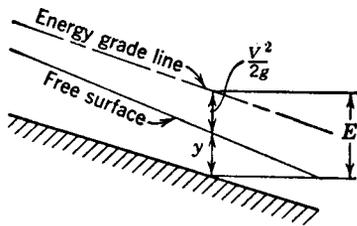

Fig. 46 Specific energy.

For a unit width of rectangular channel, with q the discharge per unit width,

$$E = y + \frac{q^2}{2gy^2} \tag{187}$$

A plot of specific energy against depth, Fig. 47, for a constant q , reveals that a certain minimum specific energy is required for the flow, found by setting $dE/dy = 0$. Calling this depth y_c the *critical depth*, we have

$$y_c = \left(\frac{q^2}{g}\right)^{1/3} \tag{188}$$

In terms of the velocity, $V_c = \sqrt{gy_c}$. Hence the critical depth is the depth at which the velocity of flow V_c is just equal to the velocity of an elementary wave \sqrt{gy} in still liquid. Greater specific energy is required for both greater and lesser depths of flow. It is obvious from Fig. 47 that there are two depths at which the flow has the same specific energy.

For nonrectangular channels the critical depth occurs when

$$\frac{Q^2}{g} = \frac{A^3}{b} \tag{189}$$

where b is the top width of the cross section at the liquid surface.

8.2 Steady, Nonuniform Flow

Gradually varied channel flow is steady flow in which changes in depth, section, slope, and roughness with respect to length along the channel are small. By assuming that the energy loss at any section is the same as in uniform flow at the same discharge and

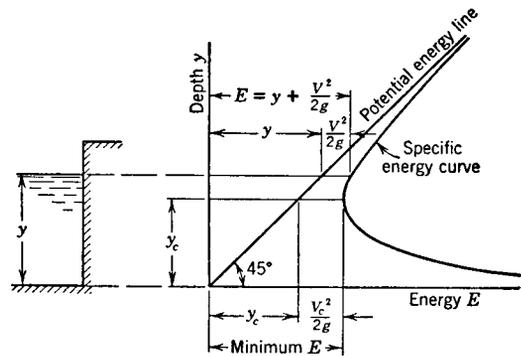

Fig. 47 Specific energy diagram. (Courtesy of R. A. Dodge, University of Michigan, Ann Arbor.)

the same depth, a differential equation for change in depth as a function of distance along the channel can be developed:

$$\frac{dy}{dl} = \frac{S_0 - n^2 Q^2 / [(1.49)^2 A^2 R^{4/3}]}{1 - Q^2 b / (g A^3)} \quad (190)$$

where y is the depth, l the distance along the channel, S_0 the sine of the angle the bottom makes with the horizontal, n the Manning roughness factor, Q the discharge, A the cross-sectional area, R the hydraulic radius, and b the width of cross section at the liquid surface. Solving for l ,

$$l = \int \frac{1 - Q^2 b / (g A^3)}{S_0 - n^2 Q^2 / [(1.49)^2 A^2 R^{4/3}]} dy \quad (191)$$

For constant S_0 and n , the integrand is a function of y only, and l may be determined as a function of y , usually by numerical integration. When the integrand is zero, $Q^2 b / g A^3 = 1$, which is the condition for critical depth. Hence for a change in depth there is no change in l ; that is, neglecting the effects of the curvature of streamlines and the nonhydrostatic pressure distribution, the liquid surface is vertical as the flow goes through critical. When the denominator is zero, uniform flow occurs, and there is no change in depth along the channel.

The various possible free-surface profile given by the preceding equation are shown in Fig. 48. In each case the flow is from left to right. Here, y_0 is the normal depth, that is, the depth given by the Manning

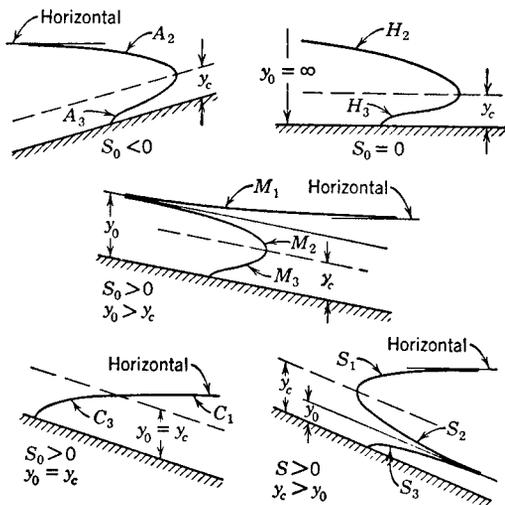

Fig. 48 Surface profiles on adverse, horizontal, mild, critical, and steep slopes. (Courtesy of Hunter Rouse, State University of Iowa, Iowa City.)

uniform flow equation; y_c is the critical depth. When the normal depth is greater than the critical depth, the slope of the channel is *mild*; when normal depth equals *critical* depth; the slope is *critical*; when normal depth is less than critical depth, the slope is *steep*. The two other cases are *horizontal* and *adverse*.

The determination of surface profile from the equation is effected by starting the numerical integration at a *control* section. When the flow is above critical depth, the control is always downstream, and the depth is evaluated first for the control section, and then use is made of the gradually varied flow equation. Writing the equation in the form

$$l = \int F(y) dy$$

a plot of $F(y)$ as ordinate against y as abscissa is made, starting with the control depth and varying y in the direction indicated by the characteristic curves. This plot (Fig. 49) gives the value of l from the control section to the new depth y as the area under the curve between the values of y . In this manner the whole profile may be worked out.

When the depth of flow is less than critical, the control section is upstream (i.e., flow is out from under a gate), and the integration is handled in a similar fashion for determination of the profile downstream from the control.

A phenomenon known as the *hydraulic jump* occurs under certain conditions in channel flow. The flow prior to the jump must always be below the critical depth, and when the downstream depth is such that the momentum equation is satisfied for the liquid contained in the jump, the hydraulic jump will occur. The momentum equation applied to the liquid between sections 1 and 2 of Fig. 50 for a rectangular channel

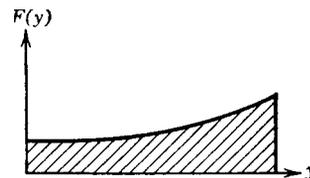

Fig. 49 Plot for determination of liquid surface profile.

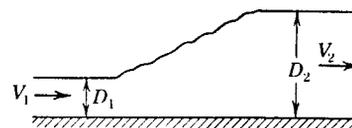

Fig. 50 Hydraulic jump.

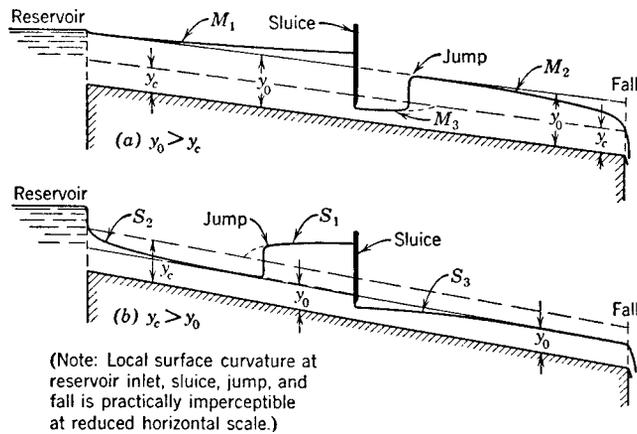

Fig. 51 Examples of surface profiles. (Courtesy of Hunter Rouse, State University of Iowa, Iowa City.)

yields the relation between depths

$$D_2 = -\frac{D_1}{2} + \sqrt{\frac{2D_1V_1^2}{g} + \frac{D_1^2}{4}} \quad (192)$$

Examples of occurrence of the surface profiles including situations where the jump results, are given in Fig. 51.

8.3 Unsteady, Nonuniform Flow

Any change in discharge in an open channel results in an unsteady nonuniform flow. The changes in flow result in gravity waves moving through the system. In certain cases, waves of fixed form propagate along the channel. The most common is the surge wave depicted in Fig. 52. In a rectangular channel, the celerity of the surge can be computed by the equation

$$c = \sqrt{gy_1} \left[\frac{1}{2} \frac{y_2}{y_1} \left(\frac{y_2}{y_1} + 1 \right) \right]^{1/2} \quad (193)$$

where c is the surge celerity relative to the undisturbed fluid velocity V_1 .

There are other waves of fixed form, including the monoclinal rising flow wave, the solitary wave, and roll waves. All of these are the result of special flow or channel conditions and can be found in the literature.

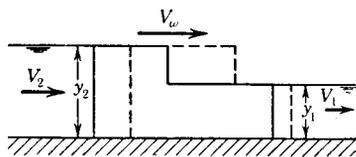

Fig. 52 Surge wave.

The most general approach to open-channel unsteady flow is through a procedure similar to that used in pipe flow. The principles of continuity and momentum are employed to develop a pair of nonlinear partial differential equations:

$$\frac{\partial A}{\partial t} + V \frac{\partial A}{\partial x} + A \frac{\partial V}{\partial x} = q \quad (194)$$

$$g \frac{\partial y}{\partial x} + \frac{\partial V}{\partial t} + V \frac{\partial V}{\partial x} = g(S_0 - S_f) - \frac{V}{A} q \quad (195)$$

where A = cross-sectional area, V = velocity of flow, y = depth of flow, S = slope of energy gradient, and q = lateral inflow per unit length.

In a manner similar to that in pipe flow these two equations can be transformed into ordinary differential equations so that

$$\frac{dV}{dt} + \frac{g}{c} \frac{dy}{dt} + g(S - S_0) + \frac{q}{A}(V + c) = 0 \quad (196)$$

if

$$\frac{dx}{dt} = V + c \quad (197)$$

and

$$\frac{dV}{dt} - \frac{g}{c} \frac{dy}{dt} + g(S - S_0) + \frac{q}{A}(V - c) = 0 \quad (198)$$

if

$$\frac{dx}{dt} = V - c \quad (199)$$

where $c = \sqrt{gA/b}$ and b = surface width of the channel.

The equations can now be solved numerically by finite-difference methods. This application of the method of characteristics requires that considerable care be exercised to guarantee that the Courant condition-relating time step, length step, and wave celerity,

$$\Delta t \leq \frac{\Delta x}{|V| + c} \quad (200)$$

be satisfied. The work of Wylie and Streeter¹⁴ detail this general approach to the analysis of unsteady flow in open channels.

9 FLOW ABOUT IMMERSED OBJECTS

Flow about immersed objects has been discussed in Section 4 for the case of an ideal (frictionless) fluid. This section considers the effects of viscosity.

When a viscous fluid flow past an object, the fluid exerts a shear stress on the surface of the object as well as a normal pressure force. If the components of the surface shear and pressure in the direction of the flow are summed, the resulting force is known as the *drag*. The drag consists of a contribution from shear (skin friction drag) and pressure (form drag). In the case of well-formed bodies, the skin friction drag is the most significant. For blunt bodies, form drag dominates.

If the components of shear and pressure forces normal to the oncoming flow are summed, the *lift* on the body results. Typically, shear forces play a minor *direct* role on lift. Pressure is the dominant contributor. However, viscous forces can have a considerable indirect effect on lift and drag by causing boundary layer separation. It is common to represent lift L and drag D in terms of lift and drag coefficients

$$D = C_D \frac{1}{2} \rho A V_o^2 \quad (201)$$

$$L = C_L \frac{1}{2} \rho A V_o^2 \quad (202)$$

where C_D , C_L = drag and lift coefficients, respectively, ρ = fluid density, A = frontal area of object, and V_o = free-stream velocity.

In 1904 Prandtl developed the concept of the boundary layer and thus forged the link between ideal

fluid mechanics and viscous flow. For fluids of relatively small viscosity, the effects of fluid friction are confined to a thin layer of fluid adjacent to the boundary known as the boundary layer. The flow outside the boundary layer can be determined with the tools of ideal fluid flow analysis. It is important to note that the boundary layer is thin and there is little normal acceleration; hence, the pressure variation along the body is determined, for all practical purposes, by the ideal fluid flow. This revelation led to the first analytical approach to the calculation of drag.

9.1 Flat-Plate Boundary Layer

Flow across a flat plate parallel to the flow direction is subject to boundary layer growth. The forward portion of the plate develops a laminar boundary layer. The laminar boundary layer then "breaks down", forming a turbulent boundary layer that continues downstream indefinitely (see Fig. 53). The laminar boundary layer exists until a Reynolds number of 3900 occurs:

$$Re = \frac{V\delta}{\nu} \quad (203)$$

where δ = boundary layer thickness. Note that if the approaching flow is turbulent or the leading edge of the plate is rough, the laminar boundary layer may be considerably shorter.

Analysis of the flow on a flat plate provides the following values of shear stress and drag for the laminar flow portion:

$$\tau_o = c_f \frac{1}{2} \rho V_o^2 \quad (204)$$

where

$$c_f = \sqrt{\frac{8}{15Re_x}} \quad \text{and} \quad Re_x = \frac{V_o x}{\nu} \quad (205)$$

where x = distance from forward edge of the plate. The total drag force D is given by

$$D = C_f \frac{1}{2} A \rho V_o^2 \quad (206)$$

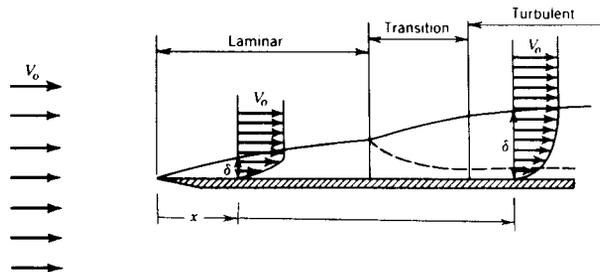

Fig. 53 Boundary layers on flat plate. By permission from J. K. Vennard and R. L. Street, *Elementary Fluid Mechanics*, 5th ed., Wiley, New York, 1975.

where

$$C_f = \sqrt{\frac{32}{15\text{Re}_x}} \quad (207)$$

These formulas are valid for Reynolds numbers based on Re_x up to 500,000 where

$$\text{Re}_x = \frac{Vx}{\nu} \quad (208)$$

If the flow over the flat plate is largely turbulent, then the drag coefficient C_f can be expressed as

$$\frac{1}{\sqrt{C_f}} = 4.13 \log C_f \text{Re}_x \quad (209)$$

In general the C_f values in Fig. 54 can be used in the drag force equation to compute total drag on a smooth flat plate.

9.2 Drag on Immersed Objects

The total drag on an immersed object may be dominated by skin friction or form drag but, in any case, is generally obtained by experiment. The data are presented as drag coefficient and plotted as C_D versus Reynolds number. The total drag force can then be calculated from Eq. (201). Data on drag coefficients for common objects are presented in Figs. 55 and 56.

9.3 Lift

Lift is also presented through graphs of C_L . However, Chapter 6 adequately covers lift, and the reader should refer to that section for more detailed information.

10 FLUID MEASUREMENTS*

In spite of the advances in numerical analysis, analytical techniques, and computer power in recent years, the complex phenomena of fluid flow must still be addressed empirically. The measurement of pressure, shear, discharge, velocity, and so forth remain necessary skills to the serious fluid mechanician. Many techniques and devices remain relatively unchanged over the years. Others, particularly in velocity measurement, reflect the recent advances in technology. This section presents an abbreviated review of the range of devices available.

10.1 Fluid Property Measurement

Specific Weight or Density Measurement of the specific weight of a liquid relies on fundamental concepts and devices that generally need no calibration. Figure 57 illustrates three methods that depend on buoyancy calculations and one (Fig. 57d) that utilizes hydrostatics. Probably the simplest method is not illustrated—simply weighing a known volume of liquid. The device or method selected depends on the availability of the required equipment.

Figure 57a utilizes the submerged weight of a known volume of liquid. Figure 57b, in a somewhat reversed approach, submerges a known weight and volume into the unknown liquid. Figure 57c uses calibrated hydrometers. Figure 57d illustrates the U-tube method, which requires no calibration.

Viscosity Measurement Viscosity-measuring devices (viscometers) generally employ one of three

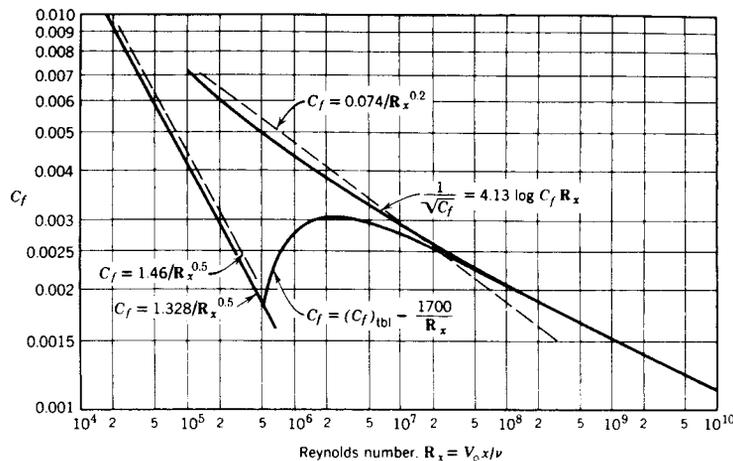

Fig. 54 Drag coefficients for smooth, flat plates. By permission from J. K. Vennard and R. L. Street, *Elementary Fluid Mechanics*, 5th ed., Wiley, New York, 1975.

*This section follows closely the treatment in Vennard and Street.¹

approaches to measuring viscosity—the falling sphere, the flowin tube, or the rotating cylinder. All the devices require that laminar flow be maintained throughout the measurement period.

The falling-sphere device is illustrated in Fig. 58. Stokes's law for a sphere falling in a viscous liquid is employed. The time required for a sphere of known size and weight to fall a specific distance is measured. The absolute viscosity can be calculated from the equation

$$\mu = \frac{d^2(\gamma_s - \gamma_l)}{18V} \quad (210)$$

where d = sphere diameter, V = sphere velocity, and γ_s , γ_l = specific weight of sphere and liquid, respectively.

The flowing-tube devices (Ostwald, Saybolt, Bingham, Redwood, and Engler viscometers) are typified by

the Ostwald and Saybolt devices in Fig. 59. All these devices depend on the laminar unsteady flow of a liquid. The time required for a given volume of liquid to flow through a small tube is measured, and an empirical formula based on laminar flow principles is used to calculate kinematic viscosity. For example, in the Saybolt device, the time required for the liquid level to drop from level B to C is recorded. The kinematic viscosity is calculated from the equation

$$\nu(\text{ft}^2/\text{sec}) = 0.00002365t - \frac{0.001935}{t} \quad (211)$$

where t = time in seconds required for liquid level to drop.

The other devices will not be discussed here as the principles are similar and instructions and calibrated equations are supplied with the devices.

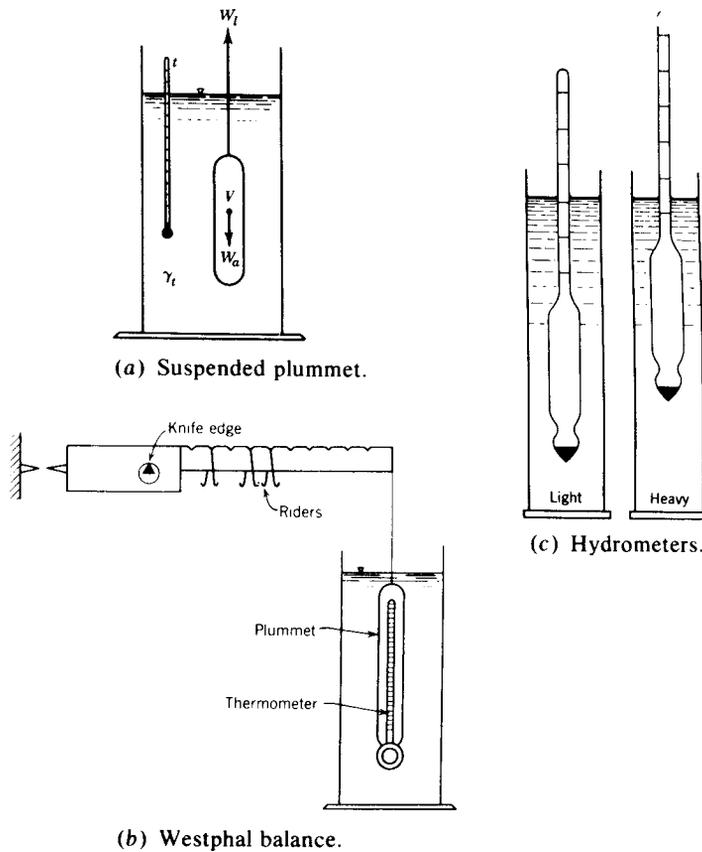

Fig. 57 Devices for density measurement. By permission from J. K. Vennard and R. L. Street, *Elementary Fluid Mechanics*, 5th ed., Wiley, New York, 1975.

The rotating-cylinder devices (Stormer, MacMichael, Brookfield generally employ a fixed cylindrical container and a rotating inner cylinder (see Fig. 60). The space between the two cylinders and the speed of rotation is purposely kept small enough to maintain laminar flow. Measurement of the time required to complete a given number of revolutions under a constant torque leads to a calculation of absolute viscosity. The fundamental equation used is

$$T = \frac{2\pi R^2 h \mu V}{\Delta R} + \frac{\pi R^3 \mu V}{2\Delta h} \quad (212)$$

10.2 Pressure Measurement

Pressure measurement in a fluid at rest is relatively easy to accomplish. The manometers and Bourdon gauges discussed in Section 3 are common devices used for this purpose. If the fluid is moving, pressure measurement is more difficult

Of primary concern is the pressure-sensing connection between the fluid and the pressure-measuring

system. In measuring *static* pressure (pressure unaffected by the velocity of flow) an opening is made in the conduit wall or the pressure probe, such as a pitot-static tube (see Fig. 61), so that the pressure in the fluid at the surface may be conducted to the pressure-measuring device. The surface opening must be small (less than 1 mm) and well finished (square edged, no burr) so that the flow is not disturbed. In the case of a probe, the device must be small enough to not disturb the flow and alter the pressure situation and properly oriented to produce the true static pressure.

The pressure-measuring devices used in fluid flow may be manometers or gauges. However, for electronic recording as well as measurement of fluctuating pressures, a pressure transducer is commonly used. A typical pressure transducer is a small diaphragm to which is attached a strain gauge to measure deflection of the diaphragm. The gauge is part of a Wheatstone bridge circuit and is calibrated to an electrical output that can be processed to produce a plot, directed to a computer for further analysis, or simply stored on some electronic device.

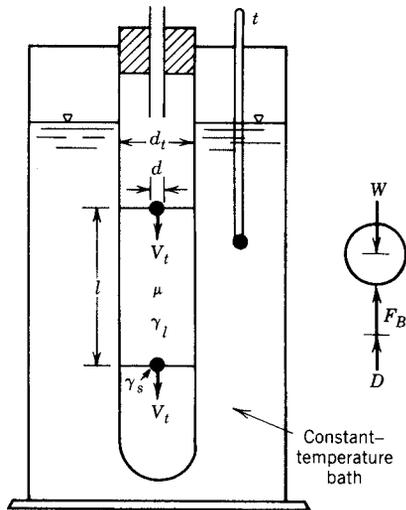

Fig. 58 Falling-sphere viscometer. By permission from J. K. Vennard and R. L. Street, *Elementary Fluid Mechanics*, 5th ed., Wiley, New York, 1975.

Piezoelectric transducers are also used wherein the sensing device is a piezoelectric crystal that produces an electric field when deformed. Care must be taken to install the sensors in a shock-free environment as they are very sensitive to any vibration of the facility hardware.

Pressure-sensitive paint (PSP) is a special paint material that adjusts its color based on the local pressure acting on the paint. Due to its nature, PSP provides nonintrusive, global surface pressure measurements. Therefore, PSP can be applied to the model surface being tested, and through special imaging equipment,

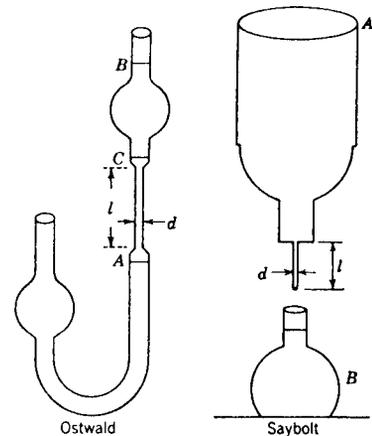

Fig. 59 Tube viscometers. By permission from J. K. Vennard and R. L. Street, *Elementary Fluid Mechanics*, 5th ed., Wiley, New York, 1975.

a quantitative picture of surface pressure values can be produced. Although PSP technology was initially developed in the 1970s, its use for flow visualization was first proposed in 1980. Since then, many different chemical formulations have been developed and have been used in all fields of aerodynamics, including low subsonic, high subsonic, transonic, and supersonic.

The working mechanism of PSP is simple but it is not reflected in its name. Actually, the paint is sensitive not to the local pressure but to the local partial pressure of oxygen. If the fluid that is used in the experiment is air and at constant composition (nonreacting), then the partial pressure of oxygen is directly proportional with the pressure of the air. Therefore, the higher the air pressure, the higher the "quenching effect." As a

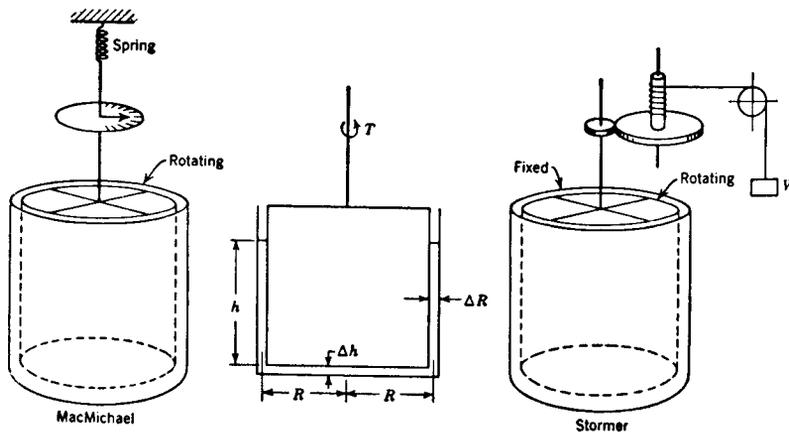

Fig. 60 Rotational viscometers (schematic). By permission from J. K. Vennard and R. L. Street, *Elementary Fluid Mechanics*, 5th ed., Wiley, New York, 1975.

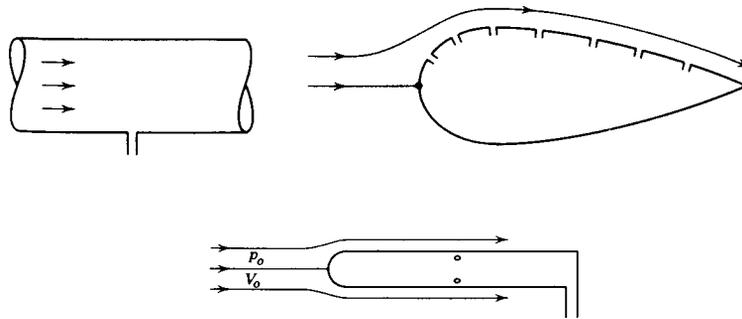

Fig. 61 Static tube. By permission from J. K. Vennard and R. L. Street, *Elementary Fluid Mechanics*, 5th ed., Wiley, New York, 1975.

result of this quenching effect, the energy of the fluorescent light coming from the PSP decreases, which translates to an increase in the wavelength of the fluorescent light. Modified wavelength leads to variable color based on the magnitude of the quenching, and hence the local pressure. Once calibrated for different wavelength–pressure correspondence, PSP can be used on the model object.

A PSP system consists of a light source to excite the paint for luminescence, the model painted with the PSP, a high-definition camera, and a processing unit for matching the light intensity values to the pressure values. As in all other measurement devices, PSPs also have their own error sources and they require a calibration for different operating conditions.

10.3 Velocity Measurement

One of the commonest and simplest devices for the measurement of velocity is a pitot-static tube (see Fig. 62). The device senses the difference in pressure between the tip of the pitot-static tube and the side of the tube. This pressure difference can be used to calculate the velocity from the equation

$$V_o = \sqrt{\frac{2(p_s - p_o)}{\rho}} = \sqrt{\frac{2g(p_s - p_o)}{\gamma}} \quad (213)$$

where $p_s - p_o$ is the aforementioned difference in pressure.

In very low velocity flows the anemometer or current meter is often used (see Fig. 63). These are

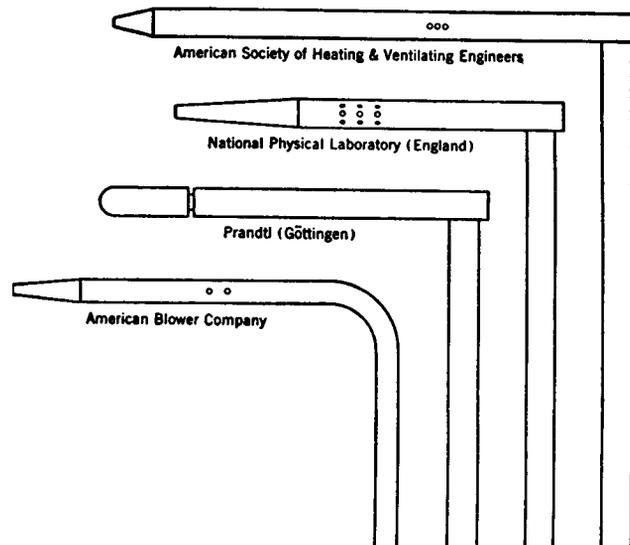

Fig. 62 Pitot-static tubes (to scale). By permission from J. K. Vennard and R. L. Street, *Elementary Fluid Mechanics*, 5th ed., Wiley, New York, 1975.

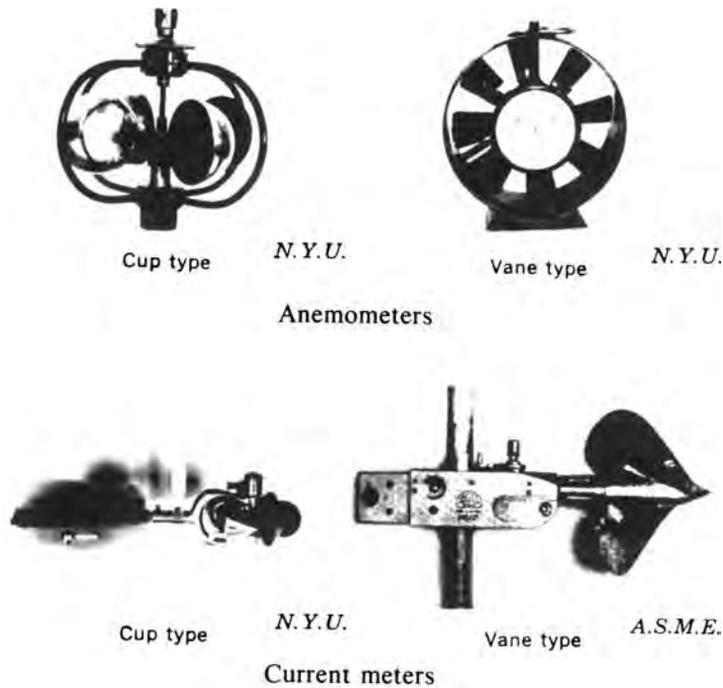

Fig. 63 By permission from J. K. Vennard and R. L. Street, *Elementary Fluid Mechanics*, 5th ed., Wiley, New York, 1975.

calibrated devices that relate flow velocity to the number of revolutions per minute of the rotating element in the meter. Anemometers are typically used to measure wind speeds, and current meters are employed to measure water velocities in rivers.

Measurement of rapidly fluctuating velocities in air and water require devices that can respond quickly to changes in velocity. The hot-wire anemometer is commonly used to measure velocity fluctuation in air. A thin wire connected between two supports passes an electric current that heats the wire (see Fig. 64a). Air moving perpendicular to the wire cools the wire in proportion to the flow velocity. The electronics of the system measures the increased voltage necessary to keep the wire temperature constant and relates that voltage to the flow velocity. In some devices the current flowing through the probe is kept constant and the voltage change required for this to occur is related to the flow velocity. However, the constant-temperature device is by far the most popular.

A variation on the hot-wire anemometer is the hot-fil anemometer. The hot-fil device is similar to the hot wire except the wire is coated to protect it from contaminated environments. In addition to coated wires, hot-fil anemometry employs probes of other shapes that are sturdier and less likely to trap impurities in the flow (lint, small pieces of organic material, etc.). Figure 65 illustrates a few of these different types of probes. Hot-fil devices are commonly used in liquid

flows. Both these devices are capable of measuring velocity fluctuation frequencies of better than 300 kHz.

Another technique for measuring velocities is laser-Doppler velocimetry (LDV). The fundamental basis for the technique is the Doppler shift of light that is scattered from extremely small particles in a moving fluid. One valuable attribute of LDV is that it is non-intrusive, that is, the sensing device is not in the flow. It only needs visual access to the flow for the required light beams. Refer to Goldstein¹⁶ for a thorough treatment of the subject. One of the most recent advances in measuring fluid velocities is particle image velocimetry (PIV), which also makes use of the laser and seed particles but works with a planar laser light sheet. This provides the advantage of measuring an entire two-dimensional plane of the flow field simultaneously, as compared to LDV, which only offers a point measurement. For more details on PIV, see Raffel et al.¹⁷

10.4 Flow Rate Measurement

Methods of measuring flow rate or discharge can generally be categorized into total quantity measurements, pressure drop or pressure difference measuring devices, tracer transport techniques, and devices that induce critical flow conditions or simply changes in water surface depth in open channels. Another indirect approach is the measurement of velocity at several

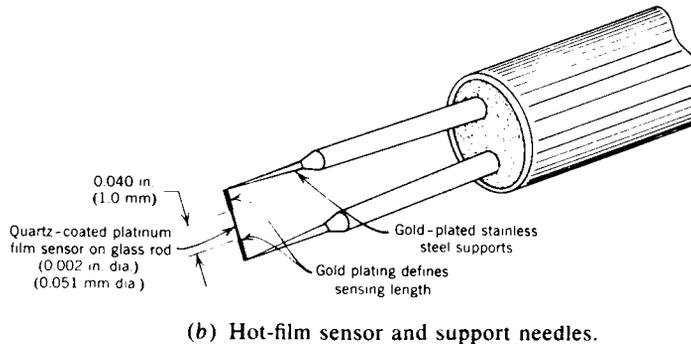

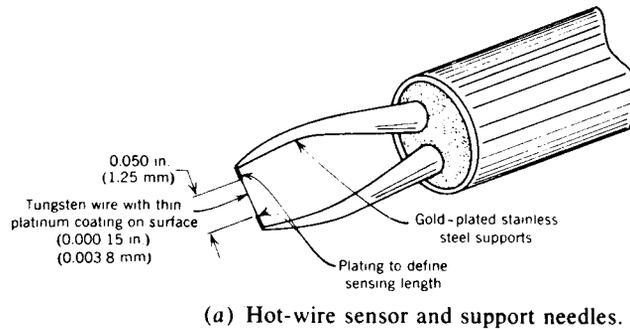

Fig. 64 Anemometer sensors. Reproduced from TB5, Thermo-Systems, Inc., 2500 Cleveland Ave. North, St. Paul, Minnesota, 55113. By permission from J. K. Vennard and R. L. Street, *Elementary Fluid Mechanics*, 5th ed., Wiley, New York, 1975.

points and a numerical integration of velocity times area to calculate discharge.

Total Quantity Methods The success of these methods depends on the availability of a means to collect and measure (or weigh) the amount of liquid captured in the container in a given time period. Advantages are the lack of any need to calibrate a device. This approach is often used to calibrate other flow-rate-measuring devices.

Pressure Difference Methods All the devices that create pressure differences in a fluid flow to permit calculation of flow rate also create friction losses in the flow. One of the devices that has the lowest friction loss is the venturi meter (see Fig. 66). In the venturi meter the Bernoulli effect is used to generate a pressure difference between the entrance and the throat of the device. This pressure difference is related to the flow rate through the equation

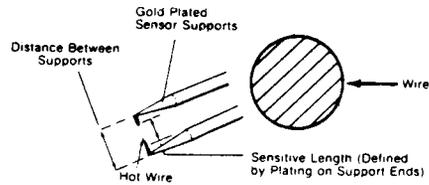

$$Q = \frac{C_v A_2}{\sqrt{1 - (A_2/A_1)^2}} \sqrt{2g \left(\frac{p_1}{\gamma} + z_1 - \frac{p_2}{\gamma} - z_2 \right)} \quad (214)$$

where A is the cross-sectional area of the meter and C_v is a calibration coefficient shown in Fig. 66. Venturi meters are relatively expensive but produce very little friction loss and are quite accurate.

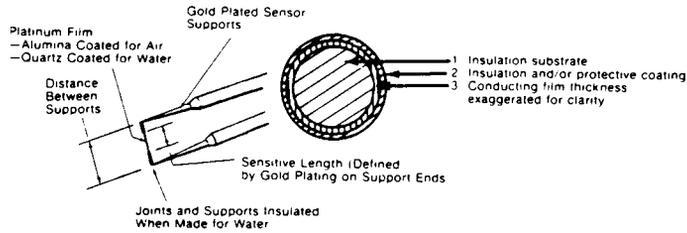

A device based on a similar technique to the venturi meter is the flow nozzle. This device resembles the upstream portion of a venturi meter (see Fig. 67). Pressure recovery experienced in the downstream section of the venturi meter is not realized here so the flow nozzle creates a larger friction loss than the venturi meter. The calculation for discharge is made with the same equation used for the venturi meter with the C_v value taken from Fig. 67.

One further step in the direction of simplicity (and lower cost) is the orific meter (see Fig. 68). This device is simply a circular plate with a hole cut out of its center and installed in a pipe, generally in a flanged connection. The orific meter creates considerably more friction loss than the venturi meter or flow nozzle but its low cost makes it attractive in many instances. Flow rates through an orific meter may be calculated with the equation

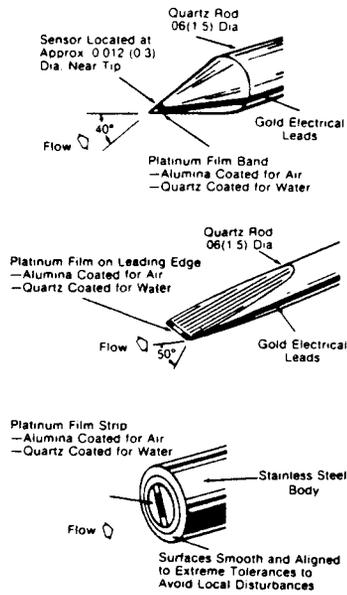

$$Q = CA \sqrt{2g \left(\frac{p_1}{\gamma} + z_1 - \frac{p_2}{\gamma} - z_2 \right)} \quad (215)$$

(a) CROSS SECTION OF HOT-WIRE SENSOR

(b) CROSS SECTION OF HOT-FILM SENSOR

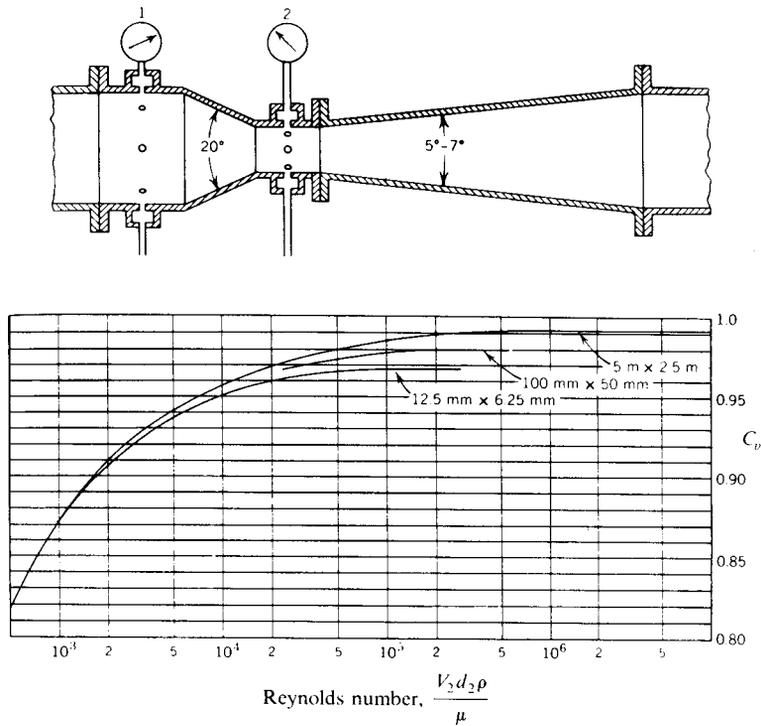

Fig. 66 Venturi meter and coefficients. By permission from J. K. Vennard and R. L. Street, *Elementary Fluid Mechanics*, 5th ed., Wiley, New York, 1975.

The value of C for a given flow rate is found from Fig. 69.

There are certain special cases of “orific meters” shown in Fig. 70 where discharges through the orifice can be related to liquid levels on one (or two) side(s) of the opening. The equations used to compute the discharge are

$$Q = A_2 V_2 = C_c C_v A \sqrt{2g(h_1 - h_2)}$$

$$= CA \sqrt{2g(h_1 - h_2)} \tag{216}$$

$$= C_c C_v A \sqrt{2gh} = CA \sqrt{2gh} \tag{217}$$

All the C values for various types of orifice can be found in Fig. 71. More precise data for C values of sharp-edged orifice over a large range of heads are given in Fig. 72.

Probably the most inexpensive technique for calculating flow rate by the pressure difference method is the elbow meter (see Fig. 73). The only requirements are two pressure taps on the inner and outer portions of the elbow. The flow rate is calculated from the equation

$$Q = CA \sqrt{2g \left(\frac{P_o}{\gamma} + z_o - \frac{P_i}{\gamma} - z_i \right)} \tag{218}$$

Because the value of C depends strongly on the elbow geometry, it must generally be determined through a calibration procedure.

Tracer Transport Techniques This technique is based on the premise that the discharge in a conduit can be measured by the time of travel of the average concentration of a tracer between two points. The tracer could be as simple as salt where concentration is measured via conductivity instruments (see Fig. 74), although any other tracer may be employed. Fluorescent dyes are commonly used because they have little effect on water quality and are detectable in minute quantities. From Fig. 74, the average velocity is computed from dividing the length l between sensors by the time t required for the centroid of the concentration curve to travel over the distance. This approach is particularly useful in open channels of relatively constant cross section and conduits where, for one reason or another, other techniques cannot be used.

Open-Channel Flow-Measuring Devices In free-surface flows the common techniques for flow measurement center on either (a) constricting the flow to create differences in water surface elevations that can be related to flow rate or (b) creating critical flow

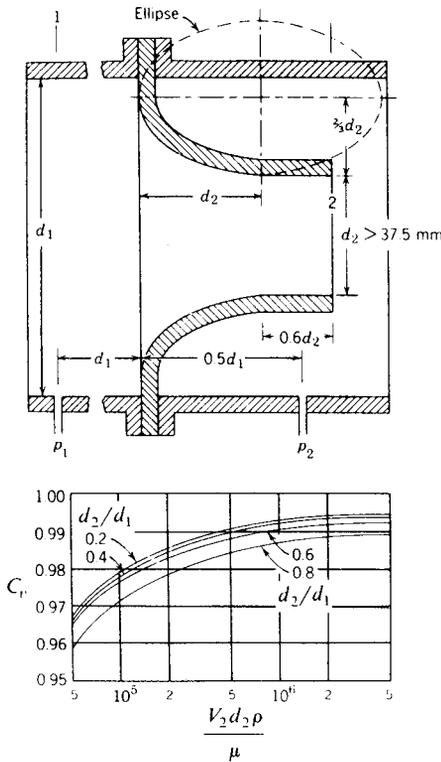

Fig. 67 ASME flow nozzle and coefficients. By permission from J. K. Vennard and R. L. Street, *Elementary Fluid Mechanics*, 5th ed., Wiley, New York, 1975.

conditions (see Section 8) that provide a strong analytical connection to discharge calculation.

The simplest devices are venturi flumes which are the open-channel version of venturi meters. The drop in water surface in the flume throat is measured and related to the flow rate. Although not extremely accurate, this approach does not create large friction losses.

A simpler version similar to the flow nozzle in closed conduits is the cutthroat flume where the diverging recovery section is not present.

A somewhat more complicated version of the venturi flume which causes critical or near-critical flow to occur, is the Parshall flume (see Fig. 75). This device has been commonly used in irrigation systems for well over 70 years. The discharge is calculated from the equation

$$Q = 4Bh_a^{1.522} B^{0.26} \quad (219)$$

Another category of open-channel flow-measuring devices is weirs. These devices generally generate more friction loss than the previously described devices, but they are relatively simple and accurate. A typical sharp-crested rectangular weir is shown in Fig. 76. The other types of weirs are broad-crested (Fig. 77) and triangular (Fig. 78). The general form of the discharge equation per foot of width for weirs with two-dimensional flow is

$$q = C_w \frac{2}{3} \sqrt{2g} H^{3/2}. \quad (220)$$

where H is defined in Figs. 76 and 77 as the head on the weir. The value of C_w for sharp-crested well-ventilated weirs (Fig. 76) is given by the equation

$$C_w = 0.605 + 0.08 \frac{H}{P} + \frac{1}{305H} \quad (221)$$

For broad-crested weirs (Fig. 77), the flow rate per foot of width is given by

$$q = \sqrt{g} \left(\frac{2E}{3} \right)^3 = \left(\frac{2}{3} \right)^{3/2} \sqrt{g} E^{3/2} \quad (222)$$

or Eq. (220) where

$$C_w = \frac{1}{\sqrt{3}} \left(\frac{E}{H} \right)^{3/2} \quad (223)$$

where E is defined in Fig. 77.

For triangular notch weirs (Fig. 78) the equation for computing discharge is

$$Q = C_w \frac{8}{15} \tan \alpha \sqrt{2g} H^{5/2} \quad (224)$$

where C_w depends on the notch angle α . For $\alpha = 90^\circ$,

$$C_w = 0.56 + \frac{0.70}{R^{0.165} W^{0.170}} \quad (225)$$

6.4	Solution with Control Surface Deflection and Rolling Rate	649			

1 INTRODUCTION AND NOTATION

Aerodynamics is the science of predicting and controlling the forces and moments that act on an object moving through the atmosphere. The aerodynamic forces and moments acting on any such object originate from only two sources:

1. The pressure distribution over the body surface
2. The shear stress distribution over the body surface

A resultant aerodynamic force \mathbf{F}_a and a resultant aerodynamic moment \mathbf{M}_a are the net effects of the pressure and shear stress distributions integrated over the entire surface of the body. To express these two vectors in terms of components, we must define a coordinate system. While several different coordinate systems are used in aeronautics, the coordinate system commonly

used in the study of aerodynamics is referred to here as *Cartesian aerodynamic coordinates*. When considering flow over a body such as an airfoil, wing, or airplane, the x axis of this particular coordinate system is aligned with the body axis or *chord line*, pointing in the general direction of relative airflow. The origin is located at the front of the body or *leading edge*. The y axis is chosen normal to the x axis in an upward direction. Choosing a conventional right-handed coordinate system requires the z axis to be pointing in the spanwise direction from right to left, as shown in Fig. 1. Here, the components of the resultant aerodynamic force and moment, described in this particular coordinate system, are denoted as

$$\mathbf{F}_a = A\mathbf{i}_x + N\mathbf{i}_y + B\mathbf{i}_z$$

$$\mathbf{M}_a = -l\mathbf{i}_x - m\mathbf{i}_y - m\mathbf{i}_z$$

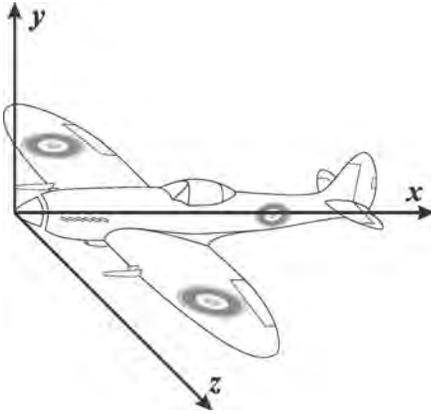

Fig. 1 Cartesian aerodynamic coordinate system used in the study of aerodynamics.

where \mathbf{i}_x , \mathbf{i}_y , and \mathbf{i}_z are the unit vectors in the x , y , and z directions, respectively. The terminology that describes these components is

A \equiv aftward axial force $\equiv x$ component of \mathbf{F}_a (parallel to chord)

N \equiv upward normal force $\equiv y$ component of \mathbf{F}_a (normal to chord and span)

B \equiv leftward side force $\equiv z$ component of \mathbf{F}_a (parallel with span)

ℓ \equiv rolling moment (positive right wing down)

n \equiv yawing moment (positive nose right)

m \equiv pitching moment (positive nose up)

The traditional definition for the moments in roll, pitch, and yaw do not follow the right-hand rule in this coordinate system. It is often convenient to split the resultant aerodynamic force into only two components,

D \equiv drag \equiv component of \mathbf{F}_a parallel to \mathbf{V}_∞ ($D = \mathbf{F}_a \cdot \mathbf{i}_\infty$)

L \equiv lift \equiv component of \mathbf{F}_a perpendicular to \mathbf{V}_∞ ($L = |\mathbf{F}_a - D\mathbf{i}_\infty|$)

where \mathbf{V}_∞ is the free-stream velocity or *relative wind* far from the body and \mathbf{i}_∞ is the unit vector in the direction of the free stream.

For two-dimensional flow (2D), it is often advantageous to define the *section force* and *section moment* to be the force and moment per unit span. For these definitions the notation used here will be

\tilde{D} \equiv section drag \equiv drag force per unit span (parallel to \mathbf{V}_∞)

\tilde{L} \equiv section lift \equiv lift force per unit span (perpendicular to \mathbf{V}_∞)

\tilde{A} \equiv section axial force \equiv axial force per unit span (parallel to chord)

\tilde{N} \equiv section normal force \equiv normal force per unit span (perpendicular to chord)

\tilde{m} \equiv section moment \equiv pitching moment per unit span (positive nose up)

where the chord is a line extending from the leading edge to the trailing edge of the body. The chord length, c , is the length of this chord line.

The aerodynamic forces and moments are usually expressed in terms of dimensionless force and moment coefficients. For example,

$$C_D \equiv \text{drag coefficient} \equiv \frac{D}{\frac{1}{2}\rho_\infty V_\infty^2 S}$$

$$C_L \equiv \text{lift coefficient} \equiv \frac{L}{\frac{1}{2}\rho_\infty V_\infty^2 S}$$

$$C_A \equiv \text{axial force coefficient} \equiv \frac{A}{\frac{1}{2}\rho_\infty V_\infty^2 S}$$

$$C_N \equiv \text{normal force coefficient} \equiv \frac{N}{\frac{1}{2}\rho_\infty V_\infty^2 S}$$

$$C_m \equiv \text{pitching moment coefficient} \equiv \frac{m}{\frac{1}{2}\rho_\infty V_\infty^2 S c}$$

where ρ_∞ is the free-stream density, S is the reference area, and c is the reference length. For a streamlined body such as a wing, S is the planform area and c is the mean chord length. For a bluff body, the frontal area is used as the reference. For 2D flow, the section aerodynamic coefficients per unit span are defined

$$\tilde{C}_D \equiv \text{section drag coefficient} \equiv \frac{\tilde{D}}{\frac{1}{2}\rho_\infty V_\infty^2 c}$$

$$\tilde{C}_L \equiv \text{section lift coefficient} \equiv \frac{\tilde{L}}{\frac{1}{2}\rho_\infty V_\infty^2 c}$$

$$\tilde{C}_A \equiv \text{section axial force coefficient} \equiv \frac{\tilde{A}}{\frac{1}{2}\rho_\infty V_\infty^2 c}$$

$$\tilde{C}_N \equiv \text{section normal force coefficient} \equiv \frac{\tilde{N}}{\frac{1}{2}\rho_\infty V_\infty^2 c}$$

$$\tilde{C}_m \equiv \text{section moment coefficient} \equiv \frac{\tilde{m}}{\frac{1}{2}\rho_\infty V_\infty^2 c^2}$$

The resultant aerodynamic force acting on a 2D airfoil section is completely specific in terms of either lift and drag or axial and normal force. These two equivalent descriptions of the resultant aerodynamic force are related to each other through the angle of attack, as shown in Fig. 2:

α \equiv angle of attack \equiv angle from \mathbf{V}_∞ to chord line (positive nose up)

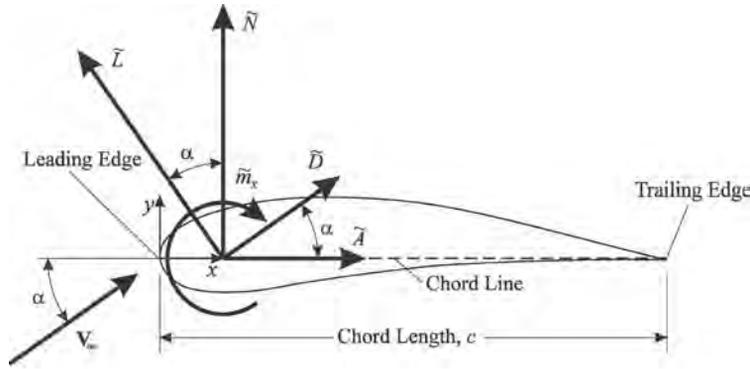

Fig. 2 Section forces and moment.

If the normal and axial coefficients are known, the lift and drag coefficients can be found from the relations

$$\tilde{C}_L = \tilde{C}_N \cos \alpha - \tilde{C}_A \sin \alpha \quad (1)$$

$$\tilde{C}_D = \tilde{C}_A \cos \alpha + \tilde{C}_N \sin \alpha \quad (2)$$

and when the lift and drag coefficient are known, the normal and axial coefficients are found from

$$\tilde{C}_N = \tilde{C}_L \cos \alpha + \tilde{C}_D \sin \alpha \quad (3)$$

$$\tilde{C}_A = \tilde{C}_D \cos \alpha - \tilde{C}_L \sin \alpha \quad (4)$$

Because the lift is typically much larger than the drag, from Eq. (4) we see why the axial force is sometimes negative even though the angle of attack is small.

The resultant aerodynamic force and moment acting on a body must have the same effect as the distributed loads. Thus, the resultant moment will depend on where the resultant force is placed on the body. For example, let x be the coordinate measured along the chord line of an airfoil, from the leading edge toward the trailing edge. If we place the resultant force and moment on the chord line, the value of the resultant moment will depend on the x location of the resultant force. The resultant moment about some arbitrary point on the chord line a distance x from the leading edge, \tilde{m}_x , is related to the resultant moment about the leading edge, \tilde{m}_{le} , according to

$$\tilde{m}_{le} = \tilde{m}_x - x\tilde{N}$$

or in terms of dimensionless coefficients,

$$\tilde{C}_{m_{le}} = \tilde{C}_{m_x} - \frac{x}{c}\tilde{C}_N \quad (5)$$

Two particular locations along the chord line are of special interest:

x_{cp} \equiv center of pressure \equiv point about which resultant moment is zero

x_{ac} \equiv aerodynamic center \equiv point about which resultant moment is independent of α

Using the definition of center of pressure in Eq. (5), the section pitching moment coefficient relative to the leading edge can be written as

$$\tilde{C}_{m_{le}} = \tilde{C}_{m_x} - \frac{x}{c}\tilde{C}_N = -\frac{x_{cp}}{c}\tilde{C}_N$$

or, after solving for the center of pressure,

$$\frac{x_{cp}}{c} = \frac{x}{c} - \frac{\tilde{C}_{m_x}}{\tilde{C}_N} = -\frac{\tilde{C}_{m_{le}}}{\tilde{C}_N} \quad (6)$$

Using the aerodynamic center in Eq. (5), we can write

$$\tilde{C}_{m_x} - \frac{x}{c}\tilde{C}_N = \tilde{C}_{m_{ac}} - \frac{x_{ac}}{c}\tilde{C}_N \quad (7)$$

Equation (7) must hold for any angle of attack and any value of x . Thus, at the angle of attack that gives a normal force coefficient of zero, the moment coefficient about any point on the chord line is equal to the moment coefficient about the aerodynamic center, which by definition does not vary with angle of attack. Thus, the section pitching moment coefficient relative to the aerodynamic center can be expressed as

$$\tilde{C}_{m_{ac}} = (\tilde{C}_{m_x})_{\tilde{C}_N=0} \quad (8)$$

Using Eq. (8) in Eq. (7) and solving for the location of the aerodynamic center results in

$$\frac{x_{ac}}{c} = \frac{x}{c} + \frac{(\tilde{C}_{m_x})_{\tilde{C}_N=0} - \tilde{C}_{m_x}}{\tilde{C}_N} = \frac{(\tilde{C}_{m_{le}})_{\tilde{C}_N=0} - \tilde{C}_{m_{le}}}{\tilde{C}_N} \quad (9)$$

Thus, to determine the aerodynamic center of an airfoil section, one can evaluate the normal force and pitching moment coefficients for any point on the chord line, as a function of angle of attack. The moment coefficient is then plotted as a function of the normal force coefficient. The moment axis intercept is the moment coefficient about the aerodynamic center. For any nonzero normal force coefficient the location of the aerodynamic center can be determined according to Eq. (9) from knowledge of the normal force coefficient and the moment coefficient about some arbitrary point.

2 BOUNDARY LAYER CONCEPT

As pointed out in Section 1, there are only two types of aerodynamic forces acting on a body moving through the atmosphere: pressure forces and viscous shear forces. The Reynolds number provides a measure of the relative magnitude of the pressure forces in relation to the viscous shear forces. For the airspeeds typically encountered in flight Reynolds numbers are quite high and viscous forces are usually small compared to pressure forces. This does not mean that viscous forces can be neglected. However, it does allow us to apply the simplifying concept of boundary layer theory.

For flow over a streamlined body at low angle of attack and high Reynolds number, the effects of viscosity are essentially confined to a thin layer adjacent to the surface of the body, as shown in Fig. 3. Outside the boundary layer, the shear forces can be neglected and since the boundary layer is thin, the change in pressure across the thickness of this layer is insignificant. With this flow model, the pressure forces can be determined from the inviscid flow outside the boundary layer, and the shear forces can be obtained from a solution to the boundary layer equations.

While boundary layer theory provides a tremendous simplification over the complete Navier–Stokes equations, solutions to the boundary layer equations are far from trivial, especially for the complex geometry that is often encountered in an aircraft. A thorough review of boundary layer theory is beyond the intended scope of this chapter and is not a prerequisite to an understanding of the fundamental principles of wing theory. However, there are some important results of boundary layer theory that the reader should know and understand:

1. For the high-Reynolds-number flows typically encountered in flight the viscous shear forces are small compared to the pressure forces.
2. For flow at high Reynolds number, the pressure forces acting on a body can be closely approximated from an inviscid flow analysis, outside the boundary layer.
3. For 2D flow about streamlined bodies at high Reynolds numbers and low angles of attack, pressure forces do not contribute significantly to drag.
4. For bluff bodies and streamlined bodies at high angles of attack, boundary layer separation occurs, as shown in Fig. 4, and pressure forces dominate the drag.

Boundary layer separation in the flow over airfoils and wings is commonly referred to as *stall*. An understanding of stall and its effect on lift and drag is critical in the study of aeronautics. As the angle of attack for a wing is increased from zero, at first the boundary layer remains attached, as shown in Fig. 3, the lift coefficient increases as a nearly linear function of angle of attack, and the drag coefficient increases approximately with the angle of attack squared. As angle of attack continues to increase, the positive pressure gradient on the aft portion of the upper surface of the wing also increases. At some angle of attack this adverse pressure gradient may result in local boundary layer separation and the increase in lift with angle of attack will begin to diminish. At a slightly higher angle of attack, boundary layer separation becomes complete, as shown in Fig. 4, and the lift rapidly decreases as the angle of attack is increased further. Boundary layer separation also greatly accelerates the increase in drag with angle of attack. The maximum lift coefficient and the exact shape of the lift curve for angles of attack near stall depend substantially on the airfoil section geometry. As the angle of attack increases beyond stall, the lift and drag coefficients become less sensitive to section geometry and for angles of attack beyond about 25° , the lift and drag coefficient are nearly independent of the airfoil section.

The maximum lift coefficient that can be attained on a given wing before stall is quite important in aeronautics. This parameter not only determines the maximum

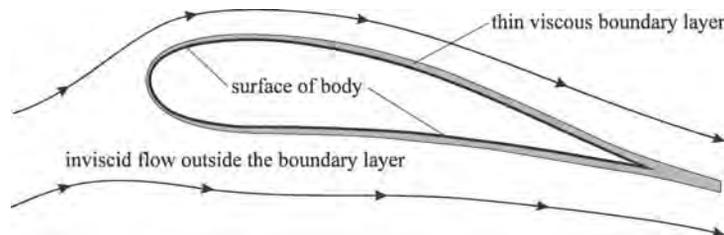

Fig. 3 Boundary layer flow over a streamlined body at a low angle of attack.

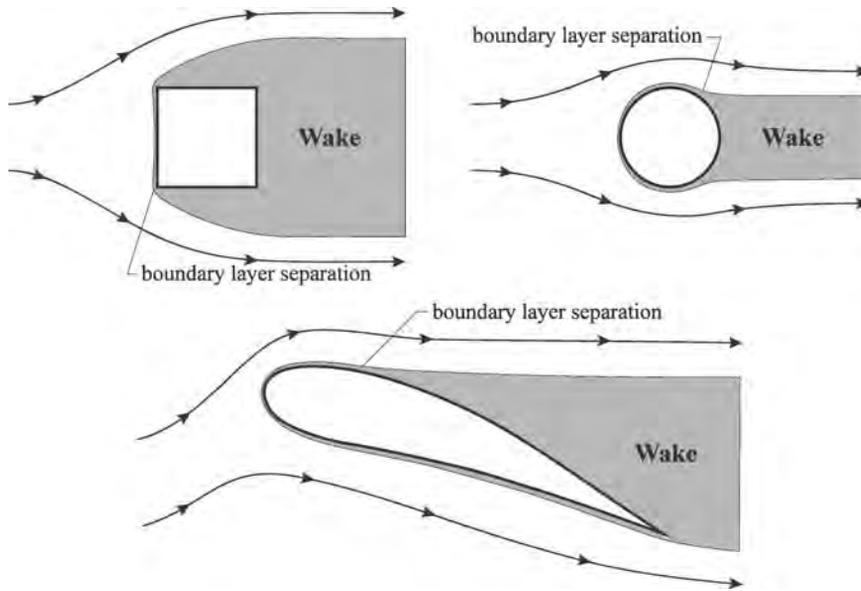

Fig. 4 Examples of boundary layer separation..

weight that can be carried by a given wing at a particular airspeed, it also affects takeoff distance, turning radius, and other measures of airplane performance.

3 INVISCID AERODYNAMICS

Since the pressure forces acting on an aircraft at high Reynolds number can be closely estimated from an inviscid analysis of the flow outside the boundary layer, inviscid aerodynamics is an important tool used in the estimation of the forces acting on an aircraft in flight. Written in vector notation, the general equations that govern inviscid fluid flow are the continuity equation

$$\frac{\partial \rho}{\partial t} + (\mathbf{V} \cdot \nabla)\rho + \rho \nabla \cdot \mathbf{V} = 0 \quad (10)$$

and the momentum equation

$$\frac{\partial \mathbf{V}}{\partial t} + (\mathbf{V} \cdot \nabla)\mathbf{V} = -\frac{\Delta p}{\rho} - g \nabla H \quad (11)$$

where \mathbf{V} is the fluid velocity vector and t is time. Using the important mathematical identity

$$(\mathbf{V} \cdot \nabla)\mathbf{V} = \nabla \left(\frac{1}{2} V^2 \right) - \mathbf{V} \times (\nabla \times \mathbf{V})$$

the momentum equation for inviscid flow can be written

$$\frac{\partial \mathbf{V}}{\partial t} + \nabla \left(\frac{1}{2} V^2 \right) + \frac{\nabla p}{\rho} + g \nabla H = \mathbf{V} \times \boldsymbol{\Omega} \quad (12)$$

where $\boldsymbol{\Omega}$ is the curl of the velocity vector, traditionally called the *vorticity*:

$$\boldsymbol{\Omega} \equiv \nabla \times \mathbf{V} \quad (13)$$

It can be shown from the application of vector calculus to Eqs. (10) and (12) that vorticity cannot be generated in an inviscid flow. In the aerodynamics problem associated with flow over an aircraft in flight, the fluid velocity far upstream from the aircraft is uniform. From the definition of vorticity given in Eq. (13), this means that the vorticity far upstream from the aircraft is zero. Since vorticity cannot be generated in an inviscid flow the vorticity must be zero everywhere in the inviscid flow outside the boundary layer. Vorticity is generated in the viscous boundary layer next to the skin of the aircraft and thus there is also vorticity in the boundary layer wake that trails behind an aircraft in flight. However, outside the boundary layer and trailing wake, the flow can be assumed to be inviscid and free of vorticity. Thus, for this flow the right-hand side of Eq. (12) will be zero. This type of flow is called *inviscid irrotational flow*.

In summary, inviscid irrotational flow can be assumed to exist outside the boundary layer and trailing wake of an aircraft in flight. For this flow the

continuity and momentum equations are

$$\frac{\partial \rho}{\partial t} + (\mathbf{V} \cdot \nabla)\rho + \rho \nabla \cdot \mathbf{V} = 0 \quad (14)$$

$$\frac{\partial \mathbf{V}}{\partial t} + \nabla \left(\frac{1}{2} V^2 \right) + \frac{\nabla p}{\rho} + g \nabla H = 0 \quad (15)$$

For the important special case of an aircraft in steady flight, the time derivatives are zero and Eq. (15) reduces to

$$\nabla \left(\frac{1}{2} V^2 \right) + \frac{\nabla p}{\rho} + g \nabla H = 0 \quad (16)$$

For the free-stream flow far from the aircraft, Eq. (16) gives

$$\nabla \left(\frac{1}{2} V_\infty^2 \right) + \frac{\nabla p_\infty}{\rho_\infty} + g \nabla H = 0$$

Since the free-stream velocity is uniform, the gradient of V_∞^2 is zero, which gives

$$g \nabla H = -\frac{\nabla p_\infty}{\rho_\infty} \quad (17)$$

This is simply a form of the hydrostatic equation. Using Eq. (17) in Eq. (16) to eliminate the geometric elevation gradient, the momentum equation for the inviscid flow about an aircraft in steady flight is

$$\nabla \left(\frac{1}{2} V^2 \right) + \frac{\nabla p}{\rho} - \frac{\nabla p_\infty}{\rho_\infty} = 0 \quad (18)$$

where p_∞ and ρ_∞ are evaluated at the same elevation as p and ρ .

A special case of Eq. (18) that is of particular interest is the case of flow with negligible variation in air density. This approximation can be applied to flight at low Mach numbers. Assuming that ρ is constant, Eq. (18) reduces to

$$\nabla \left(\frac{1}{2} V^2 + \frac{p - p_\infty}{\rho} \right) = 0 \quad (19)$$

Integrating this result from the free stream to some arbitrary point in the flow and solving for the local static pressure, the momentum equation for *incompressible inviscid flow* about an aircraft in steady flight yields

$$p = p_\infty + \frac{1}{2} \rho (V_\infty^2 - V^2) \quad (20)$$

Once the velocity field has been determined in some manner, Eq. (20) can be used to determine the pressure at any point in the flow. The net contribution that these

pressure forces make to the resultant aerodynamic force is then computed from

$$\begin{aligned} \mathbf{F}_p &= - \iint_S p \mathbf{n} d\mathcal{S} = - \iint_S p_\infty \mathbf{n} d\mathcal{S} \\ &\quad + \frac{1}{2} \rho V_\infty^2 \iint_S \left[\left(\frac{V}{V_\infty} \right)^2 - 1 \right] \mathbf{n} d\mathcal{S} \end{aligned} \quad (21)$$

where \mathbf{n} is the unit outward normal and \mathcal{S} is the surface area. The first integral on the far right-hand side of Eq. (21) is the buoyant force, and the second integral is the vector sum of the pressure contribution to the lift and drag. For most conventional airplanes the buoyant force is small and can be neglected.

From Eq. (14), the continuity equation for incompressible flow is

$$\nabla \cdot \mathbf{V} = 0 \quad (22)$$

Because the curl of the gradient of any scalar function is zero, a flow field is irrotational if the velocity field is written as the gradient of a scalar function

$$\mathbf{V} = \nabla \phi \quad (23)$$

where ϕ is normally called the *velocity potential* and could be any scalar function of space and time that satisfies the continuity equation and the required boundary conditions. Using Eq. (23) in Eq. (22), this requires that

$$\nabla \cdot \mathbf{V} = \nabla \cdot \nabla \phi = \nabla^2 \phi = 0 \quad (24)$$

Thus the incompressible velocity potential must satisfy Laplace's equation and some appropriate boundary conditions. The far-field boundary condition is uniform flow. At the surface of the aircraft the normal component of velocity must go to zero. However, since the flow is inviscid, we do not require zero tangential velocity at the surface.

For flight at higher Mach numbers the result predicted by Eq. (18) is more complex. When the density of a fluid changes with pressure, the temperature changes as well. Thus, in a compressible fluid, the pressure gradients that accompany velocity gradients also produce temperature gradients. In general, temperature gradients result in heat transfer. However, the thermal conductivity of air is extremely low. Thus, it is commonly assumed that the flow outside the boundary layer is adiabatic as well as inviscid. Inviscid adiabatic flow is isentropic. From the fundamentals of thermodynamics recall that for isentropic flow of an ideal gas, density is related to pressure according to the relation

$$\rho = \rho_\infty \left(\frac{p}{p_\infty} \right)^{1/\gamma} \quad (25)$$

where again γ is the ratio of specific heats ($\gamma = 1.4$ for air). Substituting Eq. (25) into Eq. (18) and neglecting the gradients of p_∞ and ρ_∞ yields

$$\nabla \left(\frac{1}{2} V^2 + \frac{\gamma}{\gamma - 1} \frac{p}{\rho} \right) = 0 \quad (26)$$

Integrating Eq. (26) gives

$$\frac{1}{2} V^2 + \frac{\gamma}{\gamma - 1} \frac{p}{\rho} = \text{const} \quad (27)$$

Equation (27) must apply at the stagnation state, where $V = 0$. Thus, the constant in Eq. (27) can be expressed in terms of the stagnation pressure and density, p_0 and ρ_0 .

$$\frac{1}{2} V^2 + \frac{\gamma}{\gamma - 1} \frac{p}{\rho} = \frac{\gamma}{\gamma - 1} \frac{p_0}{\rho_0} \quad (28)$$

For an ideal gas $p/\rho = RT$ and $a^2 = \gamma RT$, where R is the gas constant and a is the speed of sound. Thus, Eqs. (25) and (28) written in terms of Mach number, M , require that

$$T = T_0 \left(1 + \frac{\gamma - 1}{2} M^2 \right)^{-1} \quad (29)$$

$$p = p_0 \left(1 + \frac{\gamma - 1}{2} M^2 \right)^{-\gamma/(\gamma - 1)} \quad (30)$$

$$\rho = \rho_0 \left(1 + \frac{\gamma - 1}{2} M^2 \right)^{-1/(\gamma - 1)} \quad (31)$$

Stagnation conditions are readily evaluated by applying Eqs. (29)–(31) to the free-stream flow

$$T_0 = T_\infty \left(1 + \frac{\gamma - 1}{2} M_\infty^2 \right) \quad (32)$$

$$p_0 = p_\infty \left(1 + \frac{\gamma - 1}{2} M_\infty^2 \right)^{\gamma/(\gamma - 1)} \quad (33)$$

$$\rho_0 = \rho_\infty \left(1 + \frac{\gamma - 1}{2} M_\infty^2 \right)^{1/(\gamma - 1)} \quad (34)$$

Equation (23) applies to compressible flow as well as to incompressible flow. For any irrotational flow, the velocity vector field can always be expressed as the *gradient of a scalar potential field*. All such flows are called *potential flows*. The only requirement for potential flow is that the flow be irrotational. There are no further restrictions. It can be shown mathematically that the curl of the gradient of any scalar function is zero. Thus, it follows that every potential flow is an *irrotational flow*. It can also be shown mathematically that if the curl of any vector

field is zero, that vector field can be expressed as the gradient of some scalar function. Therefore, every irrotational flow is a potential flow. For this reason the terms potential flow and irrotational flow are used synonymously. For complete coverage of potential flow see Karamcheti.¹

4 INCOMPRESSIBLE FLOW OVER AIRFOILS

An airfoil is any 2D cross section of a wing or other lifting surface that lies in a plane perpendicular to the spanwise coordinate. An airfoil section is completely defined by the geometric shape of its boundary. However, the aerodynamic properties of an airfoil section are most profoundly affected by the shape of its centerline; see Abbott and Von Doenhoff.² This centerline is midway between the upper and lower surfaces of the airfoil and is called the camber line. If the airfoil is not symmetric, the camber line is not a straight line but rather a planar curve.

Because the shape of the camber line is such an important factor in airfoil design, it is critical that the reader understand exactly how the camber line is defined. In addition, there are several other designations that will be used throughout this chapter when referring to the geometric attributes of airfoil sections. The reader should be sure that he or she understands the following nomenclature as it applies to airfoil geometry such as that shown in Fig. 5:

The *camber line* is the locus of points midway between the upper and lower surfaces of an airfoil section as measured perpendicular to the camber line itself.

The *leading edge* is the most forward point on the camber line.

The *trailing edge* is the most rearward point on the camber line.

The *chord line* is a straight line connecting the leading edge and the trailing edge.

The *chord length*, often referred to simply as the *chord*, is the distance between the leading edge and the trailing edge as measured along the chord line.

The *maximum camber*, often referred to simply as the *camber*, is the maximum distance between the chord line and the camber line as measured perpendicular to the chord line.

The *local thickness*, at any point along the chord line, is the distance between the upper and lower surfaces as measured perpendicular to the camber line.

The *maximum thickness*, often referred to simply as the *thickness*, is the maximum distance between the upper and lower surfaces as measured perpendicular to the camber line.

The **upper and lower surface coordinates** for an airfoil can be obtained explicitly from the camber line

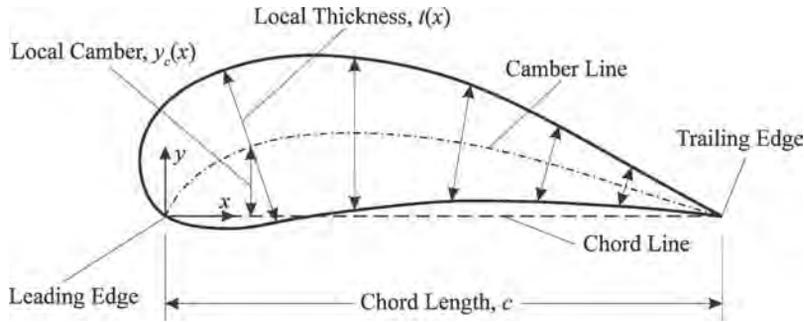

Fig. 5 Airfoil coordinates and nomenclature.

geometry $y_c(x)$ and the thickness distribution $t(x)$:

$$x_u(x) = x - \frac{t(x)}{2\sqrt{1 + (dy_c/dx)^2}} \frac{dy_c}{dx} \quad (35)$$

$$y_u(x) = y_c(x) + \frac{t(x)}{2\sqrt{1 + (dy_c/dx)^2}} \quad (36)$$

$$x_l(x) = x + \frac{t(x)}{2\sqrt{1 + (dy_c/dx)^2}} \frac{dy_c}{dx} \quad (37)$$

$$y_l(x) = y_c(x) - \frac{t(x)}{2\sqrt{1 + (dy_c/dx)^2}} \quad (38)$$

4.1 Thin Airfoil Theory

For airfoils with a maximum thickness of about 12% or less, the inviscid aerodynamic force and moment are only slightly affected by the thickness distribution. The resultant aerodynamic force and moment acting on such an airfoil depend almost exclusively on the angle of attack and the shape of the camber line. For this reason, the inviscid aerodynamics for these airfoils can be closely approximated by assuming that the airfoil thickness is zero everywhere along the camber line. Thus, airfoils with a thickness of about 12% or less can be approximated by combining a uniform flow with a vortex sheet placed along the camber line, as shown

schematically in Fig. 6. The strength of this vortex sheet is allowed to vary with the distance, s , measured along the camber line. The variation in this strength, $\gamma(s)$, is determined so that the camber line becomes a streamline for the flow.

In the development of thin airfoil theory it is shown that the vortex strength distribution necessary to make the camber line a streamline is related to the camber line geometry according to

$$\frac{1}{2\pi} \int_{x_o=0}^c \frac{\gamma(x_o)}{x - x_o} dx_o = V_\infty \left(\alpha - \frac{dy_c}{dx} \right) \quad (39)$$

This is the fundamental equation of thin airfoil theory. Any vortex strength distribution, $\gamma(x_o)$, which satisfies Eq. (39) will make the camber line a streamline of the flow at least within the accuracy of the approximations used in thin airfoil theory. For a given airfoil at a given angle of attack, the only unknown in Eq. (39) is the vortex strength distribution, $\gamma(x_o)$. This equation is subject to a boundary condition known as the *Kutta condition*, which requires that

$$\gamma(c) = 0 \quad (40)$$

Development of the general solution to Eq. (39), subject to (40), is presented in most undergraduate

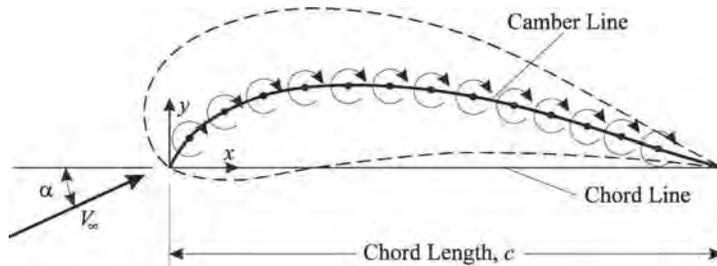

Fig. 6 Synthesis of a thin airfoil section from a uniform flow and a curved vortex sheet distributed along the camber line.

engineering textbooks on aerodynamics. This solution is found by using the change of variables, $x = c(1 - \cos \theta)/2$. Only the final result is presented here. The solution is in the form of an infinite series for the vortex strength distribution,

$$\gamma(\theta) = 2V_\infty \left(A_0 \frac{1 + \cos \theta}{\sin \theta} + \sum_{n=1}^{\infty} A_n \sin(n\theta) \right) \quad (41)$$

$$A_0 = \alpha - \frac{1}{\pi} \int_{\theta=0}^{\pi} \frac{dy_c}{dx} d\theta \quad (42)$$

$$A_n = \frac{2}{\pi} \int_{\theta=0}^{\pi} \frac{dy_c}{dx} \cos(n\theta) d\theta \quad (43)$$

$$x(\theta) \equiv \frac{c}{2}(1 - \cos \theta) \quad (44)$$

The aerodynamic force per unit span can be predicted from the *Kutta–Joukowski law*, which applies to all 2D potential flows. This requires that the net aerodynamic force is always normal to the free stream and equal to

$$\tilde{L} = \rho V_\infty \Gamma \quad (45)$$

A direct consequence of the Kutta–Joukowski law is that the pressure drag for any 2D flow without boundary layer separation is zero.

Applying the Kutta–Joukowski law to a differential segment of the vortex sheet that is used to synthesize a thin airfoil gives

$$\begin{aligned} d\tilde{L} &= \rho V_\infty d\Gamma = \rho V_\infty \gamma(x_o) dx_o \\ &= \frac{\rho V_\infty c}{2} \gamma(\theta_o) \sin \theta_o d\theta_o \end{aligned}$$

Applying Eq. (41) for the vortex strength distribution, this result can be used to evaluate the lift and moment coefficient as well as the center of pressure.

$$\begin{aligned} \tilde{C}_l &= 2\pi \left(A_0 + \frac{1}{2} A_1 \right) \\ &= 2\pi \left(\alpha - \frac{1}{\pi} \int_{\theta=0}^{\pi} \frac{dy_c}{dx} (1 - \cos \theta) d\theta \right) \\ &= 2\pi(\alpha - \alpha_{l,0}) \end{aligned} \quad (46)$$

$$\begin{aligned} \tilde{C}_{m_{le}} &= -\frac{\tilde{C}_L}{4} + \frac{\pi}{4}(A_2 - A_1) \\ &= -\frac{\tilde{C}_L}{4} + \frac{1}{2} \int_{\theta=0}^{\pi} \frac{dy_c}{dx} [\cos(2\theta) - \cos \theta] d\theta \end{aligned} \quad (47)$$

$$\begin{aligned} \tilde{C}_{m_{c/4}} &= \frac{\pi}{4}(A_2 - A_1) \\ &= \frac{1}{2} \int_{\theta=0}^{\pi} \frac{dy_c}{dx} [\cos(2\theta) - \cos \theta] d\theta \end{aligned} \quad (48)$$

$$\begin{aligned} \frac{x_{cp}}{c} &= \frac{1}{4} + \frac{\pi}{4\tilde{C}_L}(A_1 - A_2) \\ &= \frac{1}{4} + \frac{1}{2\tilde{C}_L} \int_{\theta=0}^{\pi} \frac{dy_c}{dx} [\cos \theta - \cos(2\theta)] d\theta \end{aligned} \quad (49)$$

Note from Eq. (46) that thin airfoil theory predicts a section lift coefficient that is a linear function of angle of attack, and that the change in lift coefficient with respect to angle of attack is 2π per radian. Also note that the lift coefficient at zero angle of attack is a function only of the shape of the camber line. Thus, for thin airfoils,

$$\text{Section lift slope} \equiv \frac{d\tilde{C}_L}{d\alpha} \equiv \tilde{C}_{L,\alpha} = 2\pi$$

$$\text{Zero lift angle of attack} \equiv \alpha_{L,0}$$

$$= \frac{1}{\pi} \int_{\theta=0}^{\pi} \frac{dy_c}{dx} (1 - \cos \theta) d\theta$$

Also notice that the leading-edge moment coefficient and center of pressure both depend on lift coefficient and hence on angle of attack. The quarter-chord moment coefficient on the other hand, is independent of angle of attack and depends only on the shape of the camber line. Since the aerodynamic center is defined to be the point on the airfoil where the moment is independent of angle of attack, for incompressible flow, the quarter chord is the *aerodynamic center* of a thin airfoil. Thus, the quarter chord is usually referred to as the *theoretical or ideal aerodynamic center* of the cambered airfoil. Viscous effects and airfoil thickness can cause the quarter-chord moment coefficient to vary slightly with angle of attack, but this variation is small and the aerodynamic center is always close to the quarter chord for subsonic flow. For this reason, airfoil section moment data are usually reported in terms of the quarter-chord moment coefficient. For an airfoil with no camber, Eq. (49) shows that the quarter chord is also the *center of pressure* for incompressible flow about a thin symmetric airfoil.

As is the case with all 2D potential flow, thin airfoil theory predicts a net aerodynamic force that is normal to the free stream. Thus, thin airfoil theory predicts a section drag coefficient that is exactly zero. This is not a function of the thin airfoil approximation. Numerical panel methods will also predict zero section drag, including the effects of thickness. Section drag in any

2D subsonic flow results entirely from viscous effects, which are neglected in the potential flow equations. The viscous forces also have some effect on lift, but this effect is relatively small.

4.2 Vortex Panel Method

Potential flow over an airfoil of arbitrary shape can be synthesized by combining uniform flow with a curved vortex sheet wrapped around the surface of the airfoil, as shown in Fig. 7. The vortex strength must vary along the surface such that the normal component of velocity induced by the entire sheet and the uniform flow is zero everywhere along the surface of the airfoil. In most cases, the strength distribution necessary to satisfy this condition is very difficult or impossible to determine analytically. However, for numerical computations, such a sheet can be approximated as a series of flat vortex panels wrapped around the surface of the airfoil. In the limit as the panel size becomes very small, the panel solution approaches that for the curved vortex sheet. For complete coverage of the vortex panel method see Katz and Plotkin.³

To define the vortex panels, a series of nodes is placed on the airfoil surface. For best results the nodes should be clustered more tightly near the leading and trailing edges. The most popular method for attaining this clustering is called *cosine clustering*. For this method we use the change of variables

$$\frac{x}{c} = \frac{1}{2}(1 - \cos \theta)$$

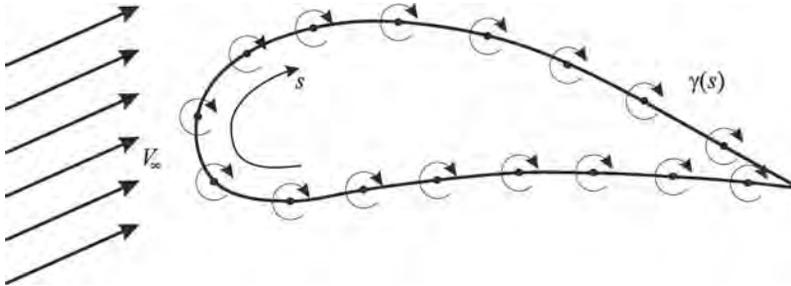

Fig. 7 Synthesis of an arbitrary airfoil section from a uniform flow and a vortex sheet.

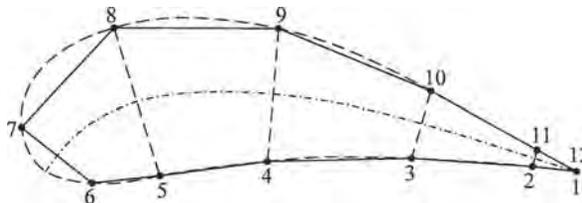

Fig. 8 Vortex panel distribution with cosine clustering and an even number of nodes.

which is the same change of variables as that used in thin airfoil theory. Distributing the nodes uniformly in θ will provide the desired clustering in x . For best results near the leading edge, an even number of nodes should always be used. For this particular distribution, the nodal coordinates are computed from the algorithm

$$\delta\theta = \frac{2\pi}{n-1} \quad (50)$$

$$\begin{Bmatrix} x_N(\frac{1}{2}n+i) \\ y_N(\frac{1}{2}n+i) \\ x_N(\frac{1}{2}n+1-i) \\ y_N(\frac{1}{2}n+1-i) \end{Bmatrix} = \begin{Bmatrix} x_u \\ y_u \\ x_l \\ y_l \end{Bmatrix},$$

$$\frac{x}{c} = 0.5\{1 - \cos[(i - 0.5)\delta\theta]\}$$

$$i = 1, \frac{1}{2}n \quad (51)$$

where n is the total number of nodes and the upper and lower surface coordinates are computed from Eqs. (35)–(38). A nodal distribution using cosine clustering with 12 nodes is shown in Fig. 8. Notice that both the first and last nodes are placed at the trailing edge. Between 50 and 200 nodes should be used for computation.

We can now synthesize an airfoil using $n - 1$ vortex panels placed between these n nodes on the airfoil surface. The panels start at the trailing edge, are

spaced forward along the lower surface, are wrapped up around the leading edge, and then run back along the upper surface to the trailing edge. The last panel ends at the trailing edge where the first panel began. The strength of each vortex panel is assumed to be linear along the panel and is required to be continuous from one panel to the next, that is, the strength at the end of one panel must equal the strength at the beginning of the next panel. The strength is not required to be continuous across the trailing edge, that is, $\gamma_1 \neq \gamma_n$. Each panel is assigned a local panel coordinate system (ξ, η) , as shown in Fig. 9. The velocity induced by each of these panels is expressed in panel coordinates, and the induced velocity components are then transformed to airfoil coordinates.

To solve for the n unknown nodal vortex strengths, control points are placed at the center of each of the $n - 1$ panels. The coordinates of these control points are given by

$$\begin{Bmatrix} x_C(i) \\ y_C(i) \end{Bmatrix} = \begin{Bmatrix} \frac{x_N(i) + x_N(i+1)}{2} \\ \frac{y_N(i) + y_N(i+1)}{2} \end{Bmatrix} \quad i = 1, n - 1 \tag{52}$$

The normal velocity at each control point, induced by all $n - 1$ panels and the uniform flow must be zero. This gives $n - 1$ equations for the n unknown nodal vortex strengths.

For the remaining equation, we know that the flow must leave the airfoil from the trailing edge. This means that the velocity just above the trailing edge must equal the velocity just below the trailing edge. If the angle between the upper and lower surfaces at the trailing edge is nonzero, the trailing edge is a stagnation point. If the angle between the upper and lower surfaces at the trailing edge is zero, the velocity at the trailing edge can be finite but the velocity must be continuous across the trailing edge. Since there is discontinuity in tangential velocity across a vortex sheet, we know that at the trailing edge, the discontinuity across the upper surface is equal and opposite to the discontinuity across the lower surface. Thus, the net discontinuity across both surfaces will be zero. Because the discontinuity in tangential velocity across any vortex sheet is equal to the local strength of the sheet, at the trailing edge, the strength of the

upper surface must be exactly equal and opposite to the strength of the lower surface. That is,

$$\gamma_1 + \gamma_n = 0$$

This is called the *Kutta condition* and it provides the remaining equation necessary to solve for the n unknown nodal strengths.

The 2×2 panel coefficient matrix in airfoil coordinates, $[\mathbf{P}]_{i(x,y)}$, for the velocity induced at the arbitrary point (x,y) by panel i , extending from the node at (x_i, y_i) to the node at (x_{i+1}, y_{i+1}) , is computed from the algorithm

$$l_i = \sqrt{(x_{i+1} - x_i)^2 + (y_{i+1} - y_i)^2} \tag{53}$$

$$\begin{Bmatrix} \xi \\ \eta \end{Bmatrix} = \frac{1}{l_i} \begin{bmatrix} (x_{i+1} - x_i) & (y_{i+1} - y_i) \\ -(y_{i+1} - y_i) & (x_{i+1} - x_i) \end{bmatrix} \begin{Bmatrix} (x - x_i) \\ (y - y_i) \end{Bmatrix} \tag{54}$$

$$\Phi = \text{atan2}(\eta l_i, \eta^2 + \xi^2 - \xi l_i) \tag{55}$$

$$\Psi = \frac{1}{2} \ln \left[\frac{\xi^2 + \eta^2}{(\xi - l_i)^2 + \eta^2} \right] \tag{56}$$

$$\begin{aligned} [\mathbf{P}]_{i(x,y)} &= \frac{1}{2\pi l_i^2} \begin{bmatrix} (x_{i+1} - x_i) & -(y_{i+1} - y_i) \\ (y_{i+1} - y_i) & (x_{i+1} - x_i) \end{bmatrix} \\ &\times \begin{bmatrix} [(l_i - \xi)\Phi + \eta\Psi] & (\xi\Phi - \eta\Psi) \\ [\eta\Phi - (l_i - \xi)\Psi - l_i] & (-\eta\Phi - \xi\Psi - l_i) \end{bmatrix} \end{aligned} \tag{57}$$

The $n \times n$ airfoil coefficient matrix, $[\mathbf{A}]$, is generated from the 2×2 panel coefficient matrix in airfoil coordinates, $[\mathbf{P}]_{ji}$, for the velocity induced at control point i by panel j , extending from node j to node $j + 1$, using the algorithm

$$\begin{aligned} A_{ij} &= 0 \quad i = 1, n \quad j = 1, n \tag{58} \\ \left. \begin{aligned} A_{ij} &= A_{ij} + \frac{x_{i+1} - x_i}{l_i} P_{21ji} - \frac{y_{i+1} - y_i}{l_i} P_{11ji} \\ A_{ij+1} &= A_{ij+1} + \frac{x_{i+1} - x_i}{l_i} P_{22ji} - \frac{y_{i+1} - y_i}{l_i} P_{12ji} \end{aligned} \right\} \\ & \quad i = 1, n - 1 \quad j = 1, n - 1 \tag{59} \end{aligned}$$

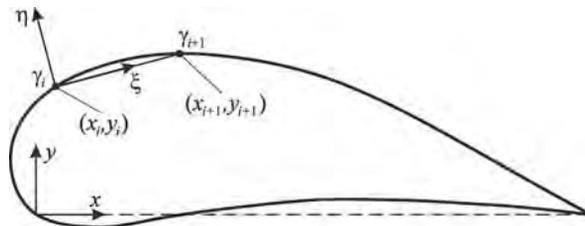

Fig. 9 A vortex panel on the surface of an arbitrary airfoil section.

$$A_{n1} = 1 \quad (60)$$

$$A_{nn} = 1 \quad (61)$$

The n nodal vortex strengths $\gamma_1, \dots, \gamma_n$ are then obtained by numerically solving the $n \times n$ linear system

$$[\mathbf{A}] \begin{Bmatrix} \gamma_1 \\ \gamma_2 \\ \vdots \\ \gamma_{n-1} \\ \gamma_n \end{Bmatrix} = V_\infty \begin{Bmatrix} [(y_2 - y_1) \cos \alpha - (x_2 - x_1) \sin \alpha]/l_1 \\ [(y_3 - y_2) \cos \alpha - (x_3 - x_2) \sin \alpha]/l_2 \\ \vdots \\ [(y_n - y_{n-1}) \cos \alpha - (x_n - x_{n-1}) \sin \alpha]/l_{n-1} \\ 0 \end{Bmatrix} \quad (62)$$

Once the nodal strengths are known, the velocity and pressure at any point in space can be computed by adding the velocity induced by all $n - 1$ vortex panels to the free-stream velocity,

$$\begin{Bmatrix} V_x \\ V_y \end{Bmatrix} = V_\infty \begin{Bmatrix} \cos \alpha \\ \sin \alpha \end{Bmatrix} + \sum_{i=1}^{n-1} [\mathbf{P}]_{i(x,y)} \begin{Bmatrix} \gamma_i \\ \gamma_{i+1} \end{Bmatrix} \quad (63)$$

$$V^2 = V_x^2 + V_y^2 \quad (64)$$

$$C_p \equiv \frac{p - p_\infty}{\frac{1}{2} \rho V_\infty^2} = 1 - \frac{V^2}{V_\infty^2} \quad (65)$$

The lift and moment coefficient for the entire airfoil are the sum of those induced by all of the $n - 1$ vortex panels,

$$\tilde{C}_L = \sum_{i=1}^{n-1} \frac{l_i}{c} \frac{\gamma_i + \gamma_{i+1}}{V_\infty} \quad (66)$$

$$\tilde{C}_{m_{te}} = -\frac{1}{3} \sum_{i=1}^{n-1} \frac{l_i}{c} \left[\frac{2x_i \gamma_i + x_i \gamma_{i+1} + x_{i+1} \gamma_i + 2x_{i+1} \gamma_{i+1}}{c V_\infty} \cos(\alpha) + \frac{2y_i \gamma_i + y_i \gamma_{i+1} + y_{i+1} \gamma_i + 2y_{i+1} \gamma_{i+1}}{c V_\infty} \sin(\alpha) \right] \quad (67)$$

4.3 Comparison with Experimental Data

Section lift and moment coefficient predicted by thin airfoil theory and panel codes are in good agreement with experimental data for low Mach numbers and

small angles of attack. In Fig. 10, the inviscid lift coefficient for an NACA 2412 airfoil, as predicted by thin airfoil theory, is compared with the inviscid lift coefficient predicted by the vortex panel method and with experimental data for total lift coefficient as reported by Abbott and Von Doenhoff.² Thin airfoil theory predicts a section lift coefficient that is independent of the thickness distribution and dependent only on angle of attack and camber line shape. At small angles of attack, the thin airfoil approximation agrees closely with experimental data based on total lift, for airfoils as thick as about 12%. The agreement seen in Fig. 10 is quite typical. For airfoils much thicker than about 12%, viscous effects become increasingly important, even at fairly low angles of attack, and the inviscid lift coefficient predicted by thin airfoil theory begins to deviate more from experimental observations based on total lift. This can be seen in Fig. 11.

The reason why thin airfoil theory predicts total lift so well over such a wide range of thickness is that thickness tends to increase the lift slope slightly, while viscous effects tend to decrease the lift slope. Since both thickness effects and viscous effects are neglected in thin airfoil theory, the resulting errors tend to cancel, giving the theory a broader range of applicability than would otherwise be expected. Coincidentally, because of these opposing errors, thin airfoil theory actually predicts a lift slope that agrees more closely with experimental data for total lift than does that predicted by the more elaborate vortex panel method. The vortex panel method accurately predicts the pressure distribution around the airfoil, including the effects of thickness. However, since the vortex panel method provides a potential flow solution, it does not account for viscous effects in any way.

After seeing that thin airfoil theory predicts total section lift better than the vortex panel method, one may wonder why we should ever be interested in the vortex panel method. For the answer, we must remember that both the vortex panel solution and the thin airfoil solution come from potential flow theory. Thus, neither of these two solutions can be expected to predict viscous forces. However, potential flow solutions are often used as boundary conditions for viscous flow analysis. Potential flow is used to predict the pressure distribution around the airfoil. The viscous forces are then computed from boundary layer theory. However, since boundary layer flow is greatly affected by the pressure distribution around the airfoil, our potential flow solution must accurately predict the section pressure distribution. Because thin airfoil theory does not account for airfoil thickness, it cannot be used to predict the surface pressure distribution on an airfoil section with finite thickness. The vortex panel method, on the other hand, accurately predicts the inviscid pressure distribution for airfoils of any thickness.

While the experimental data shown in Figs. 10 and 11 are based on total section lift, section lift data have been obtained that are based on pressure

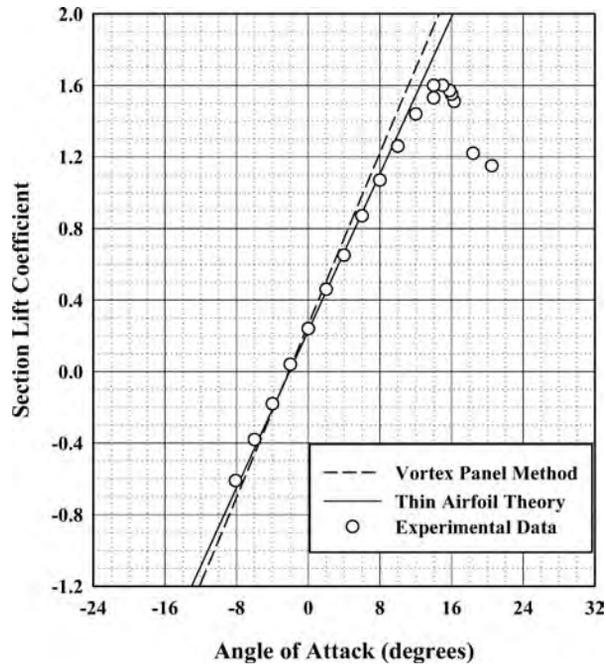

Fig. 10 Section lift coefficient comparison among thin airfoil theory, the vortex panel method, and experimental data based on total lift, for the NACA 2412 airfoil.

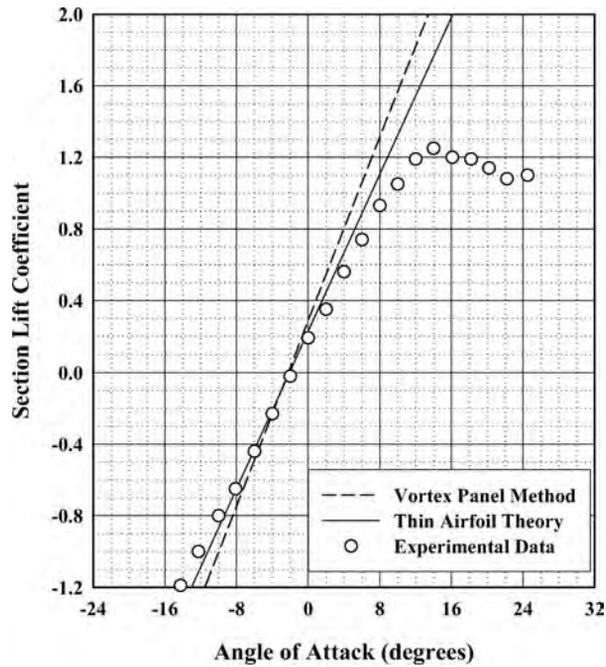

Fig. 11 Section lift coefficient comparison among thin airfoil theory, the vortex panel method, and experimental data based on total lift, for the NACA 2421 airfoil.

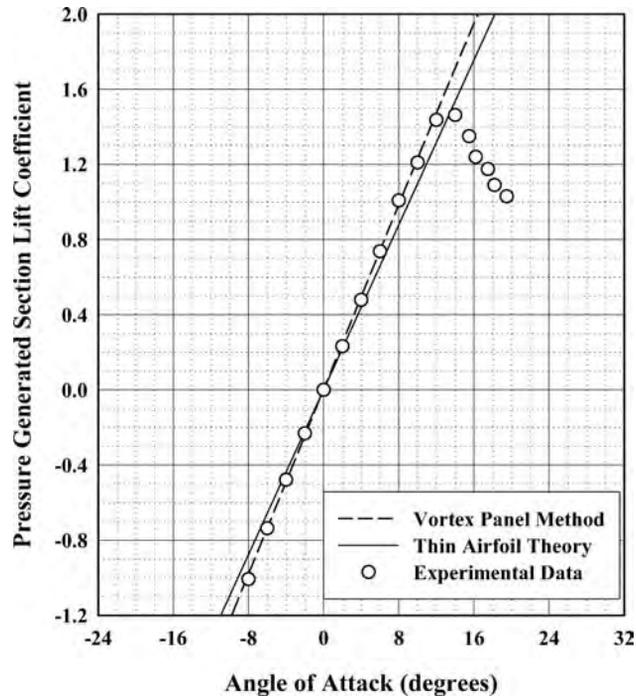

Fig. 12 Section lift coefficient comparison among thin airfoil theory, the vortex panel method, and experimental data based on pressure lift, for the NACA 0015 airfoil.

forces only. This is usually accomplished by spacing a large number of static pressure taps around the circumference of an airfoil. The net pressure force acting on the airfoil section is derived by numerically integrating the forces obtained from these pressure measurements. The lift coefficient predicted by thin airfoil theory and that predicted by the vortex panel method are compared with experimental data of this type in Fig. 12. Notice that the vortex panel method agrees very closely with these experimental data, while thin airfoil theory predicts a lift coefficient that is somewhat low.

In summary, thin airfoil theory can be used to obtain a first approximation for the total section lift coefficient at small angles of attack, produced by airfoils of thickness less than about 12%. Thin airfoil theory gives no prediction for the section drag.

To improve on the results obtained from thin airfoil theory, we can combine a boundary layer solution with the velocity and pressure distribution obtained from the vortex panel method. Since this analytical procedure accounts for both thickness and viscous effects, it produces results that agree closely with experimental data for total lift and drag over a broad range of section thickness. Another alternative available with today's high-speed computers is the use of computational fluid dynamics (CFD). However, a CFD solution

will increase the required computation time by several orders of magnitude.

In Figs. 10–12 it should be noticed that at angles of attack near the zero-lift angle of attack, the result predicted by thin airfoil theory agrees very well with that predicted by the vortex panel method and with that observed from all experimental data. Thus, we see that the thickness distribution has little effect on the lift produced by an airfoil at angles of attack near the zero-lift angle of attack. The thickness distribution does, however, have a significant effect on the maximum lift coefficient and on the stall characteristics of the airfoil section. This is seen by comparing Fig. 10 with Fig. 11. The two airfoils described in these two figures have exactly the same camber line. They differ only in thickness. Notice that the NACA 2412 section has a maximum lift coefficient of about 1.6, while the NACA 2421 airfoil produces a maximum lift coefficient of only about 1.2. Also notice that the thinner section has a sharper and more abrupt stall than that displayed by the thicker section.

5 TRAILING-EDGE FLAPS AND SECTION FLAP EFFECTIVENESS

An attached trailing-edge flap is formed by hinging some aft portion of the airfoil section so that it can be deflected either downward or upward, by rotating the

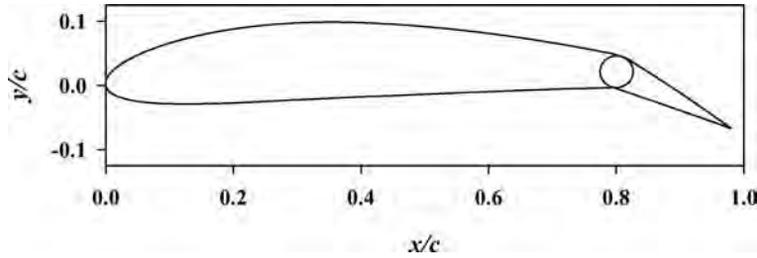

Fig. 13 NACA 4412 airfoil section with a 20% trailing-edge flap.

fla about the hinge point as shown in Fig. 13. The deflection of a trailing-edge fla effectively changes the camber of the airfoil section, and in so doing changes the aerodynamic characteristics of the section. A downward deflection of the fla increases the effective camber and is thus usually considered to be a positive deflection

For small angles of attack and small fla deflections, thin airfoil theory can be applied to an airfoil section with a deflected trailing-edge flap. Let y_d be the y position of the section camber line with the trailing-edge fla deflected as shown in Fig. 14. All of the results obtained from thin airfoil theory must apply to this modified camber line geometry. Thus from Eq. (46), we can write

$$\begin{aligned} \tilde{C}_L &= 2\pi(\alpha - \alpha_{L0}) \\ &= 2\pi \left(\alpha - \frac{1}{\pi} \int_{\theta=0}^{\pi} \frac{dy_d}{dx} (1 - \cos \theta) d\theta \right) \end{aligned} \quad (68)$$

However, within the small-angle approximation, the slope of the deflected camber line geometry can be related to the slope of the undeflected geometry according to

$$\frac{dy_d}{dx} = \begin{cases} \frac{dy_c}{dx} & x \leq c - c_f \\ \frac{dy_c}{dx} - \delta & x \geq c - c_f \end{cases} \quad (69)$$

where y_c is the undeflected camber line ordinate, c_f is the flap chord length, and δ is the deflection of the fla in radians, with positive deflection being downward.

Using Eq. (69) in Eq. (68), we have

$$\begin{aligned} \tilde{C}_L &= 2\pi(\alpha - \alpha_{L0}) \\ &= 2\pi \left(\alpha - \frac{1}{\pi} \int_{\theta=0}^{\pi} \frac{dy_c}{dx} (1 - \cos \theta) d\theta \right. \\ &\quad \left. + \frac{\delta}{\pi} \int_{\theta=\theta_f}^{\pi} (1 - \cos \theta) d\theta \right) \end{aligned} \quad (70)$$

or

$$\begin{aligned} \alpha_{L0} &= \frac{1}{\pi} \int_{\theta=0}^{\pi} \frac{dy_c}{dx} (1 - \cos \theta) d\theta \\ &\quad - \frac{\delta}{\pi} \int_{\theta=\theta_f}^{\pi} (1 - \cos \theta) d\theta \end{aligned} \quad (71)$$

where α_{L0} is the zero-lift angle of attack for the airfoil section with the flap deflected and θ_f is given by

$$\theta_f = \cos^{-1} \left(2 \frac{c_f}{c} - 1 \right) \quad (72)$$

From Eqs. (70) and (71), we see that the thin airfoil lift coefficient is affected by flap deflection only through a change in the zero-lift angle of attack. The lift coefficient is still a linear function of the angle of

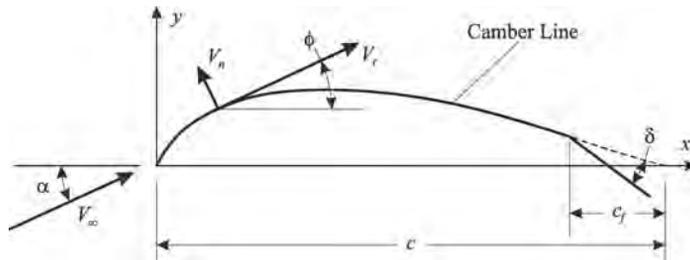

Fig. 14 Camber line geometry for an airfoil section with attached trailing-edge flap and positive flap deflection.

attack and the lift slope is not affected by the flap deflection. The first integral on the right-hand side of Eq. (71) is simply the zero-lift angle of attack with no flap deflection. The second integral in this equation is readily evaluated to yield what is commonly called the *ideal section flap effectiveness*,

$$\begin{aligned}\varepsilon_{fi} &\equiv -\frac{\partial \alpha_{L0}}{\partial \delta} = \frac{1}{\pi} \int_{\theta=\theta_f}^{\pi} (1 - \cos \theta) d\theta \\ &= 1 - \frac{\theta_f - \sin \theta_f}{\pi}\end{aligned}\quad (73)$$

Notice that the ideal section flap effectiveness depends only on the ratio of flap chord to total chord and is independent of both camber line geometry and flap deflection. Using this definition in Eq. (71), the zero-lift angle of attack for a thin airfoil with an ideal trailing-edge flap is found to vary linearly with flap deflection

$$\alpha_{L0}(\delta) = \alpha_{L0}(0) - \varepsilon_{fi} \delta \quad (74)$$

In a similar manner we can predict the quarter-chord moment coefficient for a thin airfoil with a deflecting trailing-edge flap. From Eq. (48), we have

$$\tilde{C}_{m_{c/4}} = \frac{1}{2} \int_{\theta=0}^{\pi} \frac{dy_d}{dx} [\cos(2\theta) - \cos \theta] d\theta \quad (75)$$

Using Eq. (69) in Eq. (75) gives

$$\begin{aligned}\tilde{C}_{m_{c/4}} &= \frac{1}{2} \int_{\theta=0}^{\pi} \frac{dy_c}{dx} [\cos(2\theta) - \cos \theta] d\theta \\ &\quad - \frac{\delta}{2} \int_{\theta=\theta_f}^{\pi} [\cos(2\theta) - \cos \theta] d\theta\end{aligned}\quad (76)$$

From Eq. (76) we see that the section quarter-chord moment coefficient for a thin airfoil is also a linear function of flap deflection. The first integral on the right-hand side of Eq. (76) is the quarter-chord moment coefficient for the airfoil section with no flap deflection and the second integral can be evaluated to yield the section quarter-chord moment slope with respect to flap deflection. Thus, the quarter-chord moment coefficient for a thin airfoil section with an ideal trailing-edge flap can be written as

$$\tilde{C}_{m_{c/4}}(\delta) = \tilde{C}_{m_{c/4}}(0) + \tilde{C}_{m,\delta} \delta \quad (77)$$

where the change in the section quarter-chord moment coefficient with respect to flap deflection is given by

$$\begin{aligned}\tilde{C}_{m,\delta} &\equiv \frac{\partial \tilde{C}_{m_{c/4}}}{\partial \delta} = -\frac{1}{2} \int_{\theta=\theta_f}^{\pi} [\cos(2\theta) - \cos \theta] d\theta \\ &= \frac{\sin(2\theta_f) - 2 \sin \theta_f}{4}\end{aligned}\quad (78)$$

Notice that the change in moment coefficient with respect to flap deflection depends only on the ratio of flap chord to total chord. Thus, as was the case with the ideal section flap effectiveness, the ideal section quarter-chord moment slope with respect to flap deflection is independent of both camber line geometry and flap deflection.

In summary, at angles of attack below stall, the lift coefficient for an airfoil section with a deflecting trailing-edge flap is found to be very nearly a linear function of both the airfoil angle of attack, α , and the flap deflection δ . This linear relation can be written

$$\tilde{C}_L(\alpha, \delta) = \tilde{C}_{L,\alpha}[\alpha - \alpha_{L0}(0) + \varepsilon_f \delta] \quad (79)$$

where $\tilde{C}_{L,\alpha}$ is the section lift slope, $\alpha_{L0}(0)$ is the zero-lift angle of attack with no flap deflection and ε_f is called the *section flap effectiveness*. Previously, we found that thin airfoil theory predicts a section lift slope of 2π . However, solutions obtained using the vortex panel method and experimental measurements have shown that the actual section lift slope can vary somewhat from this value. The zero-lift angle of attack with no flap deflection as predicted by thin airfoil theory, was previously shown to be in excellent agreement with both the vortex panel method and experimental data. As we shall see, the section flap effectiveness predicted by thin airfoil theory agrees with results predicted using the vortex panel method, but deviates somewhat from experimental observation.

The actual section flap effectiveness is always less than the ideal section flap effectiveness given by Eq. (73). The hinge mechanism in a real trailing-edge flap always reduces the flap effectiveness. This reduction results from local boundary layer separation and from flow leakage through the hinge from the high-pressure side to the low-pressure side. In addition, at flap deflection greater than about $\pm 10^\circ$, the error associated with the small-angle approximation used to obtain Eq. (73) begins to become significant. This results in an additional decrease in the section flap effectiveness for larger flap deflections. A comparison among the section flap effectiveness predicted by thin airfoil theory, typical results predicted by the vortex panel method, and results observed experimentally is shown in Fig. 15. The data shown in this figure are from Abbott and Von Doenhoff.²

The discrepancy between the theoretical results and the experimental data shown in Fig. 15 is only about 7% with a flap chord fraction of 0.4, but at a flap chord fraction of 0.1 this discrepancy is nearly 25%. The deviation between actual section flap effectiveness and the ideal section flap effectiveness continues to increase as the flap chord fraction becomes smaller. The poor agreement at low flap chord fraction is attributed to the thickness of the boundary layer, which is much larger near the trailing edge. The trailing-edge flap used to generate the data shown in Fig. 15 all had flap hinges that were sealed to prevent leakage from

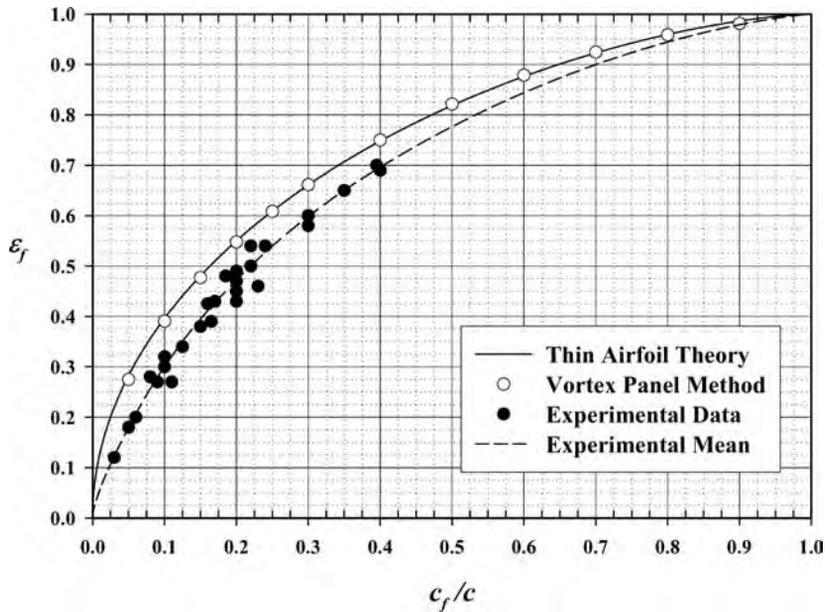

Fig. 15 Section flap effectiveness comparison among thin airfoil theory, the vortex panel method, and experimental data.

the high-pressure side to the low-pressure side. For unsealed trailing-edge flaps an additional decrease in section flap effectiveness of about 20% is observed.

The data shown in Fig. 15 were all taken at flap deflection of less than 10°. For larger deflections actual flap effectiveness deviates even more from the ideal, as a result of errors associated with the small-angle approximation. The actual section flap effectiveness for a trailing-edge flap can be expressed in terms of the ideal section flap effectiveness, ϵ_{fi} , given by Eq. (73), according to

$$\epsilon_f = \eta_h \eta_d \epsilon_{fi} \tag{80}$$

where η_h and η_d are, respectively, the section flap hinge efficiency and the section flap deflection efficiency.

For well-designed sealed flaps the section hinge efficiency can be approximated from Fig. 16. This figure is based on the mean line for the experimental data shown in Fig. 15. If the gap between the main wing and the trailing-edge flap is not sealed, it is recommended that the values found from Fig. 16 be reduced by 20%. Remember that the result given in this figure represents a mean experimental efficiency. The actual hinge efficiency for a specific trailing-edge flap installed in a particular airfoil section may deviate significantly from the value found in this figure. For flap deflection of more than ±10°, Perkins and Hage⁴ recommend the flap deflection efficiency shown in Fig. 17. For flap deflection of less

than ±10°, a flap deflection efficiency of 1.0 should be used.

At angles of attack below stall, the pitching moment coefficient for an airfoil section with a deflected trailing-edge flap is also found to be very nearly a linear function of both angle of attack, α , and flap deflection, δ . This linear relation can be written in the form

$$\tilde{C}_{m_{c/A}}(\alpha, \delta) = \tilde{C}_{m_{c/A}}(0, 0) + \tilde{C}_{m,\alpha}\alpha + \tilde{C}_{m,\delta}\delta \tag{81}$$

where $\tilde{C}_{m_{c/A}}(0, 0)$, $\tilde{C}_{m,\alpha}$, and $\tilde{C}_{m,\delta}$ are, respectively, the section pitching moment coefficient at zero angle of attack and zero flap deflection, the moment slope with angle of attack, and the moment slope with flap deflection.

Thin airfoil theory predicts that the quarter chord is the aerodynamic center of an airfoil section. Thus, thin airfoil theory predicts a zero quarter-chord moment slope with respect to angle of attack. In reality, solutions obtained from the vortex panel method and experimental observations have shown that the quarter chord is not exactly the aerodynamic center of all airfoil sections. Thus, in general, we should allow for a finite quarter-chord moment slope with angle of attack. However, for preliminary design, the quarter-chord moment slope with angle of attack is usually taken to be zero.

The section quarter-chord moment slope with respect to flap deflection is shown in Fig. 18. In this figure the ideal quarter-chord moment slope, as predicted by thin airfoil theory in Eq. (78), is compared with typical results predicted from the vortex panel

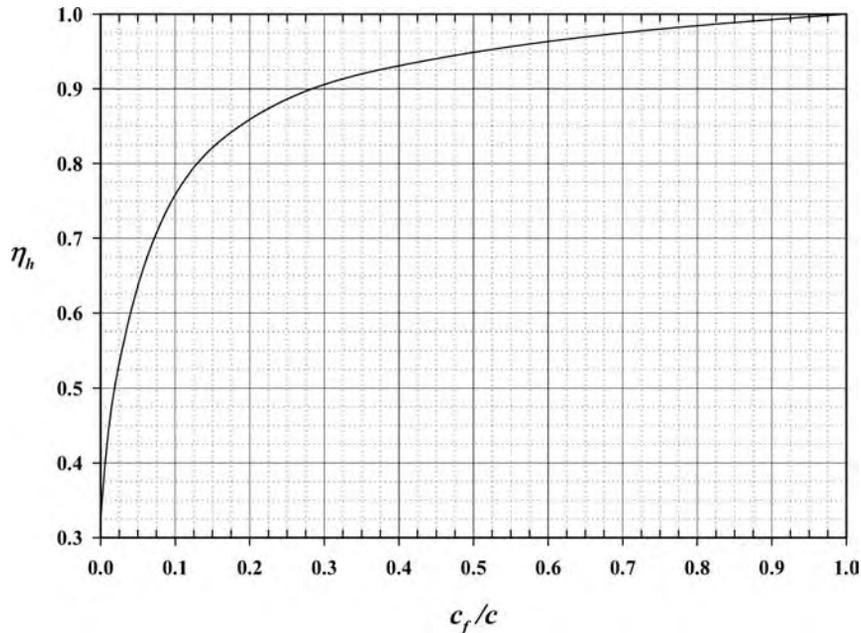

Fig. 16 Section flap hinge efficiency for well-designed and sealed trailing-edge flaps. For unsealed flaps this hinge efficiency should be decreased by about 20%.

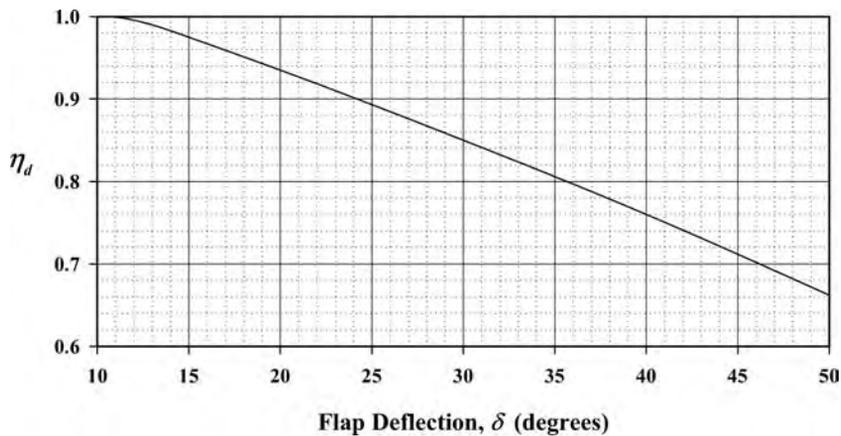

Fig. 17 Section flap deflection efficiency for trailing-edge flaps with flap deflections of more than $\pm 10^\circ$. For flap deflections of less than $\pm 10^\circ$ a deflection efficiency of 1.0 should be used.

method and with limited experimental data. Airfoil section thickness tends to increase the magnitude of the negative quarter-chord moment slope with respect to flap deflection. The hinge effects, on the other hand, tend to lessen the magnitude of this moment slope. The result from thin airfoil theory is often used for preliminary design.

6 INCOMPRESSIBLE FLOW OVER FINITE WINGS

In Section 4 we reviewed the aerodynamic properties of airfoils, which are the same as the aerodynamic properties of wings with infinite span. A wing of constant cross section and infinite span would have no variation in aerodynamic forces in the spanwise

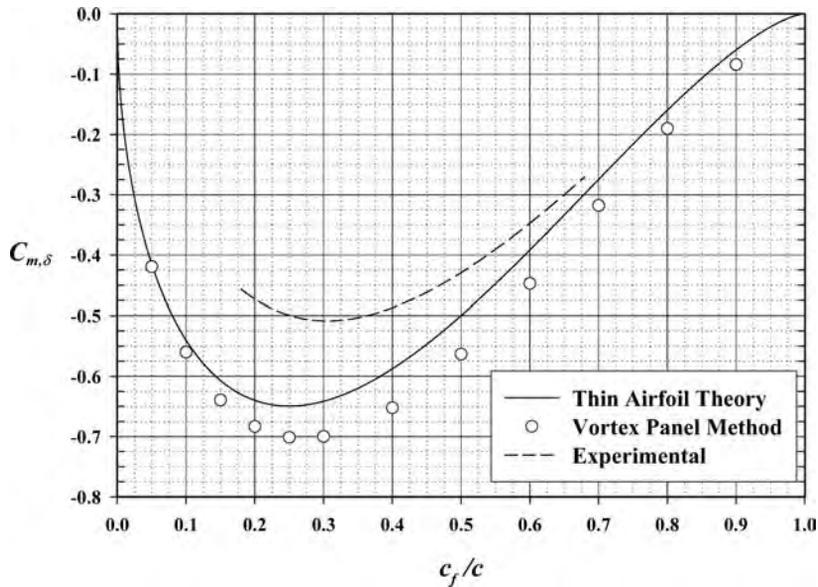

Fig. 18 Quarter-chord moment slope with respect to flap deflection.

direction. The aerodynamic forces per unit span acting on such a wing, at any point along the span, would be the same as those for an airfoil of the same cross section. An airfoil or wing of infinite span is synthesized using vortex sheets that are made up of straight vortex filaments that extend to $\pm\infty$ in the direction of span. The vortex strength can vary over the sheet as we move in a chordwise direction from one vortex filament to another. However, there is no variation in vortex strength as we move along a vortex filament in the direction of span.

Any real wing, of course, must have finite span. At the tips of a finite wing, the air on the lower surface

of the wing comes in direct contact with the air on the upper surface of the wing. Thus, at the tips of a finite wing, the pressure difference between the upper and lower surfaces must always go to zero. As a result, the lift on any finite wing must go to zero at the wingtips, as shown schematically in Fig. 19.

The pressure difference between the upper and lower surfaces of a finite wing is reduced near the wingtips because some of the air from the high-pressure region below the wing spills outward, around the wingtip, and back inward toward the low-pressure region above the wing. Thus, while the flow around an infinite wing is entirely in the plane of the airfoil

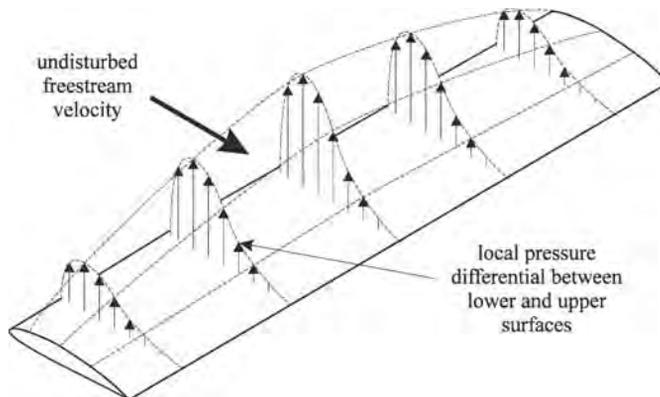

Fig. 19 Lift distribution on a finite wing.

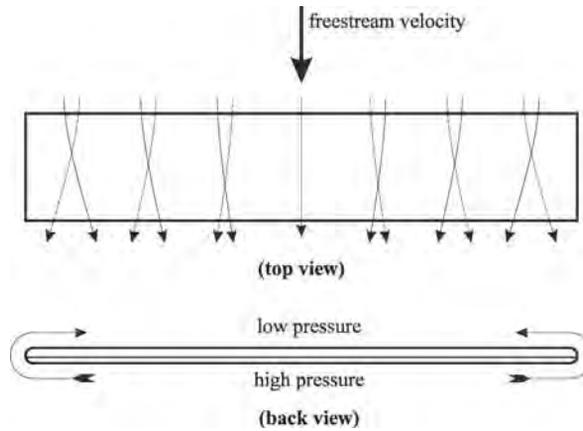

Fig. 20 Airflow around a finite wing.

section, the flow around a finite wing is three dimensional.

As air flows over a finite wing, the air below the wing moves outward toward the wingtip and the air above the wing moves inward toward the root, as shown in Fig. 20. Where the flow from the upper and lower surfaces combine at the trailing edge, the difference in spanwise velocity generates a trailing vortex sheet. Because this vortex sheet is free and not bound to the wing's surface, the flow field induced by the sheet tends to change the shape of the sheet as it moves downstream from the wing. As can be seen in Fig. 21, this vortex sheet rolls up around an axis trailing slightly inboard from each wingtip. At some distance behind the wing, the sheet becomes completely rolled up to form two large vortices, one trailing aft of each wingtip. For this reason, these vortices are referred to as *wingtip vortices*, even though they are generated over the full span of the wing. The downward velocity component that is induced between the wingtip vortices is called *downwash*. Potential

flow theory predicts that the wingtip vortices must trail behind the wing for an infinite distance with no reduction in strength. In reality, viscous effects will eventually dissipate the energy in these vortices, but this is a slow process. These vortices will still have significant energy several miles behind a large aircraft and are of sufficient strength to cause control loss or structural damage to other aircraft following too closely.

From the discussion above, we see that a wing of finite span cannot be synthesized with a vortex sheet made up of vortex filaments that are always perpendicular to the airfoil sections of the wing. We can, however, still synthesize a finite wing with a vortex sheet, but the sheet must be made up of horseshoe-shaped vortex filaments. These filaments run out along the wing in the direction of span, curving back and eventually leaving the wing from the trailing edge at some point inboard of the wingtip. This is seen schematically in the plan view of the elliptic wing shown in Fig. 22. Because the strength of a vortex filament cannot vary

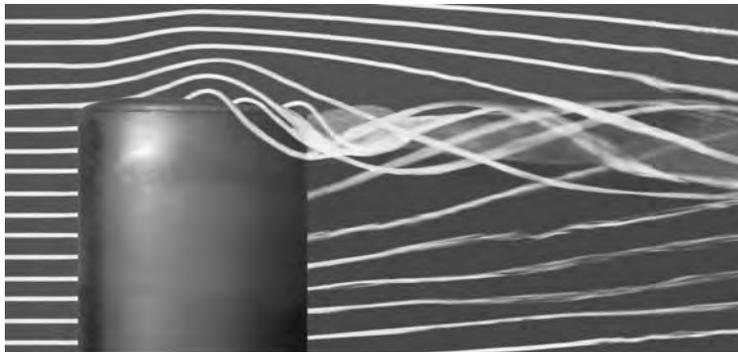

Fig. 21 Vorticity trailing aft of a finite wing.

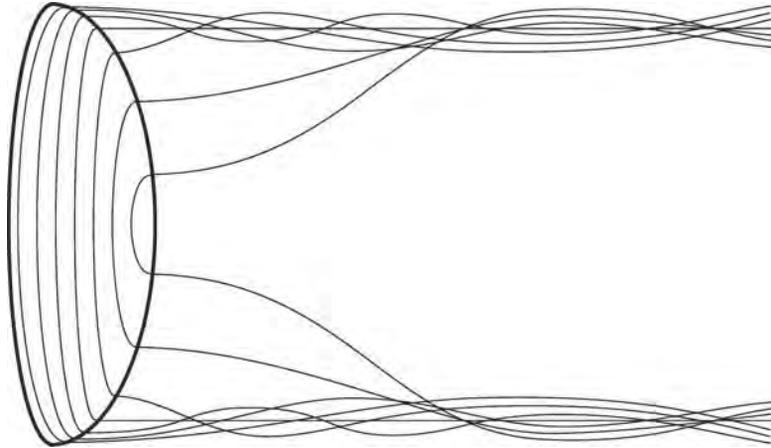

Fig. 22 Schematic of the vorticity distribution on a finite wing with elliptic planform shape.

along its length, the decrease in the circulation about the wing as we move out from the root toward the tip must result entirely from the vorticity that leaves the wing in the trailing vortex sheet.

The classical lifting-line theory developed by Ludwig Prandtl⁵ was the first analytical method to satisfactorily predict the performance of a finite wing. While a general 3D vortex lifting law was not available at the time of Prandtl's development, the 2D vortex lifting law of Kutta⁶ and Joukowski⁷ was well known. Prandtl's lifting-line theory is based on the hypothesis that each spanwise section of a finite wing has a section lift that is equivalent to that acting on a similar section of an infinite wing having the same section circulation. However, to reconcile this theory with reality, the undisturbed free-stream velocity in the Kutta–Joukowski law was intuitively replaced with the vector sum of the free-stream velocity and the velocity induced by the trailing vortex sheet.

Today we know that Prandtl's hypothesis was correct. This can be shown as a direct consequence of the *vortex lifting law*, which is a 3D counterpart to the 2D Kutta–Joukowski law. This vortex lifting law states that for any potential flow containing vortex filaments, the force per unit length exerted on the surroundings at any point along a vortex filament is given by

$$d\mathbf{F} = \rho \Gamma \mathbf{V} \times d\mathbf{l} \quad (82)$$

where $d\mathbf{F}$ is the differential aerodynamic force vector and ρ , Γ , \mathbf{V} , and $d\mathbf{l}$ are, respectively, the fluid density, vortex strength, local fluid velocity, and the directed differential vortex length vector (see Saffman⁸).

The force computed from Eq. (82) is called the *vortex force* or *Kutta lift*. The vortex lifting law is a very useful tool in the study of aerodynamics. It provides the basis for much of finite wing theory. There are two important consequences of Eq. (82).

First, for a *bound vortex filament*, the vortex force is always perpendicular to both the local velocity vector and the vortex filament. Second, since a free vortex filament can support no force, *free vortex filaments* must be aligned everywhere with the streamlines of the flow.

6.1 Prandtl's Classical Lifting-Line Theory

Prandtl's lifting-line theory gives good agreement with experimental data for straight wings of aspect ratio greater than about 4. Development of this theory is presented in any undergraduate engineering textbook on aerodynamics and will not be repeated here. Only summary results are presented in this section.

The model used by Prandtl to approximate the bound vorticity and trailing vortex sheet is shown in Fig. 23. All bound vortex filaments are assumed to follow the wing quarter-chord line, and all trailing vortex filaments are assumed to be straight and parallel with the free stream. Rollup of the trailing vortex sheet is ignored.

The foundation of lifting-line theory is the requirement that for each cross section of the wing, the lift predicted from the vortex lifting law must be equal to that predicted from airfoil section theory, that is;

$$\tilde{C}_L(z) = \tilde{C}_{L,\alpha}[\alpha_{\text{eff}}(z) - \alpha_{L0}(z)]$$

where α_{eff} is the local section angle of attack, including the effects of velocity induced by the trailing vortex sheet. Because of the downwash induced on the wing by the trailing vortex sheet, the local relative wind is inclined at an angle, α_i , to the free stream, as shown in Fig. 24. This angle is called the *induced angle of attack*. Since the lift is always perpendicular to the local relative wind, the downwash tilts the lift vector back, creating a component of lift parallel to the free stream. This is called *induced drag*.

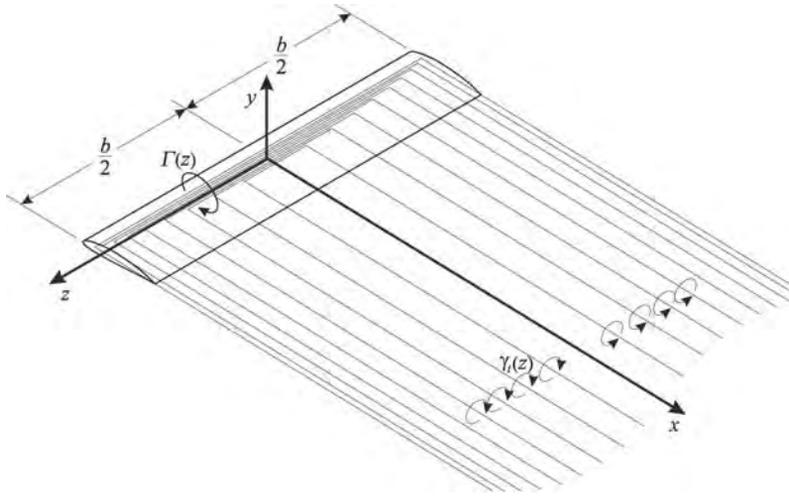

Fig. 23 Prandtl's model for the bound vorticity and the trailing vortex sheet generated by a wing of finite span.

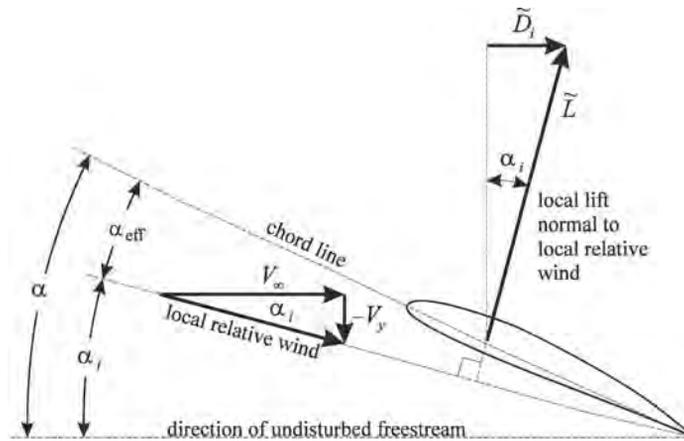

Fig. 24 Induced angle of attack.

When the downwash is accounted for, Prandtl's hypothesis requires that

$$\frac{2\Gamma(z)}{V_\infty c(z)} + \frac{\tilde{C}_{L,\alpha}}{4\pi V_\infty} \int_{\zeta=-b/2}^{b/2} \frac{1}{z-\zeta} \left(\frac{d\Gamma}{d\zeta} \right)_{\zeta=\zeta} d\zeta = \tilde{C}_{L,\alpha} [\alpha(z) - \alpha_{L0}(z)] \quad (83)$$

Equation (83) is the fundamental equation of Prandtl's lifting-line theory. It is a nonlinear integrodifferential equation that involves only one unknown, the local section circulation as a function of the spanwise position, $\Gamma(z)$. All other parameters are known for a given wing design at a given geometric angle of attack and

a given free-stream velocity. Remember that the chord length, c , the geometric angle of attack, α , and the zero-lift angle of attack, α_{L0} , are all allowed to vary in the spanwise direction. The section lift slope could also vary with z but is usually assumed to be constant.

There is certain terminology associated with spanwise variation in wing geometry with which the reader should be familiar. If a wing has spanwise variation in geometric angle of attack as shown in Fig. 25, the wing is said to have *geometric twist*. The tip is commonly at a lower angle of attack than the root, in which case the geometric twist is referred to as *washout*. A spanwise variation in zero-lift angle of attack, like that shown in Fig. 26, is called *aerodynamic twist*. Deflecting a trailing-edge flap that extends over only part of

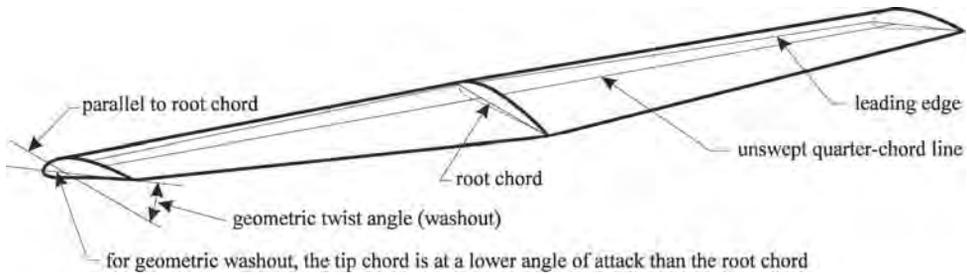

Fig. 25 Geometric twist in an unswept rectangular wing.

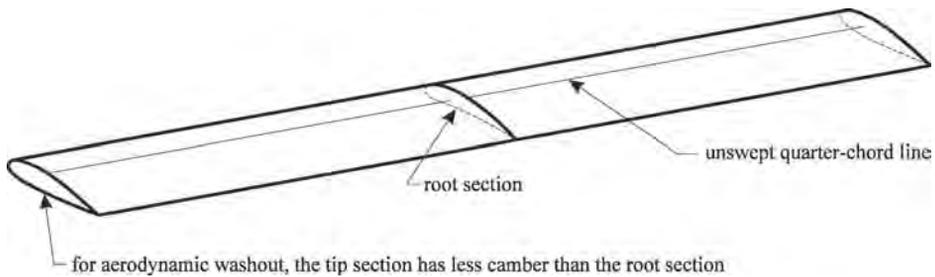

Fig. 26 Aerodynamic twist in an unswept rectangular wing.

the span is another form of aerodynamic twist (see Fig. 27).

For a single finite wing with no sweep or dihedral, an analytical solution to Prandtl's lifting-line equation can be obtained in terms of a Fourier sine series. For a given wing design, at a given angle of attack, the planform shape, $c(z)$, the geometric twist, $\alpha(z)$, and the aerodynamic twist, $\alpha_{L0}(z)$, are all known as functions of spanwise position. The circulation distribution is written as a Fourier series, the series is truncated to a finite number of terms (N), and the Fourier coefficients are determined by forcing the lifting-line equation to be satisfied at N specific sections along the span of the

wing. From this solution the circulation distribution is given by

$$\Gamma(\theta) = 2bV_\infty \sum_{n=1}^N A_n \sin(n\theta) \quad \theta = \cos^{-1} \left(\frac{-2z}{b} \right) \tag{84}$$

where the Fourier coefficients, A_n , are obtained from

$$\sum_{n=1}^N A_n \left[\frac{4b}{\tilde{C}_{L,\alpha} c(\theta)} + \frac{n}{\sin(\theta)} \right] \sin(n\theta) = \alpha(\theta) - \alpha_{L0}(\theta) \tag{85}$$

Once the circulation distribution has been determined, the section lift distribution can be obtained

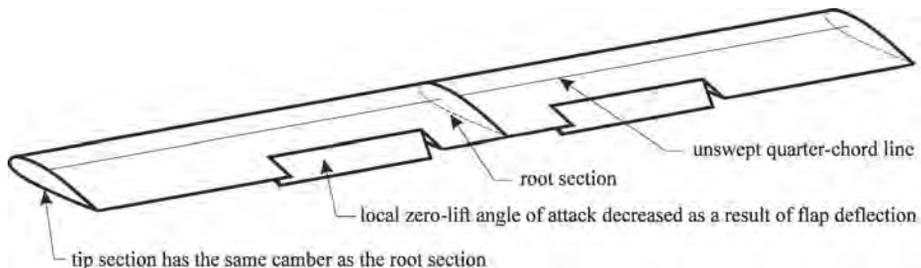

Fig. 27 Aerodynamic twist resulting from deflection of a trailing-edge flap spanning only a portion of the wing.

from the vortex lifting law. The resulting lift and induced drag coefficient for the finite wing are

$$C_L = \pi R_A A_1 \quad R_A \equiv \frac{b^2}{S} \quad (86)$$

$$C_{D_i} = \pi R_A \sum_{n=1}^N n A_n^2 = \frac{C_L^2}{\pi R_A e_s} \quad e_s \equiv \frac{1}{1 + \sigma} \quad (87)$$

$$\sigma \equiv \sum_{n=2}^N n \left(\frac{A_n}{A_1} \right)^2$$

The wingspan squared divided by the planform area, R_A , is called the *aspect ratio* and the parameter e_s is called the *span efficiency factor*.

Lifting-line theory predicts that an elliptic wing with no geometric or aerodynamic twist produces minimum possible induced drag for a given lift coefficient and aspect ratio. This planform has a chord that varies with the spanwise coordinate according to

$$c(z) = \frac{4b}{\pi R_A} \sqrt{1 - (2z/b)^2} \quad \text{or}$$

$$c(\theta) = \frac{4b}{\pi R_A} \sin(\theta)$$

As shown in Fig. 28, an unswept elliptic wing has a straight quarter-chord line. This gives the leading edge less curvature and the trailing edge more curvature than

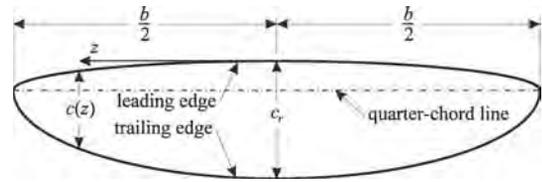

Fig. 28 Planform shape of an unswept elliptic wing with an aspect ratio of 6.

a conventional ellipse, which has a straight half-chord line. Several aircraft have been designed and built with elliptic wings. One of the best known is the British Spitfire shown in Fig. 29.

The lift and induced drag coefficients predicted from Eqs. (86) and (87) for an elliptic wing with no geometric or aerodynamic twist are

$$C_L = C_{L,\alpha}(\alpha - \alpha_{L0}) \quad C_{L,\alpha} = \frac{\tilde{C}_{L,\alpha}}{1 + \tilde{C}_{L,\alpha}/(\pi R_A)} \quad (88)$$

$$C_{D_i} = \frac{C_L^2}{\pi R_A} \quad (89)$$

where $C_{L,\alpha}$ is the lift slope for the finite wing. Equation (88) shows that the lift slope for an untwisted elliptic wing is less than the section lift slope for the airfoil from which the wing was generated. However, as the aspect ratio for the wing becomes large, the lift slope

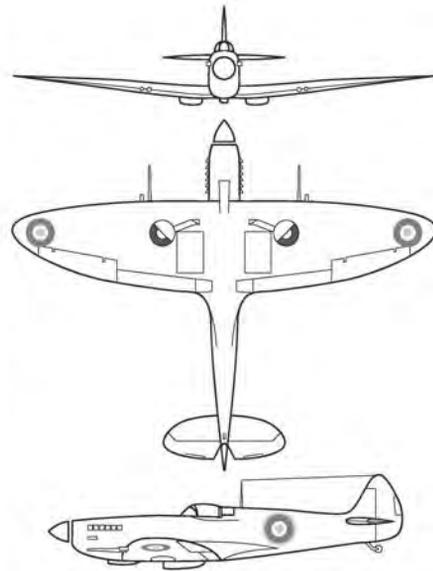

Fig. 29 Elliptic wing used on the famous British Spitfire. (Photograph by Barry Santana.)

for the finite wing approaches that of the airfoil section and the induced drag becomes small. At a given angle of attack, the untwisted elliptic wing produces more lift than any other untwisted wing of the same aspect ratio. Planform shape affects both the induced drag and the lift slope of a finite wing. However, the effect of planform shape is small compared to that of aspect ratio.

While untwisted elliptic wings produce minimum possible induced drag, they are more expensive to manufacture than simple rectangular wings. Untwisted rectangular wings are easy to manufacture, but they generate induced drag at a level that is less than optimum. The untwisted tapered wing, shown in Fig. 30, has commonly been used as a compromise. Tapered wings have a chord length that varies linearly from the root to the tip. They are nearly as easy to manufacture as rectangular wings, and they can be designed to produce induced drag close to the optimum value of an elliptic wing.

The chord length for a tapered wing varies with the spanwise coordinate according to the relation

$$c(z) = \frac{2b}{R_A(1 + R_T)} \left[1 - (1 - R_T) \left| \frac{2z}{b} \right| \right] \quad \text{or}$$

$$c(\theta) = \frac{2b}{R_A(1 + R_T)} [1 - (1 - R_T) |\cos \theta|]$$

where R_T is the taper ratio, related to the root chord, c_r , and the tip chord, c_t , by

$$R_T \equiv \frac{c_t}{c_r}$$

For a wing of any planform having no sweep, dihedral, geometric twist, or aerodynamic twist, the circulation distribution predicted from Prandtl's lifting-line theory can be written in terms of a Fourier series with coefficients a_n , that are independent of angle of attack. Under these conditions, Eq. (84) can be rearranged to give

$$\Gamma(\theta) = 2bV_\infty(\alpha - \alpha_{L0}) \sum_{n=1}^N a_n \sin(n\theta)$$

$$\theta = \cos^{-1} \left(\frac{-2z}{b} \right) \quad (90)$$

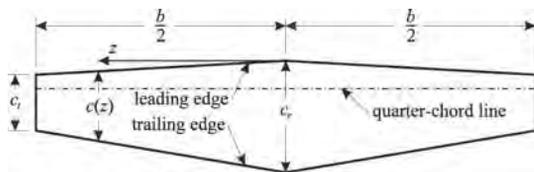

Fig. 30 Planform shape of an unswept tapered wing with a taper ratio of 0.5 and an aspect ratio of 6.

where the Fourier coefficients are obtained from

$$\sum_{n=1}^N a_n \left[\frac{4b}{\tilde{C}_{L,\alpha} c(\theta)} + \frac{n}{\sin(\theta)} \right] \sin(n\theta) = 1 \quad (91)$$

The lift and induced drag coefficient predicted from Eqs. (86) and (87) for a wing with no geometric or aerodynamic twist can be written as

$$C_L = C_{L,\alpha}(\alpha - \alpha_{L0})$$

$$C_{L,\alpha} = \frac{\tilde{C}_{L,\alpha}}{[1 + \tilde{C}_{L,\alpha}/(\pi R_A)](1 + \kappa_L)} \quad (92)$$

$$C_{D_i} = \frac{C_L^2}{\pi R_A e_s} \quad e_s = \frac{1}{1 + \kappa_D} \quad (93)$$

where the lift slope factor, κ_L , and the induced drag factor, κ_D , are given by

$$\kappa_L = \frac{1 - (1 + \pi R_A/\tilde{C}_{L,\alpha})a_1}{(1 + \pi R_A/\tilde{C}_{L,\alpha})a_1} \quad (94)$$

$$\kappa_D = \sum_{n=2}^N n \left(\frac{a_n}{a_1} \right)^2 \quad (95)$$

For untwisted tapered wings, numerical results obtained for these two factors are shown in Figs. 31 and 32. These results were generated using a section lift slope of 2π .

Glauert⁹ first presented results similar to those shown in Fig. 32. Such results have sometimes led to the conclusion that a tapered wing with a taper ratio of about 0.4 always produces significantly less induced drag than a rectangular wing of the same aspect ratio developing the same lift. As a result, tapered wings are often used as a means of reducing induced drag. However, this reduction in drag usually comes at a price. Because a tapered wing has a lower Reynolds number at the wingtips than at the root, a tapered wing with no geometric or aerodynamic twist tends to stall first in the region of the wingtips. This wingtip stall commonly leads to poor handling qualities during stall recovery.

The results shown in Fig. 32 can be misleading if one loses sight of the fact that these results apply only for the special case of wings with no geometric or aerodynamic twist. This is only one of many possible washout distributions that could be used for a wing of any given planform. Furthermore, it is not the washout distribution that produces minimum induced drag with finite lift, except for the case of an elliptic wing. When the effects of washout are included, it can be shown that the conclusions sometimes reached from consideration of only those results shown in Fig. 32 are erroneous.

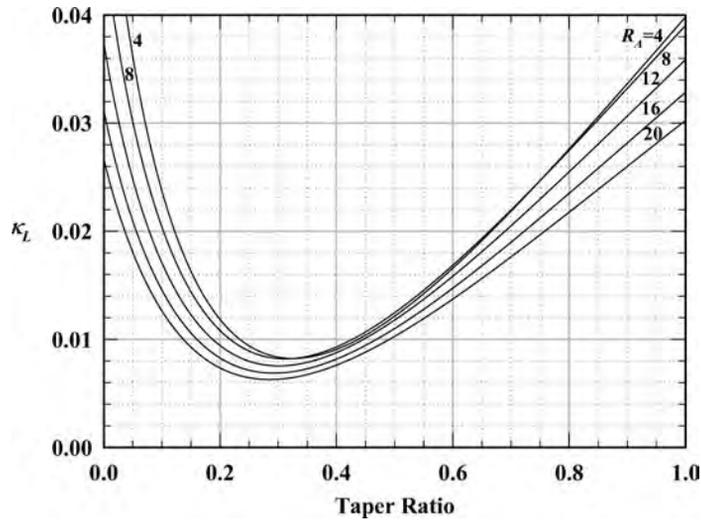

Fig. 31 Lift slope factor for untwisted tapered wings from Prandtl's lifting-line theory.

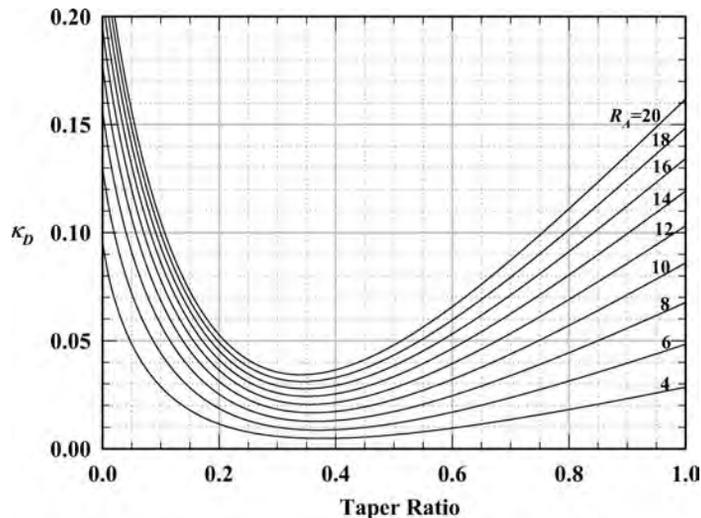

Fig. 32 Induced drag factor for untwisted tapered wings from Prandtl's lifting-line theory.

6.2 Effects of Wing Twist

For a wing with geometric and/or aerodynamic twist, the solution expressed in the form of Eqs. (84)–(87) is cumbersome for the evaluation of traditional wing properties because the Fourier coefficients depend on angle of attack and must be reevaluated for each operating point studied. Furthermore, the definition of κ_D that is given in Eq. (87) is not practical for use at an arbitrary angle of attack because the value becomes singular for a twisted wing when the lift coefficient

approaches zero. A more useful form of the solution was obtained by Phillips et al.^{10–13} using the change of variables

$$\alpha(\theta) - \alpha_{L0}(\theta) \equiv (\alpha - \alpha_{L0})_{\text{root}} - \Omega\omega(\theta) \quad (96)$$

where Ω is defined to be the maximum total washout, geometric plus aerodynamic,

$$\Omega \equiv (\alpha - \alpha_{L0})_{\text{root}} - (\alpha - \alpha_{L0})_{\text{max}} \quad (97)$$

and $\omega(\theta)$ is the local washout distribution function, which is normalized with respect to maximum total washout

$$\omega(\theta) \equiv \frac{\alpha(\theta) - \alpha_{L0}(\theta) - (\alpha - \alpha_{L0})_{\text{root}}}{(\alpha - \alpha_{L0})_{\text{max}} - (\alpha - \alpha_{L0})_{\text{root}}} \quad (98)$$

The normalized washout distribution function, $\omega(\theta)$, is independent of angle of attack and always varies from 0.0 at the root to 1.0 at the point of maximum washout, which is commonly at the wingtips.

Using Eq. (96) in Eq. (85) gives

$$\begin{aligned} \sum_{n=1}^N A_n \left[\frac{4b}{\tilde{C}_{L,\alpha C}(\theta)} + \frac{n}{\sin(\theta)} \right] \sin(n\theta) \\ = (\alpha - \alpha_{L0})_{\text{root}} - \Omega\omega(\theta) \end{aligned} \quad (99)$$

The Fourier coefficients in Eq. (99) for a wing with geometric and/or aerodynamic twist can be conveniently written as

$$A_n \equiv a_n(\alpha - \alpha_{L0})_{\text{root}} - b_n\Omega \quad (100)$$

where

$$\sum_{n=1}^N a_n \left[\frac{4b}{\tilde{C}_{L,\alpha C}(\theta)} + \frac{n}{\sin(\theta)} \right] \sin(n\theta) = 1 \quad (101)$$

$$\sum_{n=1}^N b_n \left[\frac{4b}{\tilde{C}_{L,\alpha C}(\theta)} + \frac{n}{\sin(\theta)} \right] \sin(n\theta) = \omega(\theta) \quad (102)$$

Comparing Eq. (101) with Eq. (91), we see that the Fourier coefficients defined by Eq. (101) are those corresponding to the solution for a wing of the same planform shape but with no geometric or aerodynamic twist. The solution to Eq. (102) can be obtained in a similar manner and is also independent of angle of attack.

Using Eq. (100) in Eq. (86), the lift coefficient for a wing with washout can be expressed as

$$C_L = \pi R_A A_1 = \pi R_A [a_1(\alpha - \alpha_{L0})_{\text{root}} - b_1\Omega] \quad (103)$$

Using Eq. (100) in Eq. (87), the induced drag coefficient is given by

$$\begin{aligned} C_{D_i} = \pi R_A \sum_{n=1}^N n A_n^2 = \pi R_A [a_1(\alpha - \alpha_{L0})_{\text{root}} - b_1\Omega]^2 \\ + \pi R_A \sum_{n=2}^N n [a_n(\alpha - \alpha_{L0})_{\text{root}} - b_n\Omega]^2 \end{aligned}$$

or after using Eq. (103) to express the first term on the right-hand side in terms of the lift coefficient.

$$\begin{aligned} C_{D_i} = \frac{C_L^2}{\pi R_A} + \pi R_A \sum_{n=2}^{\infty} n [a_n^2(\alpha - \alpha_{L0})_{\text{root}}^2 \\ - 2a_n b_n(\alpha - \alpha_{L0})_{\text{root}}\Omega + b_n^2\Omega^2] \end{aligned} \quad (104)$$

Equations (103) and (104) can be algebraically rearranged to yield a convenient expression for the lift and induced drag developed by a finite wing with geometric and/or aerodynamic twist:

$$C_L = C_{L,\alpha}[(\alpha - \alpha_{L0})_{\text{root}} - \varepsilon_\Omega\Omega] \quad (105)$$

$$C_{D_i} = \frac{C_L^2(1 + \kappa_D) - \kappa_{DL}C_L C_{L,\alpha}\Omega + \kappa_{D\Omega}(C_{L,\alpha}\Omega)^2}{\pi R_A} \quad (106)$$

$$C_{L,\alpha} = \pi R_A a_1 = \frac{\tilde{C}_{L,\alpha}}{[1 + \tilde{C}_{L,\alpha}/(\pi R_A)](1 + \kappa_L)} \quad (107)$$

$$\kappa_L \equiv \frac{1 - (1 + \pi R_A/\tilde{C}_{L,\alpha})a_1}{(1 + \pi R_A/\tilde{C}_{L,\alpha})a_1} \quad (108)$$

$$\varepsilon_\Omega \equiv \frac{b_1}{a_1} \quad (109)$$

$$\kappa_D \equiv \sum_{n=2}^N n \frac{a_n^2}{a_1^2} \quad (110)$$

$$\kappa_{DL} \equiv 2 \frac{b_1}{a_1} \sum_{n=2}^N n \frac{a_n}{a_1} \left(\frac{b_n}{b_1} - \frac{a_n}{a_1} \right) \quad (111)$$

$$\kappa_{D\Omega} \equiv \left(\frac{b_1}{a_1} \right)^2 \sum_{n=2}^N n \left(\frac{b_n}{b_1} - \frac{a_n}{a_1} \right)^2 \quad (112)$$

Comparing Eqs. (105)–(112) with Eqs. (92) and (95), we see that washout increases the zero-lift angle of attack for any wing but the lift slope for a wing of arbitrary planform shape is not affected by washout. Notice that the induced drag for a wing with washout is not zero at zero lift. In addition to the usual component of induced drag, which is proportional to the lift coefficient squared, a wing with washout produces a component of induced drag that is proportional to the washout squared, and this results in induced drag at zero lift. There is also a component of induced drag that varies with the product of the lift coefficient and the washout.

A commonly used washout distribution that is easy to implement is linear washout. For the special case of a linear variation in washout from the root to the tip, the normalized washout distribution function is simply

$$\omega(z) = |2z/b| \quad \text{or} \quad \omega(\theta) = |\cos(\theta)| \quad (113)$$

For tapered wings, the variation in chord length is also linear:

$$c(z) = \frac{2b}{R_A(1 + R_T)} [1 - (1 - R_T)|2z/b|] \quad \text{or}$$

$$c(\theta) = \frac{2b}{R_A(1 + R_T)} [1 - (1 - R_T)|\cos(\theta)|] \quad (114)$$

Using Eqs. (113) and (114) in Eqs. (101) and (102) yields the results for a tapered wing with linear washout,

$$\sum_{n=1}^N a_n \left[\frac{2R_A(1 + R_T)}{\tilde{C}_{L,\alpha} [1 - (1 - R_T)|\cos(\theta)|]} + \frac{n}{\sin(\theta)} \right] \times \sin(n\theta) = 1 \quad (115)$$

$$\sum_{n=1}^N b_n \left[\frac{2R_A(1 + R_T)}{\tilde{C}_{L,\alpha} [1 - (1 - R_T)|\cos(\theta)|]} + \frac{n}{\sin(\theta)} \right] \times \sin(n\theta) = |\cos(\theta)| \quad (116)$$

The solution obtained from Eq. (115) for the Fourier coefficients a_n , is the familiar result that was used to produce Figs. 31 and 32. Induced drag for a wing with washout is readily predicted from Eq. (106) with the definition given in Eqs. (110)–(112). For tapered wings with linear washout, the Fourier coefficients, b_n , can be obtained from Eq. (116) in exactly the same manner as the coefficients a_n , are obtained from Eq. (115). Using the Fourier coefficients so obtained in Eqs. (109), (111), and (112) produces the results

shown in Figs. 33–35. Notice from examining either Eq. (112) or Fig. 35 that $\kappa_{D\Omega}$ is always positive. Thus, the third term in the numerator on the right-hand side of Eq. (106) always contributes to an increase in induced drag. However, from the results shown in Fig. 34, we see that the second term in the numerator on the right-hand side of Eq. (106) can either increase or decrease the induced drag, depending on the signs of κ_{DL} and Ω . This raises an important question regarding wing efficiency. What level and distribution of washout will result in minimum induced drag for a given wing planform and lift coefficient?

6.3 Minimizing Induced Drag with Washout

For a wing of any given planform shape having a fixed washout distribution, induced drag can be minimized with washout as a result of the trade-off between the second and third terms in the numerator on the right-hand side of Eq. (106). Thus, Eq. (106) can be used to determine the optimum value of total washout, which will result in minimum induced drag for any washout distribution function and any specific lift coefficient. Differentiating Eq. (106) with respect to total washout at constant lift coefficient gives

$$\frac{\partial C_{D_i}}{\partial \Omega} = \frac{-\kappa_{DL} C_L C_{L,\alpha} + 2\kappa_{D\Omega} C_{L,\alpha}^2 \Omega}{\pi R_A} \quad (117)$$

Setting the right-hand side of Eq. (117) to zero and solving for the total washout, it can be seen that minimum induced drag is attained for any given wing planform, $c(z)$, any given washout distribution, $\omega(z)$, and any given design lift coefficient, C_{Ld} , by

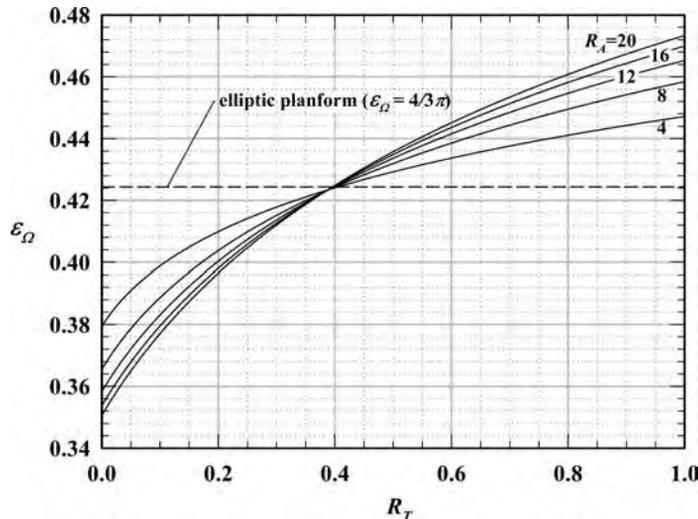

Fig. 33 Washout effectiveness for tapered wings with linear washout.

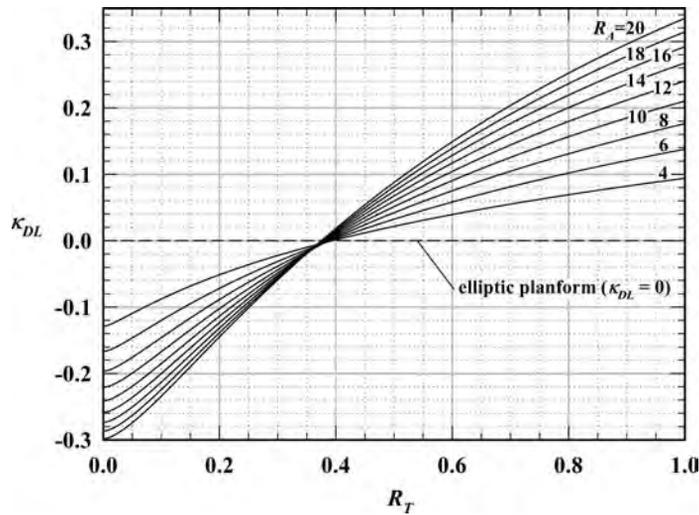

Fig. 34 Lift-washout contribution to induced drag for tapered wings with linear washout.

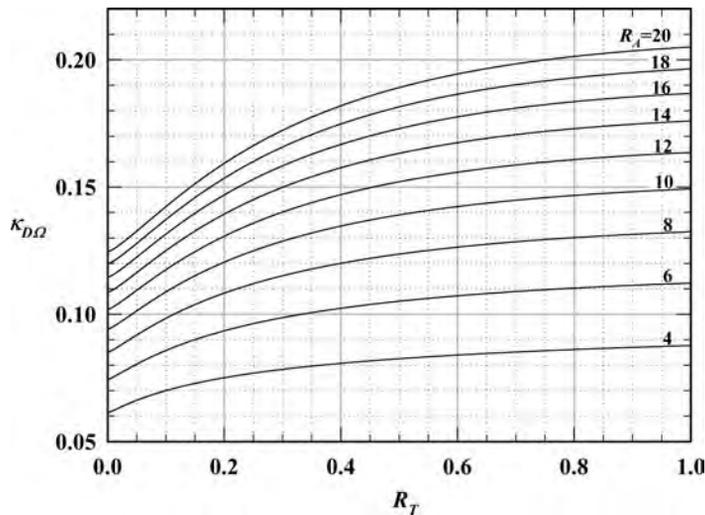

Fig. 35 Washout contribution to induced drag for tapered wings with linear washout.

using an optimum total washout, Ω_{opt} , given by the relation

$$\Omega_{opt} = \frac{\kappa_{DL} C_{Ld}}{2\kappa_{D\Omega} C_{L,\alpha}} \quad (118)$$

For the elliptic planform, all of the Fourier coefficients, a_n , are zero for n greater than 1. Thus, Eq. (111) shows that κ_{DL} is zero for an elliptic wing. As a result, elliptic wings are always optimized with no washout. From

consideration of Eq. (118) together with the results shown in Figs. 34 and 35, we see that tapered wings with linear washout and taper ratios greater than 0.4 are optimized with positive washout, whereas those with taper ratios less than about 0.4 are optimized with negative washout.

Using the value of optimum washout from Eq. (118) in the expression for induced drag coefficient given by Eq. (106), we find that the induced drag coefficient for a wing of arbitrary planform with a fixed washout

distribution and optimum total washout is given by

$$(C_{D_i})_{\text{opt}} = \frac{C_L^2}{\pi R_A} \left[1 + \kappa_D - \frac{\kappa_{DL}^2}{4\kappa_{D\Omega}} \left(2 - \frac{C_{Ld}}{C_L} \right) \frac{C_{Ld}}{C_L} \right] \quad (119)$$

From Eq. (119) it can be seen that a wing with optimum washout will always produce less induced drag than a wing with no washout having the same planform and aspect ratio, provided that the actual lift coefficient is greater than one-half the design lift coefficient. When the actual lift coefficient is equal to the design lift coefficient, the induced drag coefficient for a wing with optimum washout is

$$(C_{D_i})_{\text{opt}} = \frac{C_L^2}{\pi R_A} (1 + \kappa_{D_o}) \quad \kappa_{D_o} \equiv \kappa_D - \frac{\kappa_{DL}^2}{4\kappa_{D\Omega}} \quad (120)$$

For tapered wings with linear washout, the variations in κ_{D_o} with aspect ratio and taper ratio are shown in Fig. 36. For comparison, the dashed lines in this figure show the same results for wings with no washout. Notice that when linear washout is used to further optimize tapered wings, taper ratios near 0.4 correspond closely to a maximum in induced drag, not to a minimum.

The choice of a linear washout distribution, which was used to generate the results shown in Fig. 36, is as arbitrary as the choice of no washout. While a linear variation in washout is commonly used and simple to implement, it is not the optimum washout distribution for wings with linear taper. Minimum possible induced drag for a finite lift coefficient always occurs when the local section lift varies with the spanwise coordinate in proportion to $\sin(\theta)$. This results in uniform downwash and requires that the product of the local chord length

and local aerodynamic angle of attack, $\alpha - \alpha_{L0}$, varies elliptically with the spanwise coordinate, that is,

$$\frac{c(z)[\alpha(z) - \alpha_{L0}(z)]}{\sqrt{1 - (2z/b)^2}} = \frac{c(\theta)[\alpha(\theta) - \alpha_{L0}(\theta)]}{\sin(\theta)} = \text{const} \quad (121)$$

There are many possibilities for wing geometry that will satisfy this condition. The elliptic planform with no geometric or aerodynamic twist is only one such geometry. Since the local aerodynamic angle of attack decreases along the span in direct proportion to the increase in washout, Eq. (121) can only be satisfied if the washout distribution satisfies the relation

$$\frac{c(z)[1 - \omega(z)]}{\sqrt{1 - (2z/b)^2}} = \frac{c(\theta)[1 - \omega(\theta)]}{\sin(\theta)} = \text{const} \quad (122)$$

Equation (122) is satisfied by the optimum washout distribution

$$\omega_{\text{opt}} = 1 - \frac{\sqrt{1 - (2z/b)^2}}{c(z)/c_{\text{root}}} = 1 - \frac{\sin(\theta)}{c(\theta)/c_{\text{root}}} \quad (123)$$

$$\Omega_{\text{opt}} = \frac{4bC_L}{\pi R_A \tilde{C}_{L,\alpha} c_{\text{root}}}$$

For wings with linear taper, this gives

$$\omega_{\text{opt}} = 1 - \frac{\sqrt{1 - (2z/b)^2}}{1 - (1 - R_T)|2z/b|}$$

$$= 1 - \frac{\sin(\theta)}{1 - (1 - R_T)|\cos(\theta)|}$$

$$\Omega_{\text{opt}} = \frac{2(1 + R_T)C_L}{\pi \tilde{C}_{L,\alpha}} \quad (124)$$

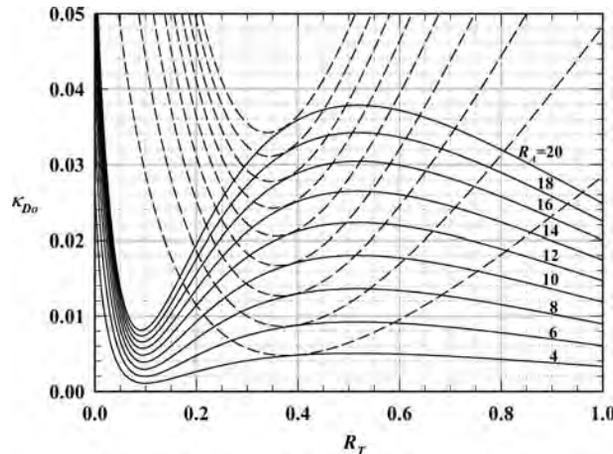

Fig. 36 Optimum induced drag factor for tapered wings with linear washout.

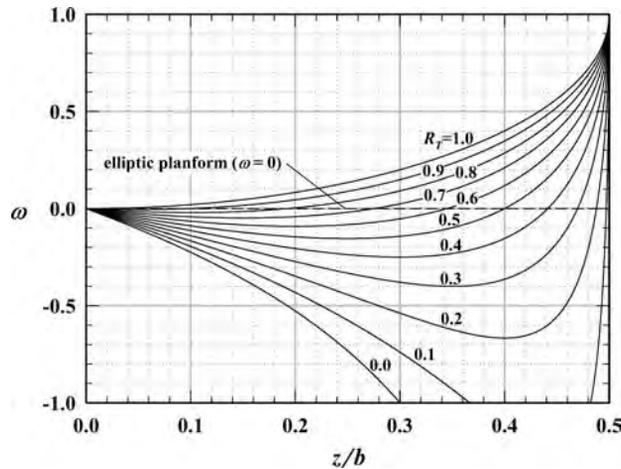

Fig. 37 Optimum washout distribution that results in production of minimum induced drag for wings with linear taper, as defined in Eq. (124).

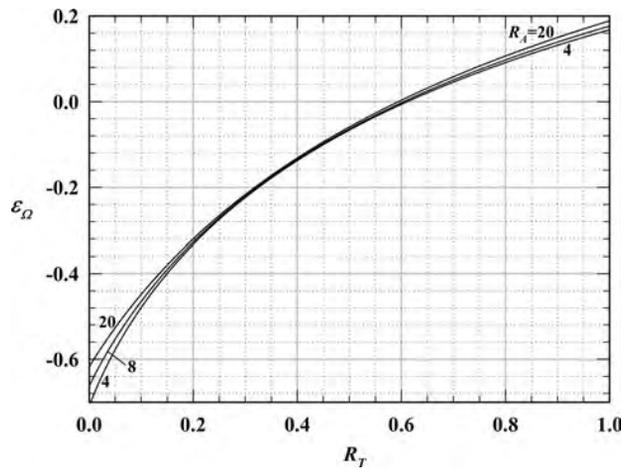

Fig. 38 Washout effectiveness for wings with linear taper and optimum washout.

This optimum washout distribution is shown in Fig. 37 for several values of taper ratio. Results obtained for tapered wings having this washout distribution are presented in Figs. 38–40. Notice that for tapered wings with the optimum washout distribution, κ_{DL} is positive for all taper ratios. Thus, we see from Eq. (118) that tapered wings with optimum washout always have positive washout at the wingtips.

When an unswept wing of arbitrary planform has the washout distribution specific by Eq. (123), the value of κ_{D_0} as define in Eq. (120) is always identically zero. With this washout distribution and the total washout set according to Eq. (118), an unswept wing

of any planform shape can be designed to operate at a given lift coefficient with the same induced drag as that produced by an untwisted elliptic wing with the same aspect ratio and lift coefficient.

6.4 Solution with Control Surface Deflection and Rolling Rate

Trailing-edge flap extending over only some portion of the wingspan are commonly used as control surfaces on an airplane wing. A spanwise symmetric control surface deflection can be used to provide pitch control, and spanwise asymmetric control surface deflection can be used to provide roll control. The

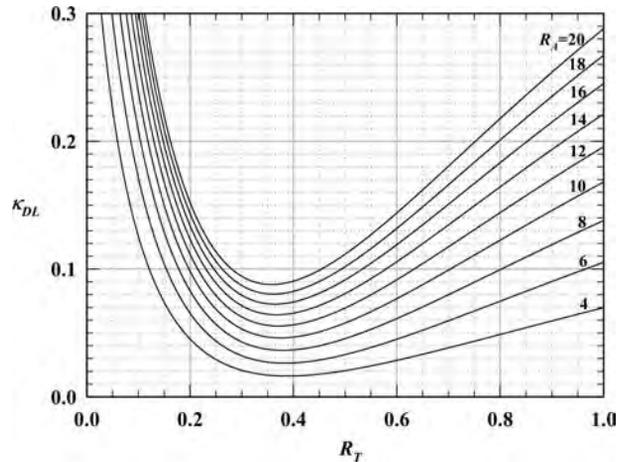

Fig. 39 Lift-washout contribution to the induced drag factor for wings with linear taper and the optimum washout distribution specified by Eq. (124).

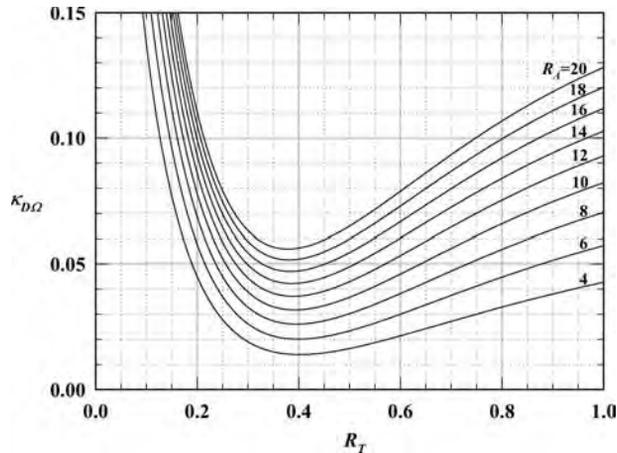

Fig. 40 Washout contribution to the induced drag factor for wings with linear taper and the optimum washout distribution specified by Eq. (124).

control surfaces commonly used to provide roll control are called *aileron*s. These are small trailing-edge flap located in the outboard sections of the wing. The ailerons are deflected asymmetrically to change the rolling moment. One aileron is deflected downward and the other is deflected upward, as shown in Fig. 41. This increases lift on the semispan with the downward-deflected aileron and decreases lift on the semispan with the upward-deflected aileron. Aileron deflection is given the symbol δ_a , and the rolling moment is denoted as ℓ . The sign convention that is commonly used for aileron deflection is shown in Fig. 41. Aileron deflection is assumed positive when the right aileron is deflected downward and the left aileron is deflected

upward. The traditional sign convention used for the rolling moment is positive to the right (i.e., a moment that would roll the right wing down). With these two sign conventions, a positive aileron deflection produces a rolling moment to the left (i.e., negative ℓ). The two ailerons are not necessarily deflected the same magnitude. The aileron angle, δ_a , is usually defined to be the average of the two angular deflections

The rolling moment produced by aileron deflection results in a rolling acceleration, which in turn produces a rolling rate. This rolling rate changes the spanwise variation in geometric angle of attack as shown in Fig. 42. The symbol traditionally used to represent rolling rate is p . As shown in Fig. 42, p is taken to be

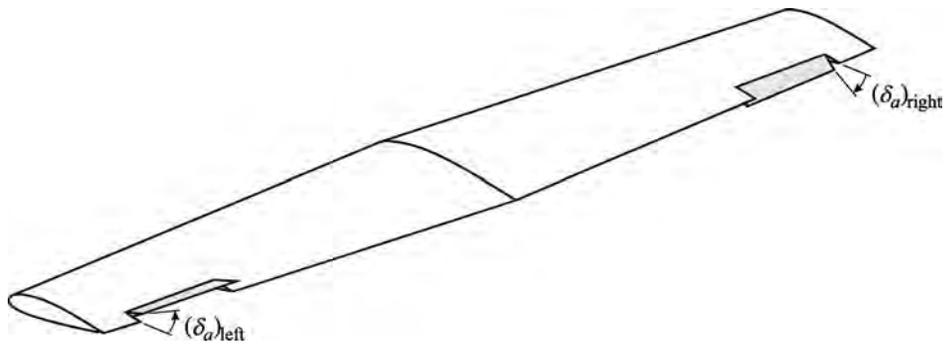

Fig. 41 Asymmetric aileron deflection typically used for roll control.

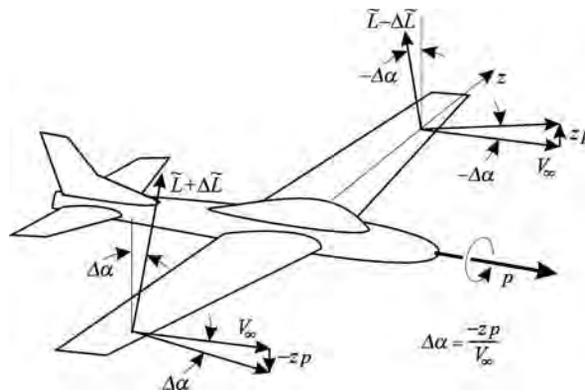

Fig. 42 Change in local section angle of attack resulting from a rolling rate.

positive when the right semispan is moving downward and the left semispan is moving upward. Thus, a positive rolling rate increases the local geometric angle of attack on the right semispan and decreases the local geometric angle of attack on the left semispan. This produces a negative rolling moment, which opposes the rolling rate.

When a small positive aileron deflection is first initiated, a negative rolling moment is produced by the asymmetric change in the wing's local aerodynamic angle of attack. This rolling moment imbalance results in negative rolling acceleration, which produces a negative rolling rate. As the magnitude of the rolling rate increases, an opposing rolling moment develops as a result of the asymmetric change in the local geometric angle of attack. This reduces the moment imbalance and slows the rolling acceleration. At some point, the positive rolling moment produced by the negative rolling rate will just balance the negative rolling moment produced by the positive aileron deflection and a constant rolling rate will develop that is proportional to the aileron deflection

Roll in a conventional airplane is what is referred to as *heavily damped motion*. This means that, when a typical fixed-wing aircraft responds to aileron input, the period of rolling acceleration is very short and the airplane quickly approaches a steady rolling rate, which is proportional to aileron deflection. This gives the pilot the perception that aileron input commands the airplane's rolling rate. Thus, analysis of an airplane's roll response must include consideration of the rolling moment produced by the rolling rate as well as that produced by aileron deflection. Lifting-line theory provides the capability to do just that.

In general, a wing's spanwise variation in local aerodynamic angle of attack can be expressed as the value at the wing root plus the changes due to washout, control surface deflection and rolling rate,

$$\alpha(z) - \alpha_{L0}(z) \equiv (\alpha - \alpha_{L0})_{\text{root}} - \Omega\omega(z) + \delta_a\chi(z) - \frac{pz}{V_\infty} \quad (125)$$

where Ω is define to be the maximum total symmetric washout for the wing, geometric plus aerodynamic,

$$\Omega \equiv [(\alpha - \alpha_{L0})_{\text{root}} - (\Delta\alpha - \Delta\alpha_{L0})_{\text{max}}]_{\text{washout}} \quad (126)$$

$\omega(z)$ is the symmetric washout distribution function,

$$\omega(z) \equiv \left[\frac{\Delta\alpha(z) - \Delta\alpha_{L0}(z) - (\alpha - \alpha_{L0})_{\text{root}}}{(\Delta\alpha - \Delta\alpha_{L0})_{\text{max}} - (\alpha - \alpha_{L0})_{\text{root}}} \right]_{\text{washout}} \quad (127)$$

and $\chi(z)$ is the control surface distribution function,

$$\chi(z) \equiv \left[\frac{\Delta\alpha(z) - \Delta\alpha_{L0}(z) - (\alpha - \alpha_{L0})_{\text{root}}}{\delta_a} \right]_{\text{control}} \quad (128)$$

For example, ailerons extend from the spanwise coordinate z_{ar} to z_{at} give

$$\chi(z) \equiv \begin{cases} 0 & z < -z_{at} \\ \varepsilon_f(z) & -z_{at} < z < -z_{ar} \\ 0 & -z_{ar} < z < z_{ar} \\ -\varepsilon_f(z) & z_{ar} < z < z_{at} \\ 0 & z > z_{at} \end{cases} \quad (129)$$

where ε_f is the local section flap effectiveness.

Using the definition of θ from Eq. (84) together with Eq. (125) in the relation for the Fourier coefficients, A_n , specific by Eq. (85), gives

$$\sum_{n=1}^N A_n \left[\frac{4b}{\widetilde{C}_{L,\alpha} c(\theta)} + \frac{n}{\sin(\theta)} \right] \sin(n\theta) = (\alpha - \alpha_{L0})_{\text{root}} - \Omega\omega(\theta) + \delta_a\chi(\theta) + \bar{p}\cos(\theta) \quad (130)$$

where \bar{p} is a dimensionless rolling rate define as $\bar{p} = pb/2V_\infty$. The Fourier coefficients in Eq. (130) can be conveniently written as

$$A_n = a_n(\alpha - \alpha_{L0})_{\text{root}} - b_n\Omega + c_n\delta_a + d_n\bar{p} \quad (131)$$

where

$$\sum_{n=1}^N a_n \left[\frac{4b}{\widetilde{C}_{L,\alpha} c(\theta)} + \frac{n}{\sin(\theta)} \right] \sin(n\theta) = 1 \quad (132)$$

$$\sum_{n=1}^N b_n \left[\frac{4b}{\widetilde{C}_{L,\alpha} c(\theta)} + \frac{n}{\sin(\theta)} \right] \sin(n\theta) = \omega(\theta) \quad (133)$$

$$\sum_{n=1}^N c_n \left[\frac{4b}{\widetilde{C}_{L,\alpha} c(\theta)} + \frac{n}{\sin(\theta)} \right] \sin(n\theta) = \chi(\theta) \quad (134)$$

$$\sum_{n=1}^N d_n \left[\frac{4b}{\widetilde{C}_{L,\alpha} c(\theta)} + \frac{n}{\sin(\theta)} \right] \sin(n\theta) = \cos(\theta) \quad (135)$$

Equations (132) and (133) are exactly Eqs. (101) and (102) and their solutions are obtained in the same manner. The solutions to Eqs. (134) and (135) can be obtained in a similar manner and are both independent of angle of attack and rolling rate.

Once the Fourier coefficients are determined from Eqs. (131)–(135), the spanwise circulation distribution is known from Eqs. (84) and the spanwise section lift distribution is given by

$$\widetilde{L}(z) = \rho V_\infty \Gamma(z)$$

Thus, in view of Eq. (84), the rolling moment coefficient can be evaluated from

$$\begin{aligned} C_\ell &= \frac{1}{\frac{1}{2}\rho V_\infty^2 S b} \int_{z=-b/2}^{b/2} \widetilde{L}(z) z dz \\ &= \frac{2}{V_\infty S b} \int_{z=-b/2}^{b/2} \Gamma(z) z dz \\ &= -\frac{b^2}{S} \sum_{n=1}^N A_n \int_{\theta=0}^{\pi} \sin(n\theta) \cos(\theta) \sin(\theta) d\theta \end{aligned}$$

or after applying the trigonometric identity, $\sin(2\theta) = 2 \sin(\theta) \cos(\theta)$, along with the definition of aspect ratio

$$C_\ell = -\frac{R_A}{2} \sum_{n=1}^N A_n \int_{\theta=0}^{\pi} \sin(n\theta) \sin(2\theta) d\theta \quad (136)$$

The integral in Eq. (136) is evaluated from

$$\int_{\theta=0}^{\pi} \sin(m\theta) \sin(n\theta) d\theta = \begin{cases} 0 & n \neq m \\ \pi/2 & n = m \end{cases} \quad (137)$$

After applying Eqs. (131) and (137), Eq. (136) becomes

$$\begin{aligned} C_\ell &= -\frac{\pi R_A}{4} A_2 = -\frac{\pi R_A}{4} [a_2(\alpha - \alpha_{L0})_{\text{root}} \\ &\quad - b_2\Omega + c_2\delta_a + d_2\bar{p}] \end{aligned} \quad (138)$$

For a wing with a *spanwise symmetric planform* and *spanwise symmetric washout*, the solutions to Eqs. (132) and (133) give

$$a_n = b_n = 0 \quad n \text{ even} \quad (139)$$

and Eq. (138) reduces to

$$C_{\ell} = C_{\ell, \delta_a} \delta_a + C_{\ell, \bar{p}} \bar{p} \quad (140)$$

where

$$C_{\ell, \delta_a} = -\frac{\pi R_A}{4} c_2 \quad (141)$$

$$C_{\ell, \bar{p}} = -\frac{\pi R_A}{4} d_2 \quad (142)$$

The Fourier coefficients obtained from Eq. (134) depend on control surface geometry as well as the planform shape of the wing. Thus, the change in rolling moment coefficient with respect to aileron deflection depends on the size and shape of the ailerons and the wing planform. On the other hand, the Fourier coefficients that are evaluated from Eq. (135) are functions of only wing planform. For an elliptic planform, the spanwise variation in chord length is given by

$$c(y) = \frac{4b}{\pi R_A} \sqrt{1 - (2y/b)^2} \quad \text{or}$$

$$c(\theta) = \frac{4b}{\pi R_A} \sin(\theta)$$

and Eq. (135) reduces to

$$\sum_{n=1}^N d_n \left(\frac{\pi R_A}{\tilde{C}_{L, \alpha}} + n \right) \sin(n\theta) = \sin(\theta) \cos(\theta) \quad (143)$$

The solution to Eq. (143) is given by the Fourier integral

$$d_n \left(\frac{\pi R_A}{\tilde{C}_{L, \alpha}} + n \right) = \frac{2}{\pi} \int_0^{\pi} \sin(\theta) \cos(\theta) \sin(n\theta) d\theta$$

$$= \frac{1}{\pi} \int_0^{\pi} \sin(2\theta) \sin(n\theta) d\theta \quad (144)$$

which is readily evaluated from Eq. (137) to give

$$d_n = \begin{cases} \frac{\tilde{C}_{L, \alpha}}{2(\pi R_A + 2\tilde{C}_{L, \alpha})} & n = 2 \\ 0 & n \neq 2 \end{cases} \quad (145)$$

Using Eq. (145) in Eq. (142) gives

$$C_{\ell, \bar{p}} = \frac{-\tilde{C}_{L, \alpha}}{8(1 + 2\tilde{C}_{L, \alpha}/\pi R_A)}$$

Thus, in view of Eq. (88), the *change in rolling moment coefficient* with respect to dimensionless rolling rate for an elliptic wing can be written as

$$C_{\ell, \bar{p}} = -\frac{\kappa_{\ell \bar{p}} C_{L, \alpha}}{8} \quad \kappa_{\ell \bar{p}} \equiv \frac{1 + \tilde{C}_{L, \alpha}/\pi R_A}{1 + 2\tilde{C}_{L, \alpha}/\pi R_A} \quad (146)$$

Similarly, in the general case of a wing with arbitrary planform,

$$C_{\ell, \bar{p}} = -\frac{\kappa_{\ell \bar{p}} C_{L, \alpha}}{8} \quad \kappa_{\ell \bar{p}} \equiv \frac{2d_2}{a_1} \quad (147)$$

Using an airfoil lift slope of 2π to determine a_1 and d_2 from Eqs. (132) and (135), the results shown in Fig. 43 are obtained for tapered wings.

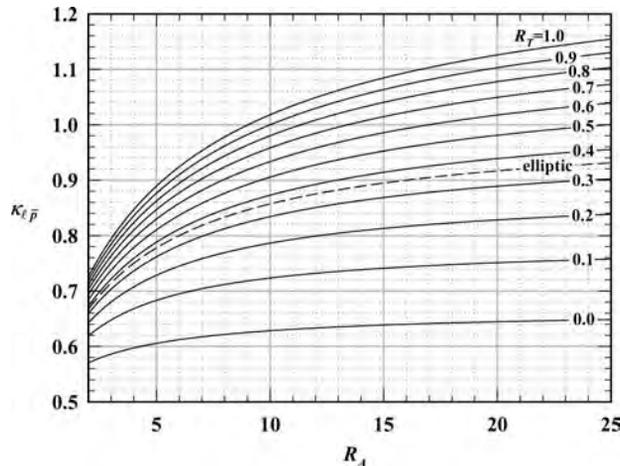

Fig. 43 Roll damping factor for wings with linear taper from Eq. (147).

The asymmetric spanwise variations in aerodynamic angle of attack, which result from aileron deflection and roll, can also produce a yawing moment. The aerodynamic yawing moment is given the symbol n , and the traditional sign convention for yaw is positive to the right (i.e., a moment that would yaw the airplane's nose to the right). The yawing moment develops as a direct result of an asymmetric spanwise variation in drag. Thus, the yawing moment coefficient can be written as

$$C_n \equiv \frac{n}{\frac{1}{2}\rho V_\infty^2 S b} = \frac{1}{\frac{1}{2}\rho V_\infty^2 S b} \int_{z=-b/2}^{b/2} (-z) \tilde{D}(z) dz \quad (148)$$

As shown in Figs. 24 and 42, the asymmetric section drag results from tilting the section lift vector through the induced angle, α_i , and the roll angle, zp/V_∞ . Thus, after expressing the section lift in terms of the section circulation, we have

$$\begin{aligned} \tilde{D}(z) &= \tilde{L} \sin\left(\alpha_i + \frac{zp}{V_\infty}\right) \cong \tilde{L} \left(\alpha_i + \frac{zp}{V_\infty}\right) \\ &= \rho V_\infty \Gamma(z) \left[\alpha_i(z) + \frac{zp}{V_\infty}\right] \end{aligned} \quad (149)$$

The induced angle of attack as predicted by lifting-line theory is

$$\alpha_i(z) = \frac{1}{4\pi V_\infty} \int_{\zeta=-b/2}^{b/2} \frac{1}{z-\zeta} \left(\frac{d\Gamma}{d\zeta}\right)_{\zeta=\zeta} d\zeta \quad (150)$$

Using Eqs. (149) and (150) in Eq. (148) gives

$$\begin{aligned} C_n &= \int_{z=-b/2}^{b/2} \frac{-2z\Gamma(z)}{V_\infty^2 S b} \\ &\quad \left[\frac{1}{4\pi} \int_{\zeta=-b/2}^{b/2} \frac{1}{z-\zeta} \left(\frac{d\Gamma}{d\zeta}\right)_{\zeta=\zeta} d\zeta + zp \right] dz \end{aligned} \quad (151)$$

From Eq. (84) we have

$$\Gamma(\theta) = 2bV_\infty \sum_{n=1}^N A_n \sin(n\theta) \quad \cos(\theta) = -\frac{2z}{b}$$

$$\frac{d\Gamma}{dz} = 4V_\infty \sum_{n=1}^N A_n \frac{n \cos(n\theta)}{\sin(\theta)}$$

and Eq. (151) can be written as

$$C_n = R_A \int_{\theta=0}^{\pi} \cos(\theta) \left[\sum_{n=1}^N A_n \sin(n\theta) \right]$$

$$\begin{aligned} &\times \left[\sum_{n=1}^N \frac{n A_n}{\pi} \int_{\phi=0}^{\pi} \frac{\cos(n\phi) d\phi}{\cos(\phi) - \cos(\theta)} \right] \sin(\theta) d\theta \\ &- R_A \bar{p} \sum_{n=1}^N A_n \int_{\theta=0}^{\pi} \cos^2(\theta) \sin(\theta) \sin(n\theta) d\theta \end{aligned}$$

Integrating in ϕ and using the trigonometric relation, $\sin(2\theta) = 2 \cos(\theta) \sin(\theta)$, yields

$$\begin{aligned} C_n &= R_A \sum_{n=1}^N \sum_{m=1}^N n A_n A_m \\ &\quad \times \int_{\theta=0}^{\pi} \cos(\theta) \sin(n\theta) \sin(m\theta) d\theta \\ &\quad - R_A \bar{p} \sum_{n=1}^N A_n \frac{1}{2} \int_{\theta=0}^{\pi} \cos(\theta) \sin(2\theta) \sin(n\theta) d\theta \end{aligned} \quad (152)$$

Since m and n are positive integers, the integrals with respect to θ are evaluated from

$$\int_{\theta=0}^{\pi} \cos(\theta) \sin(n\theta) \sin(m\theta) d\theta = \begin{cases} \frac{1}{4}\pi & m = n \pm 1 \\ 0 & m \neq n \pm 1 \end{cases}$$

and after some rearranging, we obtain

$$C_n = \frac{\pi R_A}{4} \sum_{n=2}^N (2n-1) A_{n-1} A_n - \frac{\pi R_A \bar{p}}{8} (A_1 + A_3) \quad (153)$$

After applying Eq. (86), we find that the *yawing moment coefficient* for a wing of arbitrary geometry is given by

$$\begin{aligned} C_n &= \frac{C_L}{8} (6A_2 - \bar{p}) + \frac{\pi R_A}{8} (10A_2 - \bar{p}) A_3 \\ &\quad + \frac{\pi R_A}{4} \sum_{n=4}^N (2n-1) A_{n-1} A_n \end{aligned} \quad (154)$$

where the Fourier coefficients, A_n , are related to Ω , δ_a , and \bar{p} through Eq. (131).

If the wing planform and washout distribution are both spanwise symmetric, all even coefficient in both a_n and b_n are zero. The change in aerodynamic angle of attack that results from roll is always a spanwise odd function. Thus, all odd coefficient in d_n are zero for a spanwise symmetric wing. If the ailerons produce an equal and opposite change on each semispan, the control surface distribution function is a spanwise odd function as well and all odd coefficient in c_n are also zero. With this wing symmetry the Fourier coefficients

must satisfy the relations $a_n = b_n = 0$ for n even and $c_n = d_n = 0$ for n odd. Thus, Eq. (131) reduces to

$$A_n = \begin{cases} a_n(\alpha - \alpha_{L0})_{\text{root}} - b_n\Omega & n \text{ odd} \\ c_n\delta_a + d_n\bar{p} & n \text{ even} \end{cases} \quad (155)$$

Using the Fourier coefficients from Eq. (155) in Eq. (154), the yawing moment coefficient with the wing symmetry described above is given by

$$\begin{aligned} C_n = & \frac{C_L}{8}[6c_2\delta_a - (1 - 6d_2)\bar{p}] + \frac{\pi R_A}{8}[10c_2\delta_a \\ & - (1 - 10d_2)\bar{p}][a_3(\alpha - \alpha_{L0})_{\text{root}} - b_3\Omega] \\ & + \frac{\pi R_A}{4} \left[\sum_{n=4}^N (2n - 1)[a_{n-1}(\alpha - \alpha_{L0})_{\text{root}} \right. \\ & \left. - b_{n-1}\Omega](c_n\delta_a + d_n\bar{p}) \right]_{n \text{ even}} \\ & + \frac{\pi R_A}{4} \left[\sum_{n=5}^N (2n - 1)(c_{n-1}\delta_a + d_{n-1}\bar{p}) \right. \\ & \left. \times [a_n(\alpha - \alpha_{L0})_{\text{root}} - b_n\Omega] \right]_{n \text{ odd}} \end{aligned} \quad (156)$$

For the special case of a symmetric wing operating with optimum washout, which is specific by Eqs. (118) and (123), $a_n(\alpha - \alpha_{L0})_{\text{root}} - b_n\Omega$ is always zero for $n > 1$ and

$$\begin{aligned} C_n = C_{n,\delta_a}\delta_a + C_{n,\bar{p}}\bar{p} \quad C_{n,\delta_a} &= \frac{3C_L}{4}c_2 \\ C_{n,\bar{p}} &= -\frac{C_L}{8}(1 - 6d_2) \end{aligned} \quad (157)$$

For wings without optimum washout, the higher-order terms in Eq. (156) are not too large and the linear relation from Eq. (157) can be used as a rough approximation.

By comparing Eq. (140) with Eq. (157) we find that within the accuracy of Eq. (157), the yawing moment can be expressed in terms of the rolling moment and the rolling rate,

$$C_n = -\frac{3C_L}{\pi R_A}C_\ell - \frac{C_L}{8}\bar{p} \quad (158)$$

When an airplane responds to aileron input, the rolling rate quickly reaches the steady-state value, which results in no rolling moment. Thus, we see from Eq. (158) that the magnitude of the steady yawing moment produced by aileron deflection is proportional to the lift coefficient developed by the wing and the steady rolling rate that develops as a result of the

aileron deflection. From Eq. (158), we can also see that the sign of the yawing moment, which is induced on a wing by aileron deflection is opposite to that of the rolling moment induced by the same aileron deflection. Positive aileron deflection induces a wing rolling moment to the left and a wing yawing moment to the right. For this reason, the yawing moment induced on the wing by aileron deflection is commonly called *adverse yaw*. We can also see from Eq. (158) that adverse yaw is more pronounced at low airspeeds, which require higher values of C_L .

6.5 Wing Aspect Ratio and Mean Chord Length

We have seen that the aspect ratio of a finite wing has a profound effect on the wing's performance. As defined in Eq. (86), the *aspect ratio* for a wing of arbitrary planform can be computed as the square of the wingspan divided by the planform area:

$$R_A \equiv \frac{b^2}{S} \quad (159)$$

In a more general sense, aspect ratio is defined to be the ratio of the longer to the shorter dimension for any 2D shape. The aspect ratio of a rectangle is simply the length of the long side divided by the length of the short side. Thus, the aspect ratio of a rectangular wing having a constant chord, c and wingspan, b , can be defined as

$$R_A \equiv \frac{b}{c} \quad (160)$$

Because the planform area of a rectangular wing is simply the wingspan multiplied by the chord length, $S = bc$, the definition given in Eqs. (159) and (160) are equivalent. For the more general case of a wing having a chord length that varies with the spanwise coordinate, z , the aspect ratio can be written as the ratio of the wingspan to the average or *mean chord length*, \bar{c} ,

$$R_A \equiv \frac{b}{\bar{c}} \quad (161)$$

where, by comparison of Eqs. (159) and (161), the mean chord length is defined as

$$\bar{c} \equiv \frac{S}{b} = \frac{1}{b} \int_{z=-b/2}^{b/2} c(z) dz \quad (162)$$

Because the wing aspect ratio defined by Eq. (159) has such a profound effect on wing performance, both the wingspan and the mean chord length defined by Eq. (162) are important characteristic dimensions for a finite wing.

For a wing with linear taper, the planform area is one half the sum of the root chord, c_r , and the tip chord, c_t , multiplied by the wingspan, b . Thus, the mean chord length for a wing with linear taper is

$$\begin{aligned}\bar{c} &\equiv \frac{S}{b} = \frac{1}{b} \int_{z=-b/2}^{b/2} \left[c_r - (c_r - c_t) \left| \frac{2z}{b} \right| \right] dz \\ &= \frac{c_r + c_t}{2} = \frac{1 + R_T}{2} c_r\end{aligned}\quad (163)$$

For an elliptic wing the mean chord length is

$$\bar{c} \equiv \frac{S}{b} = \frac{1}{b} \int_{z=-b/2}^{b/2} c_r \sqrt{1 - \left(\frac{2z}{b} \right)^2} dz = \frac{\pi}{4} c_r \quad (164)$$

7 FLOW OVER MULTIPLE LIFTING SURFACES

Prandtl's classical lifting-line equation, expressed in Eq. (83), applies only to a single lifting surface with no sweep or dihedral. In the development of this relation it was assumed that the only downwash induced on the wing was that induced by the trailing vortex sheet, which is shed from the wing itself. Airplanes are usually designed with more than one lifting surface. A typical configuration could be a wing combined with horizontal and vertical stabilizers. Each of these surfaces can generate lift and vorticity. The vorticity that is generated by one lifting surface will alter the flow about another. For example, a lifting wing will induce downwash on an aft horizontal stabilizer, and a lifting aft stabilizer will induce upwash on the main wing. Such lifting surface interactions are not accounted for in Eq. (83).

Even a flying wing cannot be analyzed using Eq. (83) if the wing has sweep or dihedral. In a wing with sweep and/or dihedral, the quarter-chord line on one semispan makes an angle with the quarter-chord line of the other semispan, as shown in Fig. 44. A wing

is said to have *positive sweep* if the wing is swept back from the root to the tip, with the wingtips being aft of the root. A wing has *positive dihedral* if the wing slopes up from the root to the tip, with the wingtips being above the root. *Negative dihedral* is usually called *anhedral*. Because a wing can also have taper and/or geometric twist, defining the sweep and dihedral angles can be somewhat ambiguous. For a conventional tapered wing, the sweep angle for the leading edge is greater than that for the trailing edge. For a wing with geometric washout, the dihedral angle for the trailing edge is greater than that for the leading edge. Furthermore, neither the sweep nor the dihedral must remain constant over the semispan of a lifting surface. For this reason, local sweep and dihedral angles are defined in terms of the wing quarter-chord line and the orientation of the local streamwise airfoil section, as shown in Fig. 44.

When constant dihedral is added to a wing, each side of the wing is rotated about the root as a solid body. The rotation of the left-hand side is opposite to that of the right-hand side, so that both wingtips are raised above the root and brought closer together. Since dihedral is a solid-body rotation, the local airfoil sections rotate with the quarter-chord line. For a wing with no dihedral, a vector drawn normal to a local airfoil section is also normal to the aircraft plane of symmetry. As dihedral is added to the wing, both the quarter-chord and the airfoil section normal are rotated upward, so that the normal to the local airfoil section always forms an angle equal to the dihedral angle with the normal to the aircraft plane of symmetry. For example, the vertical stabilizer of a conventional airplane usually has a dihedral angle of 90° . For the rarely encountered case of an aircraft that does not have a plane of symmetry, the dihedral angle must be defined relative to some other defined reference plane.

Typically, for an airplane with fixed wings, constant sweep is not a solid-body rotation of each semispan. For a wing with no sweep, the normal to each local airfoil section is aligned with the wing quarter-chord line, and the quarter-chord line is straight. As constant positive sweep is added to a wing, the quarter-chord

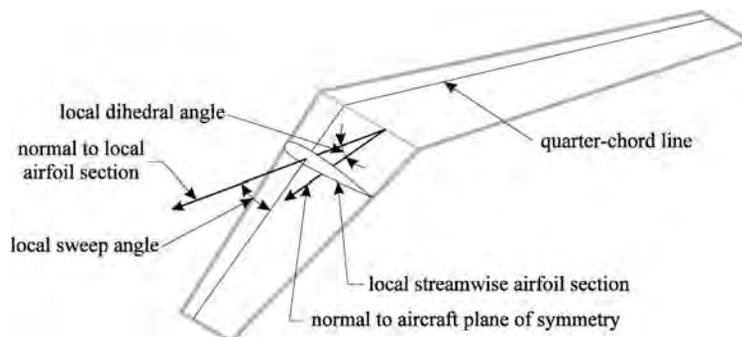

Fig. 44 Local sweep and dihedral angles.

line for each semispan is rotated back, moving the wingtips aft of the root. However, for constant planform area and aspect ratio, the local airfoil sections are not rotated with the quarter-chord line. Each airfoil section is translated straight back to the new quarter-chord location and the length of the quarter-chord line is increased, so that the distance from wingtip to wingtip does not change. A local sweep angle can be defined as the angle between the normal to the streamwise airfoil section and the quarter-chord line. Thus, the sweep angle for a wing with no dihedral is measured relative to a horizontal line, while the sweep angle for a vertical stabilizer with 90° dihedral is measured relative to a vertical line.

Supersonic airplanes are sometimes designed with wings that can be rotated to vary the sweep angle in flight. This type of sweep variation is solid-body rotation. However, varying sweep in this manner changes not only the sweep but the shape of the streamwise airfoil section, the wingspan, and usually even the planform area of the wing.

Most airplanes are designed with some sweep and/or dihedral in the wing and/or the horizontal and vertical stabilizers. While the reasons for using sweep and dihedral will be left for a later discussion, it is clear from looking at the myriad of airplanes parked at any airport that a means for analyzing the effects of sweep and dihedral is needed. In addition, the downwash created by one lifting surface, such as the wing, has a dramatic effect on the performance of other lifting surfaces, such as the horizontal stabilizer. Thus, a means for predicting the effects of such interactions is also needed.

To predict the aerodynamic forces and moments acting on a complete airplane in flight, 3D panel codes and CFD analysis are often used. However, these methods are very computationally intensive and may not

be suitable for use in all phases of aircraft design and analysis. An alternative method that provides excellent accuracy at very low computational cost is the numerical lifting-line method, which is presented here.

7.1 Numerical Lifting-Line Method

In developing Prandtl's lifting-line equation, a single lifting surface with no sweep or dihedral was assumed. The lifting line was confined to the z axis and the trailing vortex sheet was assumed to be in the $x-z$ plane (see Fig. 23). This significantly simplifies the expressions for downwash and induced angle of attack. In order to use lifting-line theory to study the effects of sweep, dihedral, and/or the interactions between lifting surfaces, the theory must be generalized to allow for an arbitrary position and orientation of both the lifting line and the trailing vortex sheet. Here we shall examine a numerical lifting-line method that can be used to obtain a potential flow solution for the forces and moments acting on a system of lifting surfaces, each with arbitrary position and orientation. For a detailed development of this numerical method and a comparison with panel codes, CFD, and experimental data, see Phillips and Snyder.¹⁴

A first-order numerical lifting-line method can be obtained by synthesizing a system of lifting surfaces using a composite of horseshoe-shaped vortices. The continuous distribution of bound vorticity over the surface of each lifting surface, as well as the continuous distribution of free vorticity in the trailing vortex sheets, is approximated by a finite number of discrete horseshoe vortices, as shown in Fig. 45.

The bound portion of each horseshoe vortex is placed coincident with the wing quarter-chord line and is, thus, aligned with the local sweep and dihedral. The trailing portion of each horseshoe vortex is aligned with the trailing vortex sheet. In Fig. 45, a small gap

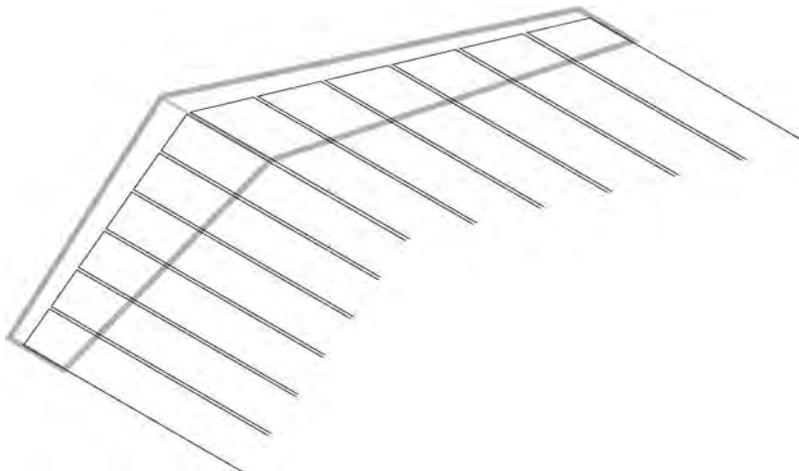

Fig. 45 Horseshoe-shaped vortices distributed along the lifting line of a finite wing with sweep and dihedral.

is shown between the left-hand trailing segment of one horseshoe vortex and the right-hand trailing segment of the next. This is for display purposes only. In reality, the left-hand corner of one horseshoe and the right-hand corner of the next are both placed on the same nodal point. Thus, except at the wingtips, each trailing vortex segment is coincident with another trailing segment from the adjacent vortex. If two adjacent vortices have exactly the same strength, then the two coincident trailing segments exactly cancel, since one has clockwise rotation and the other has counterclockwise rotation. The net vorticity that is shed from the wing at any internal node is simply the difference in strength of the two adjacent vortices that share the node.

Each horseshoe vortex is composed of three straight segments, a finite bound segment and two semi-infinite trailing segments. We can calculate the velocity induced at an arbitrary point in space (x, y, z) by a general horseshoe vortex. As shown in Fig. 46, a general horseshoe vortex is completely defined by two nodal points (x_1, y_1, z_1) and (x_2, y_2, z_2) , a trailing unit vector \mathbf{u}_∞ , and a vortex strength Γ . The horseshoe vortex starts at the fluid boundary, an infinite distance downstream. The inbound trailing vortex segment is directed along the vector $-\mathbf{u}_\infty$ to node 1 at (x_1, y_1, z_1) . The bound vortex segment is directed along the wing quarter-chord line from node 1 to node 2 at (x_2, y_2, z_2) . The outbound trailing vortex segment is directed along the vector \mathbf{u}_∞ from node 2 to the fluid boundary, an infinite distance back downstream. The velocity induced by the entire horseshoe vortex is simply the vector sum of the velocities induced by each of the three linear segments that make up the horseshoe.

The vorticity vector is assumed to point in the direction of \mathbf{u}_∞ as determined by the right-hand rule. However, the inbound trailing vortex segment can be treated like an outbound segment with negative circulation. Thus, the *velocity vector induced at an arbitrary*

point in space by a complete horseshoe vortex is

$$\mathbf{V} = \frac{\Gamma}{4\pi} \left[\frac{\mathbf{u}_\infty \times \mathbf{r}_2}{r_2(r_2 - \mathbf{u}_\infty \cdot \mathbf{r}_2)} + \frac{(r_1 + r_2)(\mathbf{r}_1 \times \mathbf{r}_2)}{r_1 r_2 (r_1 r_2 + \mathbf{r}_1 \cdot \mathbf{r}_2)} - \frac{\mathbf{u}_\infty \times \mathbf{r}_1}{r_1(r_1 - \mathbf{u}_\infty \cdot \mathbf{r}_1)} \right] \quad (165)$$

where \mathbf{u}_∞ is the unit vector in the direction of the trailing vortex sheet, \mathbf{r}_1 is the spatial vector from (x_1, y_1, z_1) to (x, y, z) , and \mathbf{r}_2 is the spatial vector from (x_2, y_2, z_2) to (x, y, z) ,

$$\mathbf{r}_1 = (x - x_1)\mathbf{i}_x + (y - y_1)\mathbf{i}_y + (z - z_1)\mathbf{i}_z \quad (166)$$

$$\mathbf{r}_2 = (x - x_2)\mathbf{i}_x + (y - y_2)\mathbf{i}_y + (z - z_2)\mathbf{i}_z \quad (167)$$

In obtaining the classical lifting-line solution for a single wing without sweep or dihedral, the trailing vortex sheet was assumed to be aligned with the wing chord. This was done to facilitate obtaining an analytical solution. In obtaining a numerical solution, there is little advantage in aligning the trailing vortex sheet with a vehicle axis such as the chord line. More correctly, the trailing vortex sheet should be aligned with the free stream. This is easily done in the numerical solution by setting \mathbf{u}_∞ equal to the unit vector in the direction of the free stream. When using this method to predict the forces and moments on a single lifting surface, there is very little difference between the results obtained from slightly different orientations of the trailing vortex sheet.

When a system of lifting surfaces is synthesized using N of these horseshoe vortices, in a manner similar to that shown in Fig. 45, Eq. (165) can be used to determine the resultant velocity induced at any point in space if the vortex strength of each horseshoe vortex is known. However, these strengths are not known a priori. To compute the strengths of the N vortices, we must have a system of N equations relating these

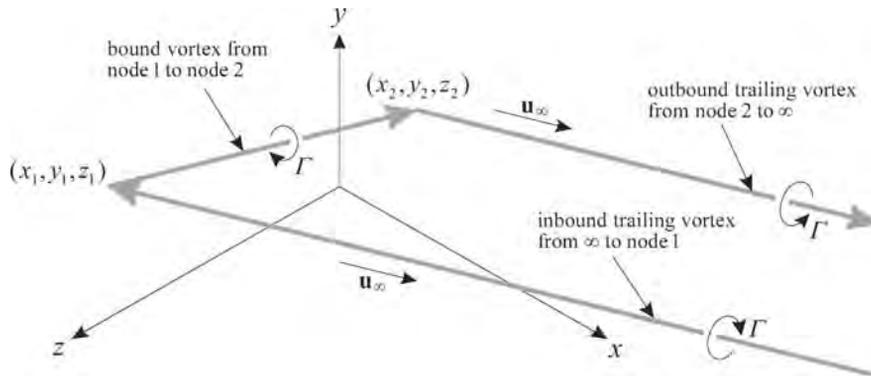

Fig. 46 General horseshoe vortex.

N strengths to some known properties of the wing. For this we turn to the 3D vortex lifting law given in Eq. (82).

If flow over a finite wing is synthesized from a uniform flow combined with horseshoe vortices placed along the wing quarter chord, from Eq. (165), the local velocity induced at a control point placed anywhere along the bound segment of horseshoe vortex i is

$$\mathbf{V}_i = \mathbf{V}_\infty + \sum_{j=1}^N \frac{\Gamma_j \mathbf{v}_{ji}}{\bar{c}_j} \quad (168)$$

where \mathbf{V}_∞ is the velocity of the uniform flow Γ_j is the strength of horseshoe vortex j , \mathbf{v}_{ji} is a dimensionless velocity that would be induced at control point i by horseshoe vortex j , having a unit strength

$$\mathbf{v}_{ji} = \begin{cases} \frac{\bar{c}_j}{4\pi} \left[\frac{\mathbf{u}_\infty \times \mathbf{r}_{j2i}}{r_{j2i}(r_{j2i} - \mathbf{u}_\infty \cdot \mathbf{r}_{j2i})} + \frac{(r_{j1i} + r_{j2i})(\mathbf{r}_{j1i} \times \mathbf{r}_{j2i})}{r_{j1i}r_{j2i}(r_{j1i}r_{j2i} + \mathbf{r}_{j1i} \cdot \mathbf{r}_{j2i})} \right] & j \neq i \\ - \frac{\mathbf{u}_\infty \times \mathbf{r}_{j1i}}{r_{j1i}(r_{j1i} - \mathbf{u}_\infty \cdot \mathbf{r}_{j1i})} & \\ \frac{\bar{c}_j}{4\pi} \left[\frac{\mathbf{u}_\infty \times \mathbf{r}_{j2i}}{r_{j2i}(r_{j2i} - \mathbf{u}_\infty \cdot \mathbf{r}_{j2i})} - \frac{\mathbf{u}_\infty \times \mathbf{r}_{j1i}}{r_{j1i}(r_{j1i} - \mathbf{u}_\infty \cdot \mathbf{r}_{j1i})} \right] & j = i \end{cases} \quad (169)$$

where \mathbf{r}_{j1i} is the spatial vector from node 1 of horseshoe vortex j to the control point of horseshoe vortex i , \mathbf{r}_{j2i} is the spatial vector from node 2 of horseshoe vortex j to the control point of horseshoe vortex i , and \mathbf{u}_∞ is the unit vector in the direction of the free

stream. At this point, \bar{c}_j could be any characteristic length associated with the wing section aligned with horseshoe vortex j . This characteristic length is simply used to nondimensionalize Eq. (169) and has no effect on the induced velocity. An appropriate choice for \bar{c}_j will be addressed at a later point. The bound vortex segment is excluded from Eq. (169), when $j = i$, because a straight vortex segment induces no downwash along its own length. However, the second term in Eq. (169), for $j \neq i$, is indeterminate when used with $j = i$ because $r_{i1i}r_{i2i} + \mathbf{r}_{i1i} \cdot \mathbf{r}_{i2i} = 0$.

From Eqs. (82) and (168), the aerodynamic force acting on a spanwise differential section of the wing located at control point i is given by

$$d\mathbf{F}_i = \rho \Gamma_i \left(\mathbf{V}_\infty + \sum_{j=1}^N \frac{\Gamma_j}{\bar{c}_j} \mathbf{v}_{ji} \right) \times d\mathbf{l}_i \quad (170)$$

Allowing for the possibility of flap deflection the local section lift coefficient for the airfoil section located at control point i is a function of local angle of attack and local flap deflection

$$\tilde{C}_{Li} = \tilde{C}_{Li}(\alpha_i, \delta_i) \quad (171)$$

where \tilde{C}_{Li} , α_i , and δ_i are, respectively, the local airfoil section lift coefficient, the local angle of attack, and the local flap deflection all evaluated for the airfoil section aligned with control point i . Define \mathbf{u}_{ni} and \mathbf{u}_{ai} to be the local unit normal and axial vectors for the airfoil section located at control point i , as shown in Fig. 47, the local angle of attack at control point i can be written as

$$\alpha_i = \tan^{-1} \left(\frac{\mathbf{V}_i \cdot \mathbf{u}_{ni}}{\mathbf{V}_i \cdot \mathbf{u}_{ai}} \right) \quad (172)$$

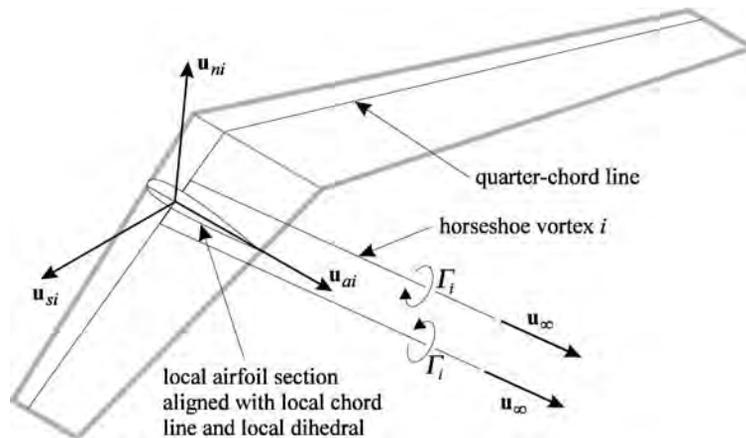

Fig. 47 Unit vectors describing the orientation of the local airfoil section.

If the relation implied by Eq. (171) is known at each section of the wing, the magnitude of the aerodynamic force acting on a spanwise differential section of the wing located at control point i can be written as

$$|d\mathbf{F}_i| = \frac{1}{2}\rho V_\infty^2 \tilde{C}_{Li}(\alpha_i, \delta_i) dS_i \quad (173)$$

where dS_i is a spanwise differential planform area element located at control point i . Setting the magnitude of the force obtained from Eq. (170) equal to that obtained from Eq. (173), applying Eqs. (168)–(172), and rearranging, we can write

$$2 \left| \left(\mathbf{u}_\infty + \sum_{j=1}^N \mathbf{v}_{ji} G_j \right) \times \boldsymbol{\zeta}_i \right| G_i - \tilde{C}_{Li}(\alpha_i, \delta_i) = 0 \quad (174)$$

$$\mathbf{u}_\infty \equiv \frac{V_\infty}{V_\infty} \quad \boldsymbol{\zeta}_i \equiv \bar{c}_i \frac{d\mathbf{l}_i}{dS_i} \quad G_i \equiv \frac{\Gamma_i}{\bar{c}_i V_\infty}$$

where the local section angle of attack is determined from

$$\alpha_i = \tan^{-1} \left[\frac{(\mathbf{u}_\infty + \sum_{j=1}^N \mathbf{v}_{ji} G_j) \cdot \mathbf{u}_{ni}}{(\mathbf{u}_\infty + \sum_{j=1}^N \mathbf{v}_{ji} G_j) \cdot \mathbf{u}_{ai}} \right] \quad (175)$$

Equation (174) can be written for N different control points, one associated with each of the N horseshoe vortices used to synthesize the lifting surface or system of lifting surfaces. This provides a system of N nonlinear equations relating the N unknown dimensionless vortex strengths, G_i , to known properties of the wing. At angles of attack below stall, this system of nonlinear equations surrenders quickly to Newton's method.

To apply Newton's method, the system of equations is written in the vector form

$$\mathbf{f}(\mathbf{G}) = \mathbf{R} \quad (176)$$

where

$$f_i(\mathbf{G}) = 2 \left| \left(\mathbf{u}_\infty + \sum_{j=1}^N \mathbf{v}_{ji} G_j \right) \times \boldsymbol{\zeta}_i \right| G_i - \tilde{C}_{Li}(\alpha_i, \delta_i) \quad (177)$$

and \mathbf{R} is a vector of residuals. We wish to find the vector of dimensionless vortex strengths, \mathbf{G} , that will make all components of the residual vector, \mathbf{R} , go to zero. Thus, we want the change in the residual vector to be $-\mathbf{R}$. We start with some initial estimate for the \mathbf{G} vector and iteratively refine this estimate by applying the Newton corrector equation

$$[\mathbf{J}] \Delta \mathbf{G} = -\mathbf{R} \quad (178)$$

where $[\mathbf{J}]$ is an $N \times N$ Jacobian matrix of partial derivatives, which is obtained by differentiating Eq. (177),

$$J_{ij} = \frac{\partial f_i}{\partial G_j} = \begin{cases} \frac{2\mathbf{w}_i \cdot (\mathbf{v}_{ji} \times \boldsymbol{\zeta}_i)}{|\mathbf{w}_i|} G_i - \frac{\partial \tilde{C}_{Li}}{\partial \alpha_i} \frac{v_{ai}(\mathbf{v}_{ji} \cdot \mathbf{u}_{ni}) - v_{ni}(\mathbf{v}_{ji} \cdot \mathbf{u}_{ai})}{v_{ai}^2 + v_{ni}^2} & j \neq i \\ 2|\mathbf{w}_i| + \frac{2\mathbf{w}_i \cdot (\mathbf{v}_{ji} \times \boldsymbol{\zeta}_i)}{|\mathbf{w}_i|} G_i - \frac{\partial \tilde{C}_{Li}}{\partial \alpha_i} \frac{v_{ai}(\mathbf{v}_{ji} \cdot \mathbf{u}_{ni}) - v_{ni}(\mathbf{v}_{ji} \cdot \mathbf{u}_{ai})}{v_{ai}^2 + v_{ni}^2} & j = i \end{cases} \quad (179)$$

$$\mathbf{w}_i \equiv \mathbf{v}_i \times \boldsymbol{\zeta}_i \quad v_{ni} \equiv \mathbf{v}_i \cdot \mathbf{u}_{ni} \quad v_{ai} \equiv \mathbf{v}_i \cdot \mathbf{u}_{ai}$$

$$\mathbf{v}_i \equiv \mathbf{u}_\infty + \sum_{j=1}^N \mathbf{v}_{ji} G_j$$

Using Eq. (179) in Eq. (178), we compute the correction vector $\Delta \mathbf{G}$. This correction vector is used to obtain an improved estimate for the dimensionless vortex strength vector, \mathbf{G} , according to the relation

$$\mathbf{G} = \mathbf{G} + \Psi \Delta \mathbf{G} \quad (180)$$

where Ψ is a relaxation factor. The process is repeated until the magnitude of the largest residual is less than some convergence criteria. For angles of attack below stall, this method converges very rapidly using almost any initial estimate for the \mathbf{G} vector with a relaxation factor of unity. At angles of attack beyond stall, the method must be highly underrelaxed and is very sensitive to the initial estimate for the \mathbf{G} vector.

For the fastest convergence of Newton's method, we require an accurate initial estimate for the dimensionless vortex strength vector. For this purpose, a linearized version of Eq. (174) is useful. Furthermore, for wings of high aspect ratio at small angles of attack, the nonlinear terms in Eq. (174) are quite small and the linearized system can be used directly to give an accurate prediction of aerodynamic performance.

Applying the small-angle approximation to Eq. (174) and neglecting all other second-order terms, we obtain

$$2|\mathbf{u}_\infty \times \boldsymbol{\zeta}_i| G_i - \tilde{C}_{Li,\alpha} \sum_{j=1}^N \mathbf{v}_{ji} \cdot \mathbf{u}_{ni} G_j = \tilde{C}_{Li,\alpha} (\mathbf{u}_\infty \cdot \mathbf{u}_{ni} - \alpha L_{0i} + \varepsilon_i \delta_i) \quad (181)$$

The linearized system of equations given by Eq. (181) gives good results, at small angles of attack, for wings

of reasonably high aspect ratio and little sweep. For larger angles of attack or highly swept wings, the nonlinear system given by Eq. (174) should be used. However, at angles of attack below stall, Eq. (181) still provides a reasonable initial estimate for the dimensionless vortex strength vector, to be used with Newton's method for obtaining a solution to the nonlinear system.

Once the vortex strengths are determined from either Eq. (174) or Eq. (181), the total aerodynamic force vector can be determined from Eq. (170). If the lifting surface or surfaces are synthesized from a large number of horseshoe vortices, each covering a small spanwise increment of one lifting surface, we can approximate the aerodynamic force as being constant over each spanwise increment. Then, from Eq. (170), the total aerodynamic force is given by

$$\mathbf{F}_a = \rho \sum_{i=1}^N \left(\Gamma_i \mathbf{V}_\infty + \sum_{j=1}^N \frac{\Gamma_i \Gamma_j}{\bar{c}_j} \mathbf{v}_{ji} \right) \times \delta \mathbf{l}_i \quad (182)$$

where $\delta \mathbf{l}$ is the spatial vector along the bound segment of horseshoe vortex i from node 1 to node 2. Nondimensionalizing this result, the *total nondimensional aerodynamic force vector* is

$$\frac{\mathbf{F}_a}{\frac{1}{2} \rho V_\infty^2 S_r} = 2 \sum_{i=1}^N \left(G_i \mathbf{u}_\infty + \sum_{j=1}^N G_i G_j \mathbf{v}_{ji} \right) \times \zeta_i \frac{\delta S_i}{S_r} \quad (183)$$

where S_r is the global reference area and δS_i is the planform area of the spanwise increment of the lifting surface covered by horseshoe vortex i . If we assume a linear variation in chord length over each spanwise increment, we have

$$\delta S_i \equiv \int_{s=s_1}^{s_2} c \, ds = \frac{c_{i1} + c_{i2}}{2} (s_{i2} - s_{i1}) \quad (184)$$

where c is the local chord length and s is the spanwise coordinate.

The aerodynamic moment generated about the center of gravity is

$$\mathbf{M}_a = \rho \sum_{i=1}^N \left\{ \mathbf{r}_i \times \left[\left(\Gamma_i \mathbf{V}_\infty + \sum_{j=1}^N \frac{\Gamma_i \Gamma_j}{\bar{c}_j} \mathbf{v}_{ji} \right) \times \delta \mathbf{l}_i \right] + \delta \mathbf{M}_i \right\} \quad (185)$$

where \mathbf{r}_i is the spatial vector from the center of gravity to control point i and $\delta \mathbf{M}_i$ is the quarter-chord moment generated by the spanwise increment of the wing covered by horseshoe vortex i . If we

assume a constant section moment coefficient over each spanwise increment, then

$$\delta \mathbf{M}_i \cong -\frac{1}{2} \rho V_\infty^2 \tilde{C}_{mi} \int_{s=s_1}^{s_2} c^2 \, ds \, \mathbf{u}_{si} \quad (186)$$

where \tilde{C}_{mi} is the local section moment coefficient and \mathbf{u}_{si} is the local unit vector in the spanwise direction as shown in Fig. 47 and define by

$$\mathbf{u}_{si} = \mathbf{u}_{at} \times \mathbf{u}_{ni} \quad (187)$$

Using Eq. (186) in Eq. (185) and nondimensionalizing gives

$$\begin{aligned} \frac{\mathbf{M}_a}{\frac{1}{2} \rho V_\infty^2 S_r l_r} &= \sum_{i=1}^N \left\{ 2 \mathbf{r}_i \times \left[\left(G_i \mathbf{u}_\infty + \sum_{j=1}^N G_i G_j \mathbf{v}_{ji} \right) \times \zeta_i \right] \right. \\ &\quad \left. - \frac{\tilde{C}_{mi}}{\delta S_i} \int_{s=s_1}^{s_2} c^2 \, ds \, \mathbf{u}_{si} \right\} \frac{\delta S_i}{S_r l_r} \quad (188) \end{aligned}$$

where l_r is the global reference length.

To this point, the local characteristic length \bar{c}_i has not been defined. It could be any characteristic length associated with the spanwise increment of the wing covered by horseshoe vortex i . From Eq. (88), the most natural choice for this local characteristic length is the integral of the chord length squared, with respect to the spanwise coordinate, divided by the incremental area. For a linear variation in chord length over each spanwise increment, this gives

$$\bar{c}_i = \frac{1}{\delta S_i} \int_{s=s_1}^{s_2} c^2 \, ds = \frac{2}{3} \frac{c_{i1}^2 + c_{i1} c_{i2} + c_{i2}^2}{c_{i1} + c_{i2}} \quad (189)$$

With this definition the *dimensionless aerodynamic moment vector* is

$$\begin{aligned} \frac{\mathbf{M}_a}{\frac{1}{2} \rho V_\infty^2 S_r l_r} &= \sum_{i=1}^N \left\{ 2 \mathbf{r}_i \times \left[\left(G_i \mathbf{u}_\infty + \sum_{j=1}^N G_i G_j \mathbf{v}_{ji} \right) \right. \right. \\ &\quad \left. \left. \times \zeta_i \right] - \tilde{C}_{mi} \bar{c}_i \mathbf{u}_{si} \right\} \frac{\delta S_i}{S_r l_r} \quad (190) \end{aligned}$$

Once the dimensionless vortex strengths, G_i , are known, Eqs. (183) and (190) are used to evaluate the components of the aerodynamic force and moment.

Each lifting surface must, of course, be divided into spanwise elements, in a manner similar to that

shown symbolically in Fig. 45. In this figure the wing is divided into elements of equal spanwise increment. However, this is not the most efficient way in which to grid a wing. Since the spanwise derivative of shed vorticity is greater in the region near the wingtips, for best computational efficiency, the nodal points should be clustered more tightly in this region. Conventional cosine clustering has been found to be quite efficient for this purpose. For straight wings, clustering is only needed near the wingtips and the cosine distribution can be applied across the entire span of the wing. However, for wings with sweep or dihedral, there is a step change in the slope of the quarter-chord line at the root of the wing. This step change produces an increase in the spanwise variation of downwash in the region near the root. Thus, in general, it is recommended that cosine clustering be applied independently over each semispan of each lifting surface. This clusters the nodes more tightly at both the tip and root. This clustering is based on the change of variables,

$$\frac{s}{b} = \frac{1 - \cos(\theta)}{4} \quad (191)$$

where s is the spanwise coordinate and b is twice the semispan. Over each semispan, θ varies from zero to π as s varies from zero to $b/2$. Distributing the nodes uniformly in θ will provide the desired clustering in s . If the total number of horseshoe elements desired on each semispan is n , the spanwise nodal coordinates are computed from

$$\frac{s_i}{b} = \frac{1}{4} \left[1 - \cos\left(\frac{i\pi}{n}\right) \right] \quad 0 \leq i \leq n \quad (192)$$

where the bound segment of horseshoe vortex i extends from node i to node $i - 1$ on any left semispan and from node $i - 1$ to node i on any right semispan. Using this nodal distribution with about 40 horseshoe elements per semispan gives the best compromise between speed and accuracy. Figure 48 shows a system of lifting surfaces overlaid with a grid of this type using 20 elements per semispan.

For maximum accuracy and computational efficiency, some attention must also be paid to the location of control points. At first thought, it would seem

most reasonable to place control points on the bound segment of each vortex, midway between the two trailing legs. However, it has been found that this does not give the best accuracy. A significant improvement in accuracy, for a given number of elements, can be achieved by placing the control points midway in θ rather than midway in s . Thus, the spanwise control point coordinates should be computed from

$$\frac{s_i}{b} = \frac{1}{4} \left[1 - \cos\left(\frac{i\pi}{n} - \frac{\pi}{2n}\right) \right] \quad 1 \leq i \leq n \quad (193)$$

This distribution places control points very near the spatial midpoint of each bound vortex segment over most of the wing. However, near the root and the tip, these control points are significantly offset from the spatial midpoint.

This numerical lifting-line method can be used to predict the aerodynamic forces and moments acting on a system of lifting surfaces with arbitrary position and orientation. Each lifting surface is synthesized by distributing horseshoe vortices along the quarter chord in the manner shown in Fig. 48. Because all of the horseshoe vortices used to synthesize the complete system of lifting surfaces are combined and forced to satisfy either Eq. (174) or Eq. (181) as a single system of coupled equations, all of the interactions between lifting surfaces are accounted for directly.

Unlike the closed-form solution to Prandtl's classical lifting-line theory, the numerical lifting-line method can be applied to wings with sweep and/or dihedral. To examine how well the numerical lifting-line method predicts the effects of sweep, Phillips and Snyder¹⁴ compared results obtained from this method, a numerical panel method, and an inviscid CFD solution. These results were also compared with experimental data for two different wings. Some of the results from this comparison are shown in Fig. 49. The solid line and filled symbols correspond to a straight wing of aspect ratio 6.57, with experimental data obtained from McAlister and Takahashi.¹⁵ The dashed line and open symbols are for a 45° swept wing of aspect ratio 5.0, having experimental data reported by Weber and Brebner.¹⁶ Both wings have symmetric airfoil sections and constant chord throughout the span, with no geometric twist. The straight wing has a thickness of 15% and

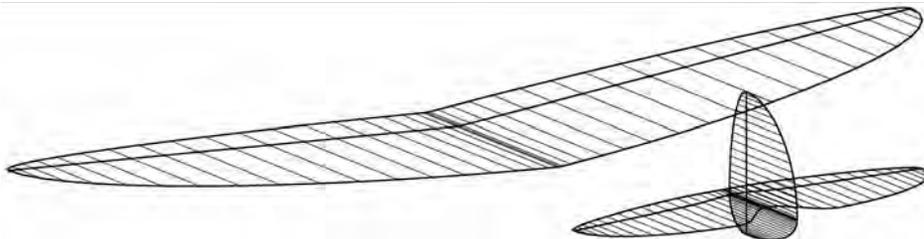

Fig. 48 Lifting-line grid with cosine clustering and 20 elements per semispan.

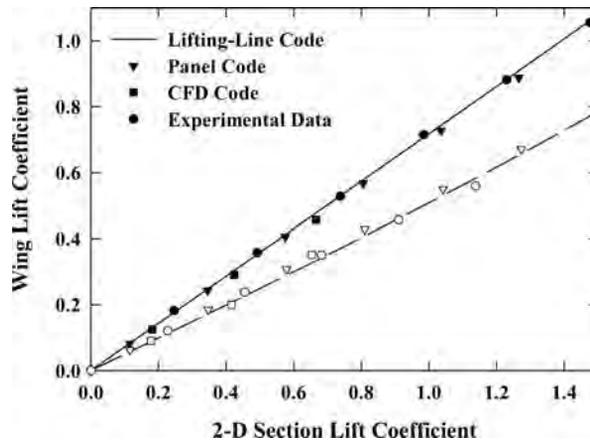

Fig. 49 Comparison between the lift coefficient predicted by the numerical lifting-line method, a numerical panel method, and an inviscid CFD solution with data obtained from wind tunnel tests for an unswept wing and a wing with 45° of sweep.

the swept wing has a thickness of 12%. From the results shown in Fig. 49, we see that the lift coefficient predicted by all four methods is in good agreement with experimental observations for both wings. However, the computational time required to obtain a solution using the numerical panel method was about 2.5×10^4 times that required for the lifting-line method, and the inviscid CFD solutions required approximately 2.7×10^6 times as long as the lift-line solutions. The accuracy of the numerical lifting-line method for predicting dihedral effects was also investigated by Phillips and Snyder,¹⁴ and the results obtained were similar to those shown in Fig. 49.

The insight of Ludwig Prandtl (1875–1953) was nothing short of astonishing. This was never more dramatically demonstrated than in the development of his classical lifting-line theory, during the period 1911–1918. The utility of this simple and elegant theory is so great that it is still widely used today. Furthermore, with a few minor alterations and the use of a modern computer, the model proposed by Prandtl can be used to predict the inviscid forces and moments acting on lifting surfaces of aspect ratio greater than about 4 with an accuracy as good as that obtained from modern panel codes or CFD, but at a small fraction of the computational cost.

Like panel methods, lifting-line theory provides only a potential flow solution. Thus, the forces and moments computed from this method do not include viscous effects. In addition to this restriction, which also applies to panel methods, lifting-line theory imposes an additional restriction, which does not apply to panel methods. For lifting surfaces with low aspect ratio, Prandtl’s hypothesis breaks down and the usual relationship between local section lift and local section angle of attack no longer applies. It has long been established that lifting-line theory gives good agreement with experimental data for lifting surfaces of aspect ratio greater than about 4. For lifting surfaces

of lower aspect ratio, panel methods or CFD solutions should be used.

The numerical lifting-line method contains no inherent requirement for a linear relationship between section lift and section angle of attack. Thus, the method can be applied, with caution, to account approximately for the effects of stall. The lifting-line method requires a known relationship for the section lift coefficient as a function of section angle of attack. Since such relationships are often obtained experimentally beyond stall, the numerical lifting-line method predicts stall by using a semiempirical correction to an otherwise potential flow solution. For this reason, the method should be used with extreme caution for angles of attack beyond stall.

The effects of viscous parasitic drag can be approximately accounted for in the present numerical lifting-line method through the vector addition of a parasitic drag component to the contribution from each segment in Eqs. (183) and (190). The parasitic segment contribution to the net aerodynamic force vector is

$$(\delta \mathbf{F}_i)_{\text{parasite}} \cong \frac{1}{2} \rho V_\infty^2 \tilde{C}_{D_i}(\alpha_i) \delta S_i \mathbf{u}_i$$

where $\tilde{C}_{D_i}(\alpha_i)$ represents a relation for the local section drag coefficient as a function of angle of attack and \mathbf{u}_i is the unit vector in the direction of the local velocity vector,

$$\mathbf{u}_i \equiv \frac{\mathbf{V}_i}{V_i}$$

A simple polynomial fit to experimental airfoil section data could be used to describe the relation for section drag coefficient as a function of angle of attack. Similarly, the parasitic segment contribution to the net aerodynamic moment vector is

$$(\delta \mathbf{M}_i)_{\text{parasite}} \cong \frac{1}{2} \rho V_\infty^2 \tilde{C}_{D_i}(\alpha_i) \delta S_i (\mathbf{r}_i \times \mathbf{u}_i)$$

Thus, the *dimensionless parasitic contributions to the force and moment vectors* are

$$\left[\frac{\mathbf{F}_a}{\frac{1}{2}\rho V_\infty^2 S_r} \right]_{\text{parasite}} = \sum_{i=1}^N \tilde{C}_{D_i}(\alpha_i) \frac{\delta S_i}{S_r} \mathbf{u}_i \quad (194)$$

$$\left[\frac{\mathbf{M}_a}{\frac{1}{2}\rho V_\infty^2 S_r l_r} \right]_{\text{parasite}} = \sum_{i=1}^N \tilde{C}_{D_i}(\alpha_i) \frac{\delta S_i}{S_r l_r} (\mathbf{r}_i \times \mathbf{u}_i) \quad (195)$$

In the study of aeronautics, we find it necessary to know how the aerodynamic force and moment components for a complete aircraft vary over a broad range of operating conditions. Ultimately, this information is commonly gathered from wind tunnel testing. However, such testing is very time consuming and expensive. Another alternative that is often used to obtain the required information is CFD computations. Although modern computers are very fast and the CFD algorithms available today are quite accurate, the volume of data needed to define the required aerodynamic parameters is large. Even with the fastest available computers, gathering the desired information from CFD computations requires considerable time. Thus, for preliminary design, it is important to have a more computationally efficient means for the estimation of aerodynamic force and moment components acting on a complete aircraft. When parasitic drag is included, the numerical lifting-line method described in this section provides such an analytical tool. This method reduces computation time by more than four orders of magnitude over that required for inviscid panel codes and by more than six orders of magnitude compared with CFD computations.

8 WING STALL AND MAXIMUM LIFT COEFFICIENT

Many aspects of aircraft design and performance analysis depend on the maximum lift coefficient that can be attained on a finite wing prior to stall. Because in general the local section lift coefficient is not constant along the span of a finite wing, it is of interest to know the value of the maximum section lift coefficient and the position along the span at which this maximum occurs. Such knowledge allows us to predict the onset of wing stall from known airfoil section properties, including the maximum airfoil section lift coefficient.

From Eq. (84) combined with the vortex lifting law, lifting-line theory predicts that the spanwise variation in local section lift for an unswept wing is given by

$$\tilde{L}(\theta) = \rho V_\infty \Gamma(\theta) = 2b\rho V_\infty^2 \sum_{n=1}^{\infty} A_n \sin(n\theta)$$

$$\theta = \cos^{-1} \left(\frac{-2z}{b} \right) \quad (196)$$

and the spanwise variation in local section lift coefficient is

$$\tilde{C}_L(\theta) \equiv \frac{\tilde{L}(\theta)}{\frac{1}{2}\rho V_\infty^2 c(\theta)} = \frac{4b}{c(\theta)} \sum_{n=1}^{\infty} A_n \sin(n\theta) \quad (197)$$

The Fourier coefficients, A_n , in Eq. (197) can be written conveniently using the change of variables given by Eq. (100). Furthermore, solving Eq. (105) for the root aerodynamic angle of attack and applying Eqs. (107) and (109) gives

$$(\alpha - \alpha_{L0})_{\text{root}} = \frac{b_1}{a_1} \Omega + \frac{C_L}{\pi R_A a_1} \quad (198)$$

Using Eq. (198) in Eq. (100) yields

$$A_n = \left(\frac{b_1 a_n}{a_1} - b_n \right) \Omega + \frac{a_n}{\pi R_A a_1} C_L \quad (199)$$

Using this change of variables, Eq. (197) can be written as

$$\tilde{C}_L(\theta) = \Omega \sum_{n=1}^{\infty} 4 \left(\frac{b_1 a_n}{a_1} - b_n \right) \frac{\sin(n\theta)}{c(\theta)/b}$$

$$+ C_L \sum_{n=1}^{\infty} \frac{4a_n}{\pi R_A a_1} \frac{\sin(n\theta)}{c(\theta)/b} \quad (200)$$

We see from Eq. (200) that the spanwise variation in local section lift coefficient can be divided conveniently into two components. The first term on the right-hand side of Eq. (200) is called the *basic section lift coefficient* and the second term is called the *additional section lift coefficient*. The basic section lift coefficient is independent of C_L and directly proportional to the total amount of wing twist, Ω . The additional section lift coefficient at any section of the wing is independent of wing twist and directly proportional to the net wing lift coefficient, C_L .

As can be seen from Eq. (200), the *basic section lift coefficient* is the spanwise variation in local section lift coefficient that occurs when the total net lift developed by the wing is zero. Examination of the first term on the right-hand side of Eq. (200) reveals that the basic section lift coefficient depends on all of the Fourier coefficients a_n and b_n . From Eq. (101) we see the Fourier coefficients a_n depend only on the wing planform. Equation (102) shows that the Fourier coefficient b_n depend on both the wing planform and the dimensionless twist distribution function, $\omega(\theta)$. Thus, the *spanwise variation* in the basic section lift coefficient depends on wing planform and wing twist but is independent of the wing angle of attack.

Examination of the second term on the right-hand side of Eq. (200) discloses that the additional section

lift coefficient depends only on the wing planform and the Fourier coefficients a_n . From Eq. (101) we have seen that the coefficients a_n do not depend on wing twist. Thus, Eq. (200) exposes the important fact that the *additional* section lift coefficient is independent of wing twist. Because the basic section lift coefficient is zero for an untwisted wing, we see that the additional section lift coefficient is equivalent to the spanwise variation in local section lift coefficient that would be developed on an untwisted wing of the same planform operating at the same wing lift coefficient.

Figure 50 shows how the net section lift coefficient and its two components obtained from Eq. (200) vary

along the span of a linearly tapered wing of aspect ratio 8.0 and taper ratio 0.5. This figure shows the spanwise variation in section lift coefficient for several values of total linear twist with the net wing lift coefficient held constant at 1.0. Similar results are shown in Fig. 51 for three different values of the net wing lift coefficient with the total linear twist held constant at 6° .

Notice that the spanwise coordinates of the maximums in both the basic and additional section lift coefficient do not change with either the amount of wing twist or the net wing lift coefficient. Because the additional section lift coefficient is independent of wing twist, the spanwise position of the aerodynamic

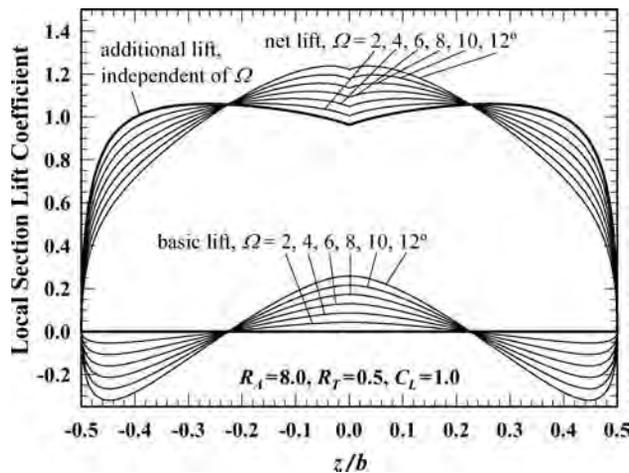

Fig. 50 Spanwise variation in local section lift coefficient as a function of the total amount of linear twist with the net wing lift coefficient held constant at $C_L = 1.0$.

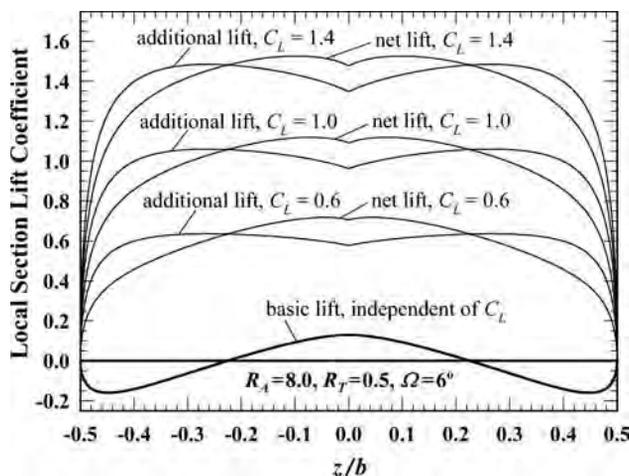

Fig. 51 Spanwise variation in local section lift coefficient as a function of the net wing lift coefficient with the total amount of linear twist held constant at $\Omega = 6^\circ$.

center of each wing semispan is *not affected* by wing twist. However, the maximum in the net section lift coefficient moves inboard as the total amount of twist is increased, and for wings with positive twist (i.e., washout), this maximum moves outboard as the wing lift coefficient increases. Thus, the spanwise position of the center of pressure on each semispan of a twisted wing *varies* with both wing twist and angle of attack.

Combining terms from the basic and additional section lift coefficients on the right-hand side of Eq. (200) and rearranging, it can be shown that the maximum section lift coefficient occurs at a value of θ that satisfies the relation

$$\frac{d\tilde{C}_L}{d\theta} = \frac{4C_L}{\pi R_A} \sum_{n=1}^{\infty} \left(\frac{a_n}{a_1} + \frac{b_1 a_n - a_1 b_n}{a_1^2} \frac{\pi R_A a_1 \Omega}{C_L} \right) \times \left[b \frac{n \cos(n\theta) c(\theta) - \sin(n\theta) dc/d\theta}{c^2(\theta)} \right] = 0 \quad (201)$$

Following the development of Phillips and Alley¹⁷ and applying Eq. (201), the spanwise location of the airfoil section that supports the largest section lift coefficient is found to be a root of the equation

$$\sum_{n=1}^{\infty} \left(a_n + \frac{b_1 a_n - a_1 b_n}{a_1} \frac{C_{L,\alpha} \Omega}{C_L} \right) \left[n \cos(n\theta) \frac{c(\theta)}{b} - \sin(n\theta) \frac{d(c/b)}{d\theta} \right] = 0 \quad (202)$$

In the most general case, this root must be found numerically.

After finding the root of Eq. (202) to obtain the value of θ , which corresponds to the airfoil section that supports the maximum section lift coefficient, this value of θ can be used in Eq. (200) to determine the maximum section lift coefficient for the wing at the specific operating condition. Dividing Eq. (200) by the net wing lift coefficient and applying Eq. (107), the ratio of the local section lift coefficient to the total wing lift coefficient can be written as

$$\frac{\tilde{C}_L(\theta)}{C_L} = \frac{4b}{\pi R_A c(\theta)} \left[\sum_{n=1}^{\infty} \frac{a_n}{a_1} \sin(n\theta) + \frac{C_{L,\alpha} \Omega}{C_L} \sum_{n=2}^{\infty} \frac{b_1 a_n - a_1 b_n}{a_1^2} \sin(n\theta) \right] \quad (203)$$

Examination of Eqs. (202) and (203) reveals that, for $\Omega = 0$, these equations are independent of the net wing lift coefficient. This means that, for an untwisted wing of any planform, the ratio of the maximum section lift coefficient to the total wing lift coefficient and the position along the span at which this maximum occurs are *independent* of operating conditions and functions of the wing planform only. Figure 52 shows how the ratio of total wing lift coefficient to maximum section lift coefficient varies with aspect ratio and taper ratio for untwisted wings with linear taper.

The spanwise coordinate of the maximum section lift coefficient for such untwisted wings is presented in Fig. 53 as a function of aspect ratio and taper

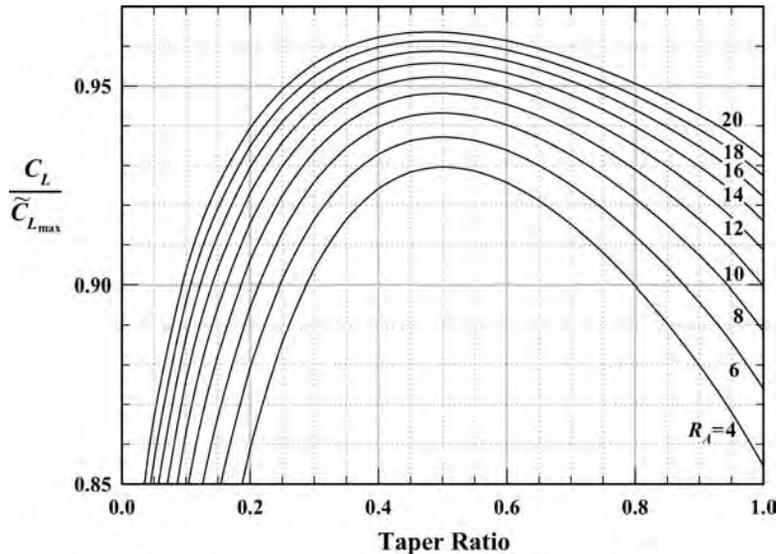

Fig. 52 Maximum lift coefficient for tapered wings with no sweep or twist.

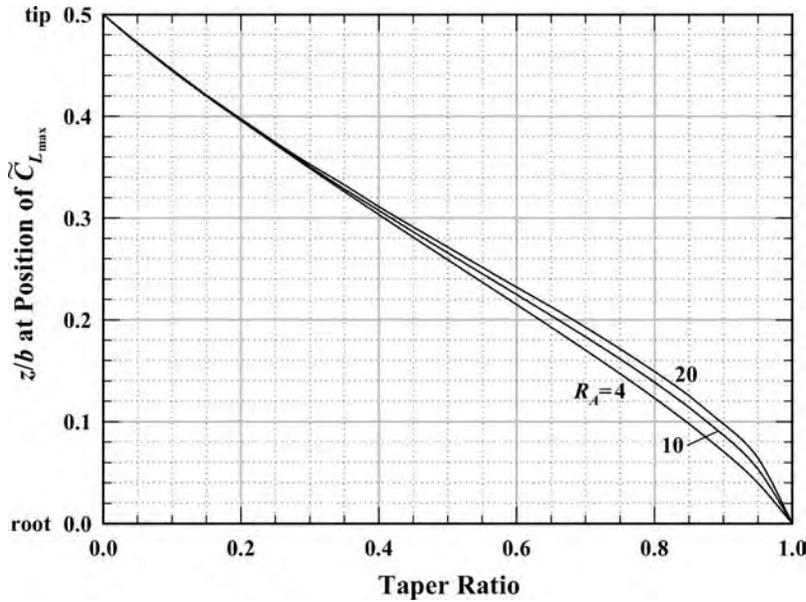

Fig. 53 Spanwise location of maximum section lift coefficient for tapered wings with no sweep or twist.

ratio. Notice that the spanwise coordinate of the airfoil section that supports the maximum section lift coefficient is quite insensitive to the aspect ratio and nearly a linear function of taper ratio.

For unswept wings of arbitrary planform and arbitrary twist, the maximum section lift coefficient is obtained by evaluating Eq. (203) at the value of θ corresponding to the root of Eq. (202). The result can be rearranged algebraically to solve for the ratio of the total wing lift coefficient to the maximum section lift coefficient which yields

$$\left(\frac{C_L}{\tilde{C}_{L_{\max}}}\right)_{\Lambda=0} = \left(\frac{C_L}{\tilde{C}_{L_{\max}}}\right)_{\Omega=0} \left(1 - \kappa_{L\Omega} \frac{C_{L,\alpha}\Omega}{\tilde{C}_{L_{\max}}}\right) \quad (204)$$

where

$$\left(\frac{C_L}{\tilde{C}_{L_{\max}}}\right)_{\Omega=0} = \frac{\pi R_A c(\theta_{\max})/(4b)}{\sum_{n=1}^{\infty} (a_n/a_1) \sin(n\theta_{\max})} \quad (205)$$

$$\kappa_{L\Omega} \equiv \frac{4b}{\pi R_A c(\theta_{\max})} \sum_{n=2}^{\infty} \frac{b_1 a_n - a_1 b_n}{a_1^2} \sin(n\theta_{\max}) \quad (206)$$

and θ_{\max} is the value of θ at the wing section that supports the maximum airfoil section lift coefficient, which is obtained from the root of Eq. (202).

For unswept rectangular wings with positive washout ($\Omega \geq 0$), the maximum section lift coefficient

occurs at the wing root ($\theta_{\max} = \pi/2$) and the constant chord length is given by $c(\theta) = b/R_A$. Using these results in Eqs. (205) and (206) and simplifying, for *unswept rectangular wings with positive washout* we obtain

$$\left(\frac{C_L}{\tilde{C}_{L_{\max}}}\right)_{\Omega=0} = \frac{\pi/4}{\sum_{i=0}^{\infty} (-1)^i [(a_{2i+1})/a_1]} \quad (207)$$

$$\kappa_{L\Omega} = \frac{4}{\pi} \sum_{i=1}^{\infty} (-1)^i \frac{b_1 a_{2i+1} - a_1 b_{2i+1}}{a_1^2}$$

For an unswept elliptic wing with $\Omega \geq 0$, the maximum section lift coefficient occurs at the wing root ($\theta_{\max} = \pi/2$), the section chord length is $c(\theta) = [4b/(\pi R_A)] \sin(\theta)$, and the planform Fourier coefficients are $a_1 = \tilde{C}_{L,\alpha}/(\pi R_A + \tilde{C}_{L,\alpha})$ and $a_n = 0$ for $n > 1$. Using these results in Eqs. (205) and (206), Phillips and Alley¹⁷ have shown that for *unswept elliptic wings with positive linear washout*

$$\left(\frac{C_L}{\tilde{C}_{L_{\max}}}\right)_{\Omega=0} = 1$$

$$\kappa_{L\Omega} = \frac{1}{\pi} \sum_{i=1}^{\infty} \frac{4}{(2i+1)^2 - 4} \left(\frac{\pi R_A + \tilde{C}_{L,\alpha}}{\pi R_A + (2i+1)\tilde{C}_{L,\alpha}}\right) \quad (208)$$

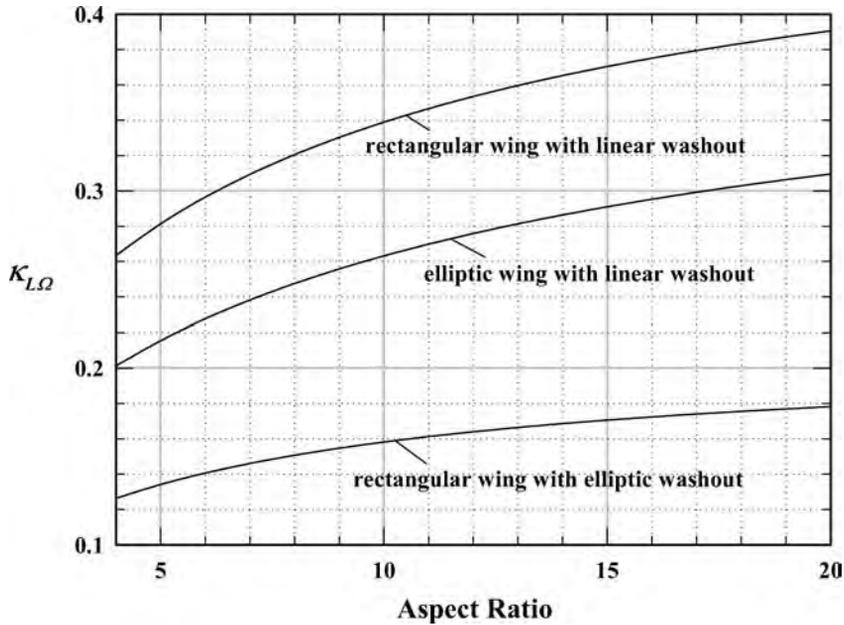

Fig. 54 Effect of wing twist on $\kappa_{L\Omega}$ for elliptic and rectangular wings.

Notice that for unswept rectangular and elliptic wings with positive washout, $\kappa_{L\Omega}$ is independent of both Ω and C_L and the ratio of wing lift coefficient to maximum section lift coefficient is a linear function of $C_{L,\alpha}\Omega/\tilde{C}_{L_{\max}}$. Results predicted from Eqs. (207) and (208) are shown in Fig. 54 as a function of aspect ratio.

As was seen in Figs. 50 and 51, for wings of arbitrary planform the maximum section lift coefficient does not necessarily occur at the root. Thus, $\kappa_{L\Omega}$ may vary with $C_{L,\alpha}\Omega/\tilde{C}_{L_{\max}}$ as well as the wing planform. The results plotted in Figs. 55 and 56 show how $\kappa_{L\Omega}$ varies with $C_{L,\alpha}\Omega/\tilde{C}_{L_{\max}}$ for wings with linear taper and linear washout.

For *unswept wings with twist optimized to produce minimum induced drag*, the optimum twist distribution and optimum total amount of twist are given in Eq. (123). For wings with linear taper, which are twisted in this manner, Phillips and Alley¹⁷ obtained a closed-form solution to Eqs. (202) and (203). From this solution, we find that the z coordinate of the wing section that supports the maximum airfoil section lift coefficient is a linear function of the taper ratio and independent of operating conditions,

$$z_{\max} \equiv z(\theta_{\max}) = \pm \frac{1}{2}(1 - R_T)b \quad (209)$$

The ratio of the total wing lift coefficient to the maximum section lift coefficient for such wings is found to be independent of operating conditions and

given by

$$\left(\frac{C_L}{\tilde{C}_{L_{\max}}} \right)_{\Lambda=0} = \frac{\pi(2R_T - R_T^2)^{1/2}}{2(1 + R_T)} \quad (210)$$

The reader is cautioned that results predicted from Eqs. (209) and (210) are only valid if the wing twist is maintained in proportion to the wing lift coefficient according to the relations provided by Eq. (123).

When Eq. (204) and Figs. 52–56 are used to estimate the total wing lift coefficient that corresponds to a given maximum airfoil section lift coefficient, the results apply only to wings without sweep. As a lifting wing of any planform is swept back, the lift near the root of each semispan is reduced as a result of the downwash induced by the bound vorticity generated on the opposite semispan. This tends to move the point of maximum section lift outboard. For wings with significant taper, this outboard shift causes the point of maximum section lift to occur at an airfoil section having a smaller section chord length, which increases the maximum airfoil section lift coefficient that is produced for a given wing lift coefficient. Because the series solution to Prandtl's lifting-line equation applies only to unswept wings, a numerical solution is required to predict the effects of wing sweep. Either the numerical lifting-line method presented in Section 7 or a numerical panel code could be used for this purpose.

The reader should also note that using the maximum airfoil section lift coefficient in Eq. (204) will

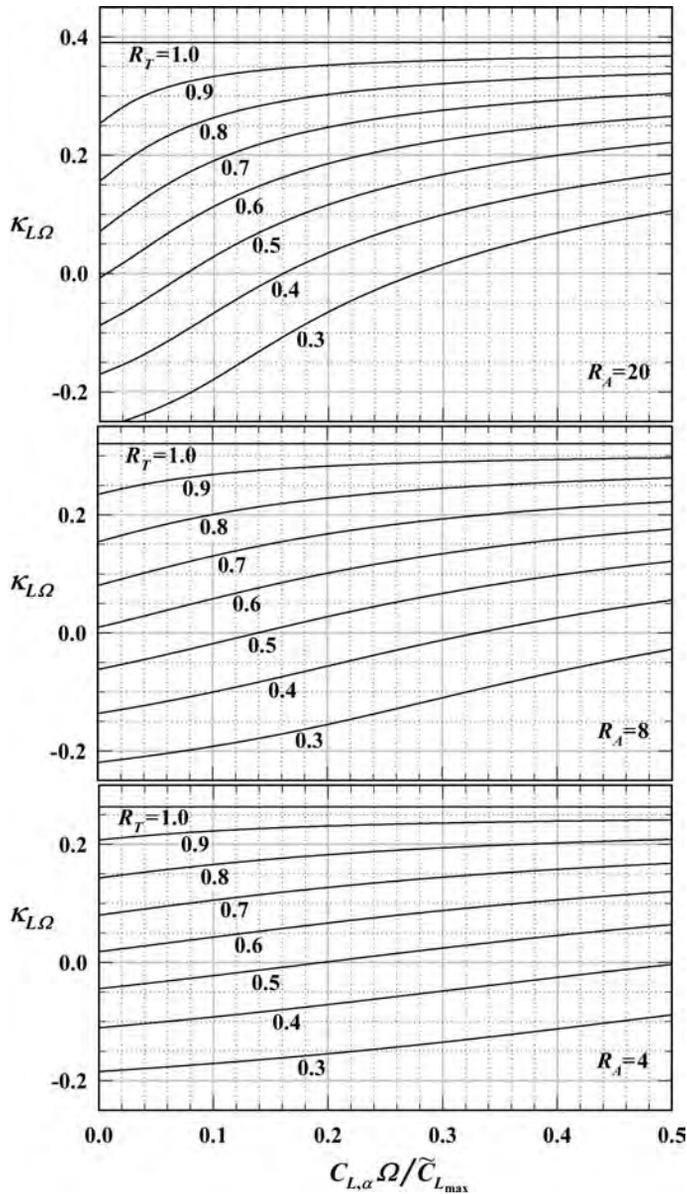

Fig. 55 Effect of wing twist and taper ratio on $\kappa_{L\Omega}$ for wings with linear taper and linear washout.

give an estimate for the wing lift coefficient at the onset of airfoil section stall. At higher angles of attack, separated flow will exist over some sections of the wing and drag will be substantially increased. However, the wing lift coefficient predicted from Eq. (204) is not exactly the maximum wing lift coefficient. Viscous interactions between adjacent sections of the wing can initiate flow separation at slightly lower angles of attack than

predicted by Eq. (204). Furthermore, as the angle of attack is increased somewhat beyond that which produces the onset of airfoil section stall, the section lift coefficient on the stalled section of the wing will decrease. However, the section lift coefficient on the unstalled sections of the wing will continue to increase with angle of attack until the maximum section lift coefficient is reached on these sections as well. Thus,

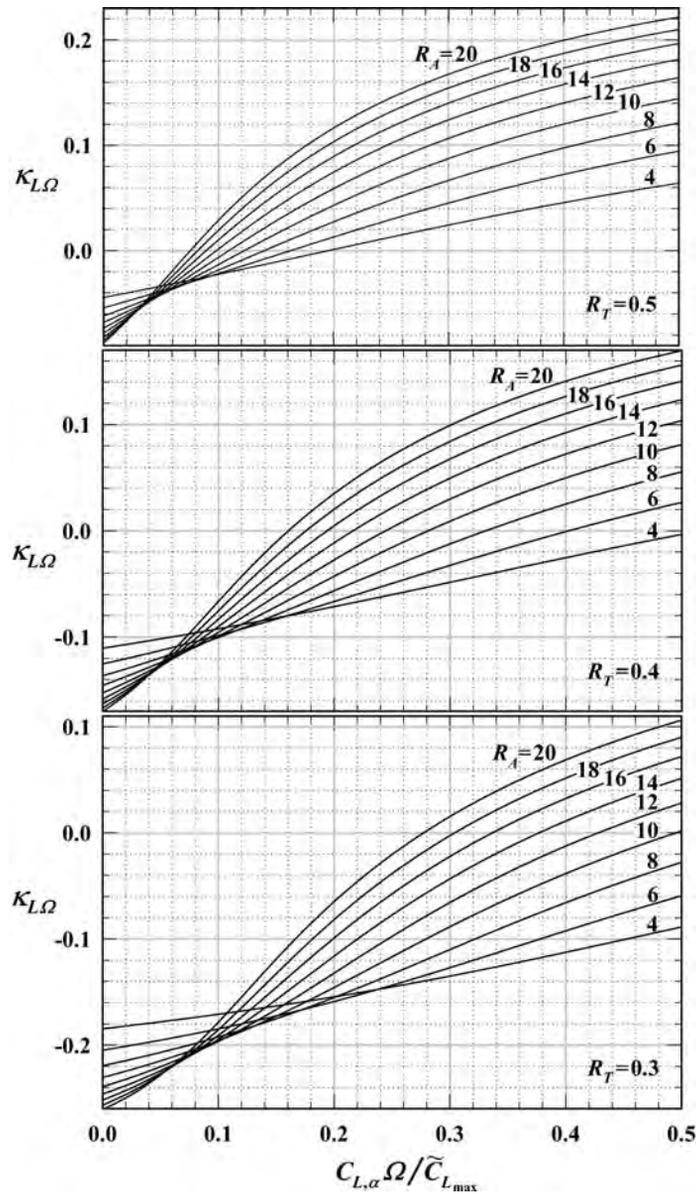

Fig. 56 Effect of wing twist and aspect ratio on $\kappa_{L\Omega}$ for wings with linear taper and linear washout.

the maximum wing lift coefficient could differ slightly from that which is predicted by Eq. (204). Because boundary layer separation is a viscous phenomenon, the maximum wing lift coefficient for a given wing geometry must be determined from experimental methods or computational fluid dynamics (CFD).

To account for the effects of wing sweep and stall, experimental data and results obtained from CFD

computations suggest that predictions from Eq. (204) can be modified by including sweep and stall correction factors,

$$C_{L_{\max}} = \left(\frac{C_L}{\tilde{C}_{L_{\max}}} \right)_{\substack{\Omega=0 \\ A=0}} \kappa_{Ls} \kappa_{L\Lambda} (\tilde{C}_{L_{\max}} - \kappa_{L\Omega} C_{L,\alpha} \Omega) \quad (211)$$

where the sweep factor $\kappa_{L\Lambda}$ depends on the wing sweep angle and planform, and the stall factor κ_{Ls} depends on wing aspect ratio and the wing twist parameter $C_{L,\alpha}\Omega/C_{L_{max}}$. For wings with linear taper, Phillips and Alley¹⁷ presented numerical lifting-line results for the sweep factor, which correlate well with the approximation

$$\kappa_{L\Lambda} \cong 1 + \kappa_{\Lambda 1}\Lambda - \kappa_{\Lambda 2}\Lambda^{1.2} \quad (212)$$

where Λ is the quarter-chord sweep angle in radians and the coefficient $\kappa_{\Lambda 1}$ and $\kappa_{\Lambda 2}$ depend on aspect ratio and taper ratio as shown in Figs. 57 and 58, respectively. For wings with linear taper and linear twist, CFD results for the stall factor obtained by Alley and co-workers¹⁸ correlate well with the approximate relation

$$\kappa_{Ls} \cong 1 + (0.0042R_A - 0.068) \left(1 + \frac{2.3C_{L,\alpha}\Omega}{\tilde{C}_{L_{max}}} \right) \quad (213)$$

Equation (213) was obtained from computations of the maximum wing lift coefficient for 25 different wing geometries. These wings had aspect ratios ranging from 4 to 20, taper ratios from 0.5 to 1.0, quarter-chord sweep angles from 0° to 30°, and linear geometric washout ranging from 0° to 8°.

When estimating a maximum wing lift coefficient from Eq. (211), it is essential that the maximum 2D

airfoil section lift coefficient be evaluated at the same Reynolds and Mach numbers as those for the 3D wing. For the case of a rectangular wing this is rather straightforward. However, for a tapered wing the section Reynolds number is not constant across the wingspan. This gives rise to an important question regarding what characteristic length should be used to define the Reynolds number associated with predicting the maximum lift coefficient for a wing of arbitrary planform. The simplest choice would be the mean chord length defined by Eq. (162). However, this does not provide a particularly suitable characteristic length for defining the Reynolds number associated with wing stall. A more appropriate characteristic length for this purpose is the chord length of the wing section supporting the maximum section lift coefficient.

The spanwise coordinate of the maximum airfoil section lift coefficient at the onset of stall depends on wing taper, twist, and sweep. For an untwisted rectangular wing with no sweep, the onset of airfoil section stall occurs at the wing root. As wing taper ratio is decreased from 1.0, the point of maximum section lift coefficient moves outboard from the root. Adding sweep to the wing also moves the point of maximum section lift coefficient outboard. On the other hand, adding washout to a wing with taper and/or sweep moves the point of maximum section lift coefficient inboard. Lifting-line theory can be used to predict the spanwise coordinate of the wing section that supports the maximum airfoil section lift coefficient. For tapered wings with no sweep or twist, the coordinate of

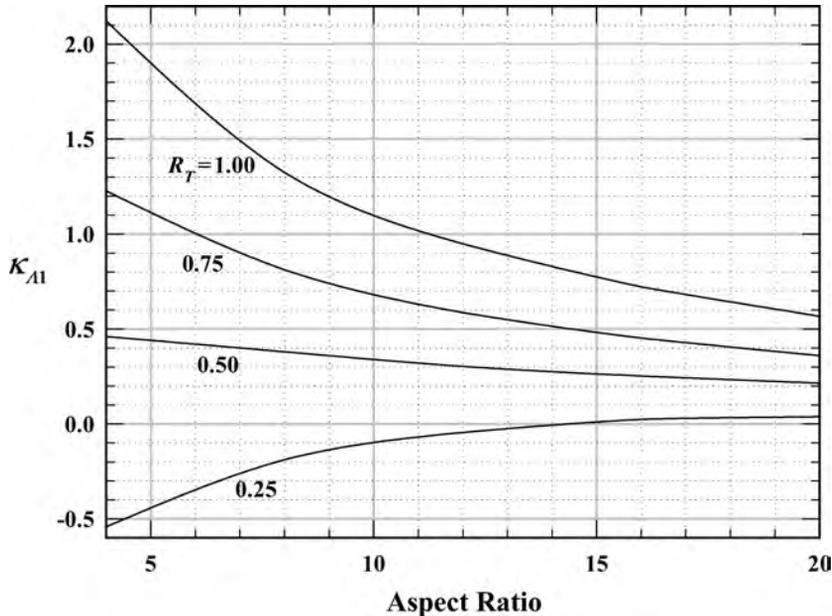

Fig. 57 Wing sweep coefficient $\kappa_{\Lambda 1}$ to be used in Eq. (212) for wings with linear taper.

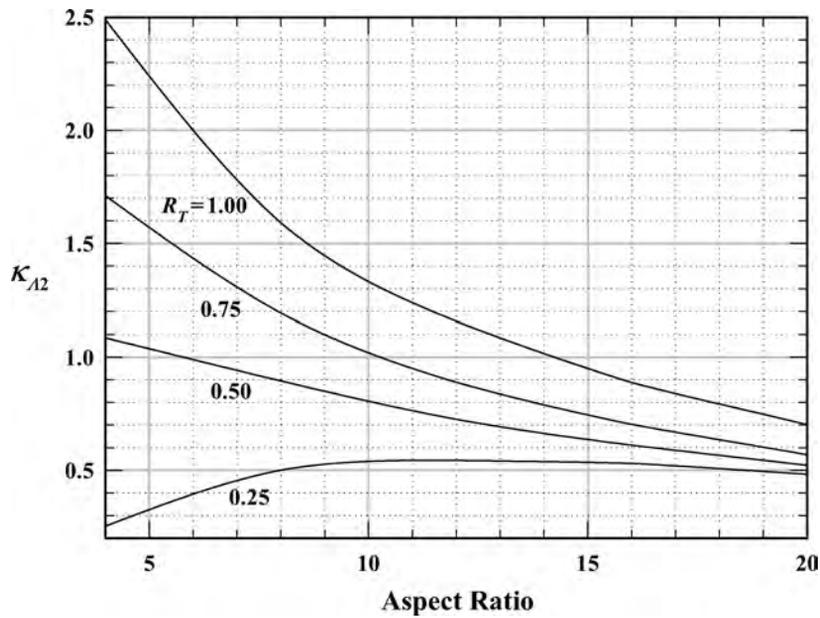

Fig. 58 Wing sweep coefficient $\kappa_{\Lambda 2}$ to be used in Eq. (212) for wings with linear taper.

the maximum section lift coefficient may be obtained from Fig. 53.

Results obtained from Fig. 53 can be modified to account for the effects of twist and sweep. The spanwise coordinate of the wing section that supports the maximum section lift coefficient can be estimated from

$$\frac{z_{\max}}{b} = 0.5 - \kappa_{Z\Lambda} \left[0.5 - \kappa_{Z\Omega} \left(\frac{Z_{\max}}{b} \right)_{\substack{\Omega=0 \\ \Lambda=0}} \right] \quad (214)$$

For wings with linear taper and linear twist, $\kappa_{Z\Omega}$ and $\kappa_{Z\Lambda}$ are obtained from Figs. 59 and 60, respectively

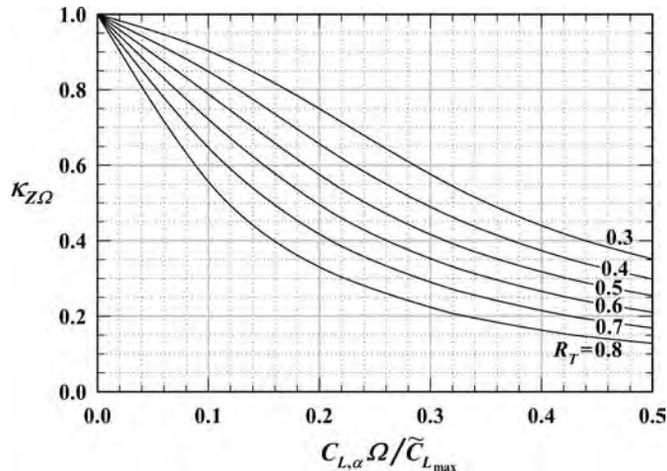

Fig. 59 Twist coefficient $\kappa_{Z\Omega}$ to be used in Eq. (214) for wings with linear twist.

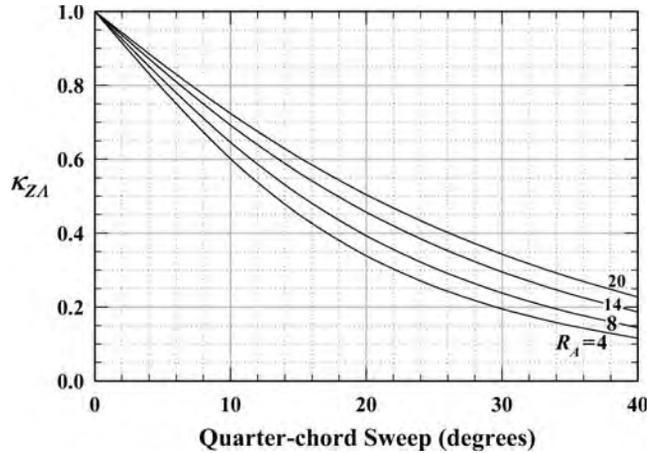

Fig. 60 Sweep coefficient $\kappa_{Z\Delta}$ to be used in Eq. (214) for wings with linear taper.

9 INVISCID COMPRESSIBLE AERODYNAMICS

In the analytical methods that were reviewed in Sections 4–7, the variation in air density was assumed to be negligible. This is a reasonable approximation for flight Mach numbers less than about 0.3. For higher flight Mach numbers, compressibility effects become increasingly important. For flight speeds near or exceeding the speed of sound, the effects of compressibility vastly alter the airflow about an aircraft in flight. In this and the following sections, we review some of the important concepts associated with compressible aerodynamics.

As discussed in Section 3, inviscid flow over any body immersed in a uniform flow is irrotational. Any irrotational flow is a potential flow. There is no requirement that the flow be incompressible. Thus, the velocity field for inviscid flow about a body immersed in uniform flow can always be expressed according to Eq. (23):

$$\mathbf{V} = \nabla\phi \tag{215}$$

where ϕ is the scalar velocity potential. From Eq. (14), the continuity equation for steady compressible flow is

$$(\mathbf{V} \cdot \nabla)\rho + \rho \nabla \cdot \mathbf{V} = 0 \tag{216}$$

Inviscid adiabatic flow is isentropic. For an ideal gas this requires that

$$\frac{p}{p_0} = \left(\frac{\rho}{\rho_0}\right)^\gamma \tag{217}$$

where p_0 and ρ_0 are the stagnation pressure and density. For steady isentropic flow of an ideal gas,

the momentum equation is expressed in Eq. (28):

$$\frac{1}{2}V^2 + \frac{\gamma}{\gamma - 1} \frac{p}{\rho} = \frac{\gamma}{\gamma - 1} \frac{p_0}{\rho_0} \tag{218}$$

For an ideal gas

$$\frac{p}{\rho} = RT \tag{219}$$

$$a^2 = \gamma RT \tag{220}$$

Substituting Eqs. (219) and (220) into Eq. (217) gives

$$\frac{p}{p_0} = \frac{RT\rho}{RT_0\rho_0} = \frac{\gamma RT\rho}{\gamma RT_0\rho_0} = \frac{a^2\rho}{a_0^2\rho_0} = \left(\frac{\rho}{\rho_0}\right)^\gamma \tag{221}$$

Similarly, applying Eqs. (219) and (220) to Eq. (218) yields

$$\frac{1}{2}V^2 + \frac{a^2}{\gamma - 1} = \frac{a_0^2}{\gamma - 1} \tag{222}$$

Solving Eq. (221) for ρ and solving Eq. (222) for the speed of sound squared results in

$$\rho = \rho_0 \left(\frac{a^2}{a_0^2}\right)^{1/(\gamma-1)} \tag{223}$$

$$a^2 = a_0^2 - \frac{\gamma-1}{2} V^2 \tag{224}$$

Substituting Eq. (224) into Eq. (223), we have

$$\rho = \rho_0 \left(1 - \frac{\gamma-1}{2} \frac{V^2}{a_0^2}\right)^{1/(\gamma-1)} \tag{225}$$

This specifies the local air density as a function of the local velocity and the stagnation conditions, which are known from the free-stream conditions according to Eqs. (32)–(34).

Applying Eq. (215) to express the velocity in Eq. (225) in terms of the velocity potential, the local air density is found to be a function only of ϕ and known stagnation properties of the flow

$$\begin{aligned}\rho &= \rho_0 \left(1 - \frac{\gamma - 1}{2a_0^2} \mathbf{V} \cdot \mathbf{V} \right)^{1/(\gamma-1)} \\ &= \rho_0 \left(1 - \frac{\gamma - 1}{2a_0^2} \nabla\phi \cdot \nabla\phi \right)^{1/(\gamma-1)}\end{aligned}\quad (226)$$

After using Eqs. (215) and (226) in (216), the *continuity equation for steady compressible potential flow* can be written as

$$\begin{aligned}\left(a_0^2 - \frac{\gamma - 1}{2} \nabla\phi \cdot \nabla\phi \right) \nabla^2\phi \\ - \frac{1}{2} (\nabla\phi \cdot \nabla)(\nabla\phi \cdot \nabla\phi) = 0\end{aligned}\quad (227)$$

This equation contains only one unknown, the velocity potential ϕ . Both γ and a_0 are known constants of the flow. Since Eq. (227) is a single scalar equation in only one scalar unknown, it provides a tremendous simplification over the more general Navier–Stokes equations. However, like the Navier–Stokes equations but unlike the Laplace equation that governs the velocity potential for incompressible flow, Eq. (227) is nonlinear. Once the velocity potential has been determined from Eq. (227), the velocity field can be evaluated from Eq. (215). With the velocity known, the speed of sound at any point in the flow can be determined from Eq. (224). Knowing the local velocity and speed of sound at every point in the flow allows us to compute the Mach number and then, using Eqs. (29)–(31), to evaluate the pressure, temperature, and air density.

It is sometimes useful to apply a change of variables in Eq. (227). Here we shall define a new velocity vector to be the difference between the local velocity and the free-stream velocity,

$$\mathbf{V}_p \equiv \mathbf{V} - \mathbf{V}_\infty \quad (228)$$

This is commonly called the *perturbation velocity*. From this definition we also define the *perturbation velocity potential*,

$$\phi_p \equiv \phi - \phi_\infty \quad (229)$$

where ϕ_∞ is the velocity potential for the uniform flow. For the uniform flow potential we have

$$\nabla\phi_\infty = \mathbf{V}_\infty \quad (230)$$

$$\nabla\phi_\infty \cdot \nabla\phi_\infty = V_\infty^2 \quad (231)$$

$$\nabla^2\phi_\infty = 0 \quad (232)$$

Using Eqs. (229)–(232) in Eq. (227) results in

$$\begin{aligned}\left[a_0^2 - \frac{\gamma - 1}{2} V_\infty^2 \left(1 + 2\mathbf{u}_\infty \cdot \nabla\hat{\phi}_p \right. \right. \\ \left. \left. + \nabla\hat{\phi}_p \cdot \nabla\hat{\phi}_p \right) \right] \nabla^2\hat{\phi}_p \\ - \frac{1}{2} V_\infty^2 [(\nabla\hat{\phi}_p + \mathbf{u}_\infty) \cdot \nabla] (2\mathbf{u}_\infty \cdot \nabla\hat{\phi}_p \\ + \nabla\hat{\phi}_p \cdot \nabla\hat{\phi}_p) = 0\end{aligned}\quad (233)$$

where \mathbf{u}_∞ is the unit vector in the direction of the free stream

$$\mathbf{u}_\infty \equiv \frac{\mathbf{V}_\infty}{V_\infty} \quad (234)$$

and

$$\hat{\phi}_p \equiv \frac{\phi_p}{V_\infty} \quad (235)$$

Equation (233) is the general equation for the perturbation velocity potential. To this point in the development, no approximation has been made in going from Eq. (227) to Eq. (233). This result applies to any irrotational flow.

Equation (233) can be linearized under the assumption that the perturbation velocity is small compared to the free-stream velocity. This approximation results in

$$\begin{aligned}\left(a_0^2 - \frac{\gamma - 1}{2} V_\infty^2 \right) \nabla^2\hat{\phi}_p \\ - V_\infty^2 (\mathbf{u}_\infty \cdot \nabla)(\mathbf{u}_\infty \cdot \nabla\hat{\phi}_p) = 0\end{aligned}\quad (236)$$

Applying Eq. (224) to the free stream gives

$$a_\infty^2 = a_0^2 - \frac{\gamma - 1}{2} V_\infty^2 \quad (237)$$

Substituting Eq. (237) in Eq. (236) and dividing through by a_∞^2 , the *linearized equation for the perturbation velocity potential* is

$$\nabla^2\hat{\phi}_p - M_\infty^2 (\mathbf{u}_\infty \cdot \nabla)(\mathbf{u}_\infty \cdot \nabla\hat{\phi}_p) = 0 \quad (238)$$

Notice that as the flight Mach number approaches zero this result reduces to Laplace's equation, which applies to incompressible flow. Equation (238) provides reasonable predictions for slender bodies at low angles of attack with subsonic Mach numbers ($M_\infty < 0.8$) and supersonic Mach numbers ($1.2 < M_\infty < 5$). It is not valid for transonic Mach numbers ($0.8 < M_\infty < 1.2$) or hypersonic Mach numbers ($M_\infty > 5$).

10 COMPRESSIBLE SUBSONIC FLOW

The aerodynamic theory of incompressible flow over airfoil sections was reviewed in Sections 4 and 5. The analytical methods that have been developed for incompressible flow over airfoils can be applied to subsonic compressible flow through a simple change of variables. However, the reader should recall that subsonic flow does not exist all the way to a flight Mach number of 1.0. For an airfoil section producing positive lift, the flow velocities just outside the boundary layer on the upper surface are greater than the free-stream velocity. Thus, at some flight speeds below Mach 1.0, supersonic flow will be encountered in some region above the upper surface of the airfoil. The flight Mach number at which sonic flow is first encountered at some point on the upper surface of the airfoil is called the *critical Mach number*. Here we review the theory of compressible flow over airfoils at flight speeds below the critical Mach number.

10.1 Prandtl–Glauert Compressibility Correction

For thin airfoils at small angles of attack and flight Mach numbers below critical, the linearized potential flow approximation given by Eq. (238) can be applied. For the special case of 2D flow and a coordinate system having the x axis aligned with the free-stream velocity vector, \mathbf{u}_∞ is simply the unit vector in the x direction, and the continuity equation as expressed in Eq. (238) becomes

$$\left(\frac{\partial^2 \phi_p}{\partial x^2} + \frac{\partial^2 \phi_p}{\partial y^2}\right) - M_\infty^2 \left(\frac{\partial}{\partial x}\right) \left(\frac{\partial \phi_p}{\partial x}\right) = 0$$

or after rearranging,

$$\frac{\partial^2 \phi_p}{\partial x^2} + \frac{1}{1 - M_\infty^2} \frac{\partial^2 \phi_p}{\partial y^2} = 0 \tag{239}$$

The nature of this partial differential equation depends on the sign of $1 - M_\infty^2$. Recall from your introductory course on differential equations that if the flight Mach number is greater than 1.0, Eq. (239) is hyperbolic. However, for subsonic Mach numbers this partial differential equation is elliptic.

For subsonic flight, Eq. (239) is simplified by using the change of independent variables

$$\hat{y} \equiv y \sqrt{1 - M_\infty^2} \tag{240}$$

With this change of variables, Eq. (239) becomes

$$\frac{\partial^2 \phi_p}{\partial x^2} + \frac{\partial^2 \phi_p}{\partial \hat{y}^2} = 0 \tag{241}$$

which is exactly Laplace’s equation that governs incompressible potential flow. Thus, with this coordinate

transformation, the incompressible flow solution can be used for compressible flow.

The local pressure coefficient obtained from any solution to Eq. (241) is given by

$$C_p = \frac{C_{pM0}}{\sqrt{1 - M_\infty^2}} \tag{242}$$

where C_{pM0} is the pressure coefficient for zero Mach number, which is the solution obtained for incompressible flow. Equation (242) relates the pressure coefficient for subsonic compressible flow to that for incompressible flow and is commonly referred to as the *Prandtl–Glauert compressibility correction*.

For inviscid flow the section lift and moment coefficient can be found from simple integrals of the pressure distribution over the surface of the airfoil. As a result, the final result for section lift and moment coefficient look much like Eq. (242):

$$\tilde{C}_L = \frac{\tilde{C}_{LM0}}{\sqrt{1 - M_\infty^2}} \tag{243}$$

$$\tilde{C}_m = \frac{\tilde{C}_{mM0}}{\sqrt{1 - M_\infty^2}} \tag{244}$$

where \tilde{C}_{LM0} and \tilde{C}_{mM0} are the section lift and moment coefficient obtained for incompressible flow. The development of Eqs. (242)–(244) can be found in any undergraduate engineering textbook on aerodynamics and will not be repeated here.

10.2 Critical Mach Number

For potential flow over an airfoil producing positive lift, the flow velocities along some portion of the upper surface are greater than the free-stream velocity. Also recall that for incompressible potential flow, the ratio of local velocity to the free-stream velocity at any point in the flow does not vary with the magnitude of the free-stream velocity. In other words, if we double the free-stream velocity in an incompressible potential flow, the velocity at every point in the flow field will double as well. This is a direct result of the linear nature of the Laplace equation, which governs incompressible potential flow. Thus, within the approximation of Eq. (239), the position of the point of maximum velocity on the upper surface of the airfoil does not change with free-stream velocity.

From the definition of pressure coefficient we can write

$$\begin{aligned} C_p &\equiv \frac{p - p_\infty}{\frac{1}{2} \rho_\infty V_\infty^2} = \frac{2}{(\rho_\infty / p_\infty) V_\infty^2} \left(\frac{p}{p_\infty} - 1\right) \\ &= \frac{2}{(\gamma / \gamma R T_\infty) V_\infty^2} \left(\frac{p}{p_\infty} - 1\right) = \frac{2}{\gamma M_\infty^2} \left(\frac{p}{p_\infty} - 1\right) \end{aligned} \tag{245}$$

From Eq. (30),

$$\frac{p}{p_\infty} = \left(\frac{1 + [(\gamma - 1)/2]M_\infty^2}{1 + [(\gamma - 1)/2]M^2} \right)^{\gamma/(\gamma-1)} \quad (246)$$

Substituting Eq. (246) into Eq. (245), the pressure coefficient can be expressed as a function of Mach number,

$$C_p = \frac{2}{\gamma M_\infty^2} \left[\left(\frac{1 + [(\gamma - 1)/2]M_\infty^2}{1 + [(\gamma - 1)/2]M^2} \right)^{\gamma/(\gamma-1)} - 1 \right] \quad (247)$$

This relation allows us to compute the local pressure coefficient at any point in the flow from the local Mach number and the free-stream Mach number.

The critical Mach number M_{cr} is the free-stream Mach number that results in a local Mach number of 1.0 at that point on the upper surface where the pressure coefficient is lowest. Using this fact together with Eqs. (242) and (247) gives the relation

$$\begin{aligned} \frac{(C_p M_0)_{\min}}{\sqrt{1 - M_{cr}^2}} \\ = \frac{2}{\gamma M_{cr}^2} \left[\left(\frac{1 + [(\gamma - 1)/2]M_{cr}^2}{1 + [(\gamma - 1)/2]} \right)^{\gamma/(\gamma-1)} - 1 \right] \end{aligned} \quad (248)$$

The minimum pressure coefficient on the airfoil surface for incompressible flow can be evaluated using a panel code. With this pressure coefficient known, Eq. (248) contains only one unknown, the critical Mach number. This is easily solved for the value of the critical Mach number by using the secant method.

10.3 Drag Divergence

While the lift and pitching moment produced on an airfoil section are generated primarily from pressure forces, at subsonic speeds the drag is attributed almost entirely to viscous forces generated in the boundary layer. Below the critical Mach number, airfoil section drag coefficient does not vary substantially with Mach number. However, beyond the critical Mach number the drag coefficient begins to increase very rapidly with increasing Mach number, reaching a maximum at Mach 1 as shown in Fig. 61. This figure is intended only to show the general shape of the drag curve that might be expected for some airfoil. The exact shape of this drag curve and the total drag rise for a particular airfoil is quite sensitive to the shape of the airfoil section. There is no simple theory capable of predicting the variation in section drag coefficient with Mach number in the transonic region. At Mach numbers near 1.0, the flow over an airfoil is extremely complex and very sensitive to section shape. In the transonic region we commonly rely on experimental data.

The large increase in drag that occurs at Mach numbers just below 1.0, called *drag divergence*, is due primarily to the shock waves that form in transonic flow and the premature boundary layer separation caused by these shocks. The dramatic increase in drag that is experienced by an airplane as it approaches Mach 1 is what gave rise to the concept and terminology of the *sound barrier*. Some early researchers believed that the drag would become infinite as the speed of sound was approached. Thus, it was thought by some that it would be impossible to exceed the speed of sound in an aircraft. As can be imagined from inspection of Fig. 61, the speed of sound does present a substantial barrier to an aircraft with limited thrust.

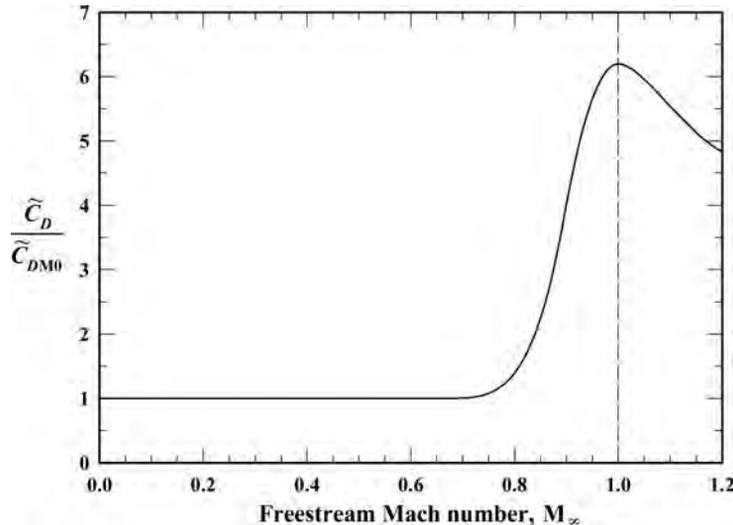

Fig. 61 Sketch of typical variation in section drag coefficient with Mach number.

Nevertheless, the drag at Mach 1 is finite, and like most things in this universe, the sound barrier will yield to sufficient power. It will yield more easily, however, if fineness is applied with the power.

In the last half-century a great deal of “engineering finesse” has been applied to help “lower the sound barrier” by increasing the critical Mach number and decreasing the peak drag experienced near Mach 1. Contributions that have led to the design of improved supersonic aircraft include the use of thinner airfoils and swept wings, the introduction of the *area rule* in the supersonic design philosophy, and development of the supercritical airfoil. All of these topics are covered in most aerodynamics textbooks and the reader is encouraged to review this material, if necessary.

11 SUPERSONIC FLOW

In an irrotational supersonic flow where the streamlines make only small angles with the free stream, the linearized potential flow approximation given by Eq. (238) can be applied. Again consider 2D flow with the x axis aligned with the free-stream velocity vector. These are exactly the conditions that were used in Section 10 to study subsonic compressible flow over an airfoil. Thus, Eq. (239) applies to supersonic flow at small angles as well as to subsonic flow. However, since our interest is now in Mach numbers greater than 1.0, Eq. (239) is more conveniently written as

$$\frac{\partial^2 \phi_p}{\partial x^2} - \frac{1}{M_\infty^2 - 1} \frac{\partial^2 \phi_p}{\partial y^2} = 0 \tag{249}$$

Solutions to this hyperbolic partial differential equation are characteristically very different from solution to the elliptic equation encountered for subsonic flow. Thus, we should expect supersonic flow to be very different from subsonic flow.

In obtaining a solution to Eq. (249), a change of variables is again useful. We wish to find a variable change that will allow us to separate the independent variables, x and y , in Eq. (249). This is a common technique used in obtaining solutions to partial differential equations. We want to find a change of variables, say $\xi(x, y)$, that will make the perturbation potential a function of ξ only, that is, $\phi_p(\xi)$. With this in mind, Eq. (249) can be written as

$$\frac{d^2 \phi_p}{d\xi^2} \left(\frac{\partial \xi}{\partial x} \right)^2 + \frac{d\phi_p}{d\xi} \frac{\partial^2 \xi}{\partial x^2} - \frac{1}{M_\infty^2 - 1} \left[\frac{d^2 \phi_p}{d\xi^2} \left(\frac{\partial \xi}{\partial y} \right)^2 + \frac{d\phi_p}{d\xi} \frac{\partial^2 \xi}{\partial y^2} \right] = 0 \tag{250}$$

Equation (250) is satisfied for ϕ_p equal to any function of ξ if

$$\frac{\partial^2 \xi}{\partial x^2} = \frac{1}{M_\infty^2 - 1} \frac{\partial^2 \xi}{\partial y^2} \quad \text{and} \quad \frac{\partial \xi}{\partial x} = \pm \frac{1}{\sqrt{M_\infty^2 - 1}} \frac{\partial \xi}{\partial y}$$

Both of these relations are satisfied if we set both sides of the second relation equal to an arbitrary constant, say C_1 . This gives

$$\frac{\partial \xi}{\partial x} = C_1 \quad \text{and} \quad \frac{\partial \xi}{\partial y} = \pm C_1 \sqrt{M_\infty^2 - 1}$$

These equations are easily integrated to yield

$$\begin{aligned} \xi(x, y) &= C_1 x + f_1(y) \quad \text{and} \\ \xi(x, y) &= \pm C_1 \sqrt{M_\infty^2 - 1} y + f_2(x) \end{aligned}$$

which require that

$$\xi(x, y) = C_1 \left(x \pm \sqrt{M_\infty^2 - 1} y \right) + C_2$$

Because C_1 and C_2 are arbitrary, we can choose $C_1 = 1$ and $C_2 = 0$, which gives

$$\xi(x, y) = x \pm \sqrt{M_\infty^2 - 1} y \tag{251}$$

Either of the two solutions for ξ that are given in Eq. (251) will provide the desired variable change. With either definition any function $\phi_p(\xi)$ will satisfy Eq. (249). Thus, any problem associated with small-angle potential flow at supersonic Mach numbers reduces to that of finding the function $\phi_p(\xi)$ that will also satisfy the required boundary conditions.

From Eq. (53), a great deal can be deduced about supersonic potential flow at small angles without applying any boundary conditions. Since the perturbation potential is a function only of ξ , lines of constant perturbation potential are lines of ξ . Thus, the *constant perturbation potential lines* are described by the equation

$$x \pm \sqrt{M_\infty^2 - 1} y = \text{const} \tag{252}$$

Since this is the equation of a straight line, the constant perturbation potential lines are all straight lines. Furthermore, solving Eq. (252) for y and differentiating with respect to x , we find that the *slope of any constant perturbation potential line* is

$$\left(\frac{\partial y}{\partial x} \right)_{\phi_p = \text{const}} = \frac{\mp 1}{\sqrt{M_\infty^2 - 1}} \tag{253}$$

The angle that the constant perturbation potential lines makes with the free stream (i.e., the x axis) is called the *Mach angle* and is given by

$$\mu = \mp \tan^{-1} \left(\frac{1}{\sqrt{M_\infty^2 - 1}} \right) \tag{254}$$

Notice that for supersonic potential flow at small angles, the Mach angle is independent of surface

geometry. It depends only on the free-stream Mach number. Also notice that there are two solutions for the Mach angle and that the signs in Eqs. (253) and (254) are opposite to those in Eqs. (251) and (252). Thus, choosing the negative sign in Eq. (251) results in a positive Mach angle, and vice versa.

From the definition of perturbation potential, given in Eq. (229), the local fluid velocity vector is given by

$$\mathbf{V} = \nabla\phi = \nabla\phi_\infty + \nabla\phi_p = \mathbf{V}_\infty + \nabla\phi_p = V_\infty\mathbf{i}_x + \nabla\phi_p$$

Using the relation

$$\phi_p = \phi_p(\xi) = \phi_p\left(x \pm \sqrt{M_\infty^2 - 1}y\right)$$

we have

$$\begin{aligned}\mathbf{V} &= \left(V_\infty + \frac{d\phi_p}{d\xi} \frac{\partial\xi}{\partial x}\right)\mathbf{i}_x + \frac{d\phi_p}{d\xi} \frac{\partial\xi}{\partial y}\mathbf{i}_y \\ &= \left(V_\infty + \frac{d\phi_p}{d\xi}\right)\mathbf{i}_x \pm \sqrt{M_\infty^2 - 1} \frac{d\phi_p}{d\xi}\mathbf{i}_y\end{aligned}\quad (255)$$

The slope of a streamline at any point in the flow can be evaluated from Eq. (255).

$$\frac{V_y}{V_x} = \pm \frac{\sqrt{M_\infty^2 - 1} (d\phi_p/d\xi)}{V_\infty + d\phi_p/d\xi}$$

Because we are considering the case of small perturbation velocity, only the first-order term in this result should be retained. Since the streamlines are tangent to the velocity vector, the *slope of the local streamline relative to the x axis* is

$$\left(\frac{\partial y}{\partial x}\right)_{\text{streamline}} = \pm \frac{\sqrt{M_\infty^2 - 1} d\phi_p}{V_\infty d\xi}\quad (256)$$

From Eq. (255), the local velocity squared is

$$\begin{aligned}V^2 &= \left(V_\infty + \frac{d\phi_p}{d\xi}\right)^2 + (M_\infty^2 - 1) \left(\frac{d\phi_p}{d\xi}\right)^2 \\ &= V_\infty^2 + 2V_\infty \frac{d\phi_p}{d\xi} + M_\infty^2 \left(\frac{d\phi_p}{d\xi}\right)^2\end{aligned}$$

Again, since we are considering the case of small perturbation velocity, the second-order term should be ignored and the *velocity at any point in the flow* is given by

$$V^2 = V_\infty^2 + 2V_\infty \frac{d\phi_p}{d\xi}\quad (257)$$

From the momentum equation for a compressible potential flow, which is given by Eq. (28), we can

express the local temperature in terms of the local velocity. Using the ideal gas law in Eq. (28) at an arbitrary point and the free stream gives

$$\frac{1}{2}V^2 + \frac{\gamma RT}{\gamma - 1} = \frac{1}{2}V_\infty^2 + \frac{\gamma RT_\infty}{\gamma - 1}$$

Solving this for temperature, using Eq. (257) to eliminate the velocity, and applying the relation $a^2 = \gamma RT$ gives the *temperature* at any point in the flow:

$$T = T_\infty \left[1 - (\gamma - 1) \frac{M_\infty}{a_\infty} \frac{d\phi_p}{d\xi}\right]\quad (258)$$

From the isentropic relations given in Eqs. (29) and (30), the pressure ratio is easily related to the temperature ratio and after applying Eq. (258), we obtain

$$\begin{aligned}\frac{p}{p_\infty} &= \left(\frac{T}{T_\infty}\right)^{\gamma/(\gamma-1)} \\ &= \left[1 - (\gamma - 1) \frac{M_\infty}{a_\infty} \frac{d\phi_p}{d\xi}\right]^{\gamma/(\gamma-1)}\end{aligned}$$

Expanding this result in a Taylor series and retaining only the first-order term results in an expression for the *pressure* at any point in the flow:

$$p = p_\infty \left(1 - \gamma \frac{M_\infty}{a_\infty} \frac{d\phi_p}{d\xi}\right)\quad (259)$$

Using Eq. (259) in the definition of pressure coefficient as expressed in Eq. (245) results in

$$C_p = \frac{2}{\gamma M_\infty^2} \left(\frac{p}{p_\infty} - 1\right) = -\frac{2}{V_\infty} \frac{d\phi_p}{d\xi}\quad (260)$$

Solving Eq. (256) for the derivative of the perturbation potential and using Eq. (254) to eliminate the free-stream Mach number in favor of the Mach angle gives

$$\begin{aligned}\frac{d\phi_p}{d\xi} &= \pm \frac{V_\infty}{\sqrt{M_\infty^2 - 1}} \left(\frac{\partial y}{\partial x}\right)_{\text{streamline}} \\ &= -V_\infty \tan(\mu) \left(\frac{\partial y}{\partial x}\right)_{\text{streamline}}\end{aligned}\quad (261)$$

Substituting Eq. (261) into Eq. (260), the *pressure coefficient at any point in a small-angle potential flow at supersonic Mach numbers* can be expressed as a function of only the Mach angle and the slope of the local streamline:

$$C_p = 2 \tan(\mu) \left(\frac{\partial y}{\partial x}\right)_{\text{streamline}}\quad (262)$$

Remember that the Mach angle can be chosen as either positive or negative as needed to satisfy the required boundary conditions. However, the positive sign in Eq. (262) holds regardless of the sign chosen for the Mach angle. If the streamline slope has the same sign as the Mach angle, the pressure coefficient is positive. If these signs are opposite, the pressure coefficient is negative.

For those of us interested in computing aerodynamic forces, this is a very simple result in comparison to most solutions that have been obtained for fluid flow. In this respect, supersonic potential flow at small angles is less complex than subsonic flow at small angles. It rivals Bernoulli's equation for raw simplicity. The Mach angle depends only on the free-stream Mach number. Furthermore, at the surface of a solid body, the streamlines must be tangent to the surface. Thus, the slope of the surface streamlines depends only on the surface geometry and the angle of attack.

11.1 Supersonic Thin Airfoils

The supersonic small-angle potential flow equations can be used to predict the aerodynamic force and moment components acting on a thin airfoil at small angles of attack, provided that the airfoil has a sharp leading edge as shown in Fig. 62. This type of leading edge is commonly used on supersonic airfoils because a blunt leading edge produces a strong bow shock in supersonic flight.

Consider supersonic flow over the cambered airfoil shown in Fig. 62. Because the flow must be symmetric for a symmetric airfoil at zero angle of attack, the positive slope is chosen for the Mach lines above the airfoil and the negative slope is chosen for those Mach lines below the airfoil. The slope of the upper surface relative to the free stream can be expressed as the slope of the chord line relative to the free stream, plus the slope of the camber line relative to the chord line, plus the slope of the thickness line relative to the camber line. Thus, for small angles of attack, the *upper surface slope* is

$$\frac{dy_u}{dx} = -\alpha + \frac{dy_c}{dx} + \frac{dy_t}{dx} \quad (263)$$

where y_c is the local camber and y_t is one-half the local thickness. Similarly, the *lower surface slope* is

$$\frac{dy_l}{dx} = -\alpha + \frac{dy_c}{dx} - \frac{dy_t}{dx} \quad (264)$$

Since the streamlines must be tangent to the airfoil surface, the results above can be used in Eq. (162) to evaluate the pressure coefficient on the airfoil surface.

The contribution of pressure on the lower surface to the section lift is the surface pressure multiplied by a differential area per unit span projected on the x axis. Similarly, the upper surface contributes to the lift in just the opposite direction. Thus, the section lift coefficient is

$$\begin{aligned} \tilde{C}_L &= \frac{\tilde{L}}{\frac{1}{2}\rho_\infty V_\infty^2 c} = \int_0^c \frac{p_l - p_u}{\frac{1}{2}\rho_\infty V_\infty^2} \frac{dx}{c} \\ &= \int_0^c (C_{pl} - C_{pu}) \frac{dx}{c} \end{aligned} \quad (265)$$

The slope of the Mach lines is positive on the upper surface and negative on the lower surface. Thus, from Eq. (254),

$$\tan(\mu_l) = \frac{-1}{\sqrt{M_\infty^2 - 1}} \quad \text{and} \quad \tan(\mu_u) = \frac{+1}{\sqrt{M_\infty^2 - 1}}$$

Using these results with Eqs. (262)–(264) applied to Eq. (265) gives

$$\begin{aligned} \tilde{C}_L &= \int_0^c \left[2 \frac{-1}{\sqrt{M_\infty^2 - 1}} \left(-\alpha + \frac{dy_c}{dx} - \frac{dy_t}{dx} \right) \right. \\ &\quad \left. - 2 \frac{+1}{\sqrt{M_\infty^2 - 1}} \left(-\alpha + \frac{dy_c}{dx} + \frac{dy_t}{dx} \right) \right] \frac{dx}{c} \\ &= \frac{4}{\sqrt{M_\infty^2 - 1}} \int_0^c \left(\alpha - \frac{dy_c}{dx} \right) \frac{dx}{c} \\ &= \frac{4}{\sqrt{M_\infty^2 - 1}} \left[\alpha - \frac{y_c(c) - y_c(0)}{c} \right] \end{aligned}$$

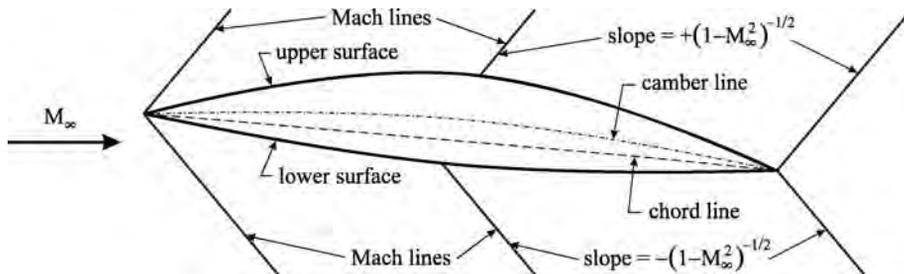

Fig. 62 Small-angle supersonic potential flow over an airfoil.

By definition the camber of any airfoil is zero at both the leading and trailing edges. Thus, the *section lift coefficient* is

$$\tilde{C}_L = \frac{4\alpha}{\sqrt{M_\infty^2 - 1}} = \tilde{C}_{L,\alpha}\alpha \quad \text{where} \quad \tilde{C}_{L,\alpha} = \frac{4}{\sqrt{M_\infty^2 - 1}} \quad (266)$$

From this result, we see that the small-angle potential flow equations predict that neither camber nor thickness makes a contribution to the lift at supersonic airspeeds.

Similarly, the pitching moment coefficient about the leading edge is evaluated from

$$\tilde{C}_{m_{le}} = \frac{\tilde{m}_{le}}{\frac{1}{2}\rho_\infty V_\infty^2 c^2} = \int_0^c (C_{pu} - C_{pl}) \frac{x dx}{c^2}$$

which gives

$$\begin{aligned} \tilde{C}_{m_{le}} &= \frac{-4}{\sqrt{M_\infty^2 - 1}} \int_0^c \left(\alpha - \frac{dy_c}{dx} \right) \frac{x dx}{c^2} \\ &= \frac{-2\alpha}{\sqrt{M_\infty^2 - 1}} + \frac{4}{\sqrt{M_\infty^2 - 1}} \left(\int_0^c \frac{dy_c x dx}{c^2} \right) \end{aligned}$$

or

$$\tilde{C}_{m_{le}} = -\frac{1}{2}\tilde{C}_L + \tilde{C}_{L,\alpha} \int_0^c \frac{dy_c x dx}{c^2}$$

From this result and the material that was reviewed in Section 1, it can be seen that the aerodynamic center is located at the half chord and the *pitching moment coefficient* about the aerodynamic center is

$$\tilde{C}_{m_{ac}} = \tilde{C}_{L,\alpha} \int_0^c \frac{dy_c x dx}{c^2} \quad \text{where} \quad \frac{x_{ac}}{c} = \frac{1}{2} \quad (267)$$

The moment coefficient about the aerodynamic center only depends on the camber line shape. Since camber does not contribute to lift in small-angle supersonic potential flow, symmetric airfoils are often used for supersonic flight. Notice from Eq. (267) that a thin symmetric airfoil produces no moment about its half chord. Thus, the half chord is also the center of pressure for a thin symmetric airfoil in supersonic flight.

The section drag for supersonic potential flow over a thin airfoil is not zero as it is for subsonic flow. This section drag is called *wave drag* and is computed from

$$\begin{aligned} \tilde{C}_D &= \frac{\tilde{D}}{\frac{1}{2}\rho_\infty V_\infty^2 c} \\ &= \int_0^c \left(\frac{p_u - p_\infty}{\frac{1}{2}\rho_\infty V_\infty^2} \frac{dy_u}{dx} - \frac{p_l - p_\infty}{\frac{1}{2}\rho_\infty V_\infty^2} \frac{dy_l}{dx} \right) \frac{dx}{c} \\ &= \int_0^c \left(C_{pu} \frac{dy_u}{dx} - C_{pl} \frac{dy_l}{dx} \right) \frac{dx}{c} \end{aligned}$$

Applying Eqs. (254) and (262)–(264) gives

$$\begin{aligned} \tilde{C}_D &= \frac{4}{\sqrt{M_\infty^2 - 1}} \\ &\times \left\{ \alpha^2 + \int_0^c \left[\left(\frac{dy_c}{dx} \right)^2 + \left(\frac{dy_t}{dx} \right)^2 \right] \frac{dx}{c} \right\} \end{aligned}$$

This result can be written in terms of the lift slope that was evaluated previously and presented in Eq. (266). Thus, the *section wave drag coefficient* is

$$\tilde{C}_D = \tilde{C}_{L,\alpha} \alpha^2 + \tilde{C}_{L,\alpha} \int_0^c \left[\left(\frac{dy_c}{dx} \right)^2 + \left(\frac{dy_t}{dx} \right)^2 \right] \frac{dx}{c} \quad (268)$$

From the results presented in Eqs. (266)–(268), we see that small-angle potential flow theory predicts that there is no advantage to using camber in a supersonic airfoil. It only contributes to the pitching moment and the drag, making no predicted contribution to the lift. Furthermore, we see that airfoil thickness makes a predicted contribution to wave drag that is proportional to thickness squared. This is one reason why thin airfoil sections are commonly used on supersonic aircraft. Most modern airplanes that are designed to fly at Mach 1.5 and above use airfoils having a thickness on the order of 4%. This approximate linearized supersonic airfoil theory agrees reasonably well with experimental observations for airfoils as thick as about 10% and angles of attack as large as 20°. As should be expected, this inviscid theory underpredicts the drag and moment coefficient and overpredicts the lift coefficient. However, the discrepancy is only a few percent. Most of the discrepancy can be attributed to viscous effects in the boundary layer. The drag that is predicted by this linear theory includes only wave drag. If a contribution for viscous drag is included from boundary layer computations, the predictions are improved. However, the viscous drag is quite small compared to the wave drag and for many purposes can be ignored.

1 GENERALIZED ONE-DIMENSIONAL GAS DYNAMICS

The steady one-dimensional flow of a chemically inert perfect gas with constant specific heats is conveniently described and governed by the following definition and physical laws.¹

1.1 Definitions

Perfect gas: $p = \rho RT$ (1)

Mach number: $M = \frac{u}{a}$ (2)

Stagnation temperature: $T_0 = T \left[1 + \frac{1}{2}(\gamma - 1)M^2 \right]$ (3)

Stagnation pressure: $p_0 = p \left[1 + \frac{1}{2}(\gamma - 1)M^2 \right]^{\gamma/\gamma - 1}$ (4)

where p = pressure, ρ = density, R = gas constant, T = temperature, M = Mach number, u = velocity, a = speed of sound, T_0 = stagnation temperature, γ = ratio of specific heat at constant pressure to specific heat at constant volume, and p_0 = stagnation pressure. It is conventional to denote those stream properties at the point in the flow where $M = 1$ by p^* , u^* , and so on.

1.2 Physical Laws

For one-dimensional flow through a control volume having the single inlet and exit flow Sections 1 and 2, respectively, we have

Continuity equation: $\rho_1 A_1 u_1 = \rho_2 A_2 u_2$ (5)

Momentum equation: $F_{\text{frict}} = (pA + \rho Au^2)_1 - (pA + \rho Au^2)_2$ (6)

Energy equation: $q = c_p(T_{02} - T_{01})$ (shaft work = 0) (7)

Entropy equation: $s_2 \geq s_1$ (adiabatic flow) (8)

where F_{frict} = frictional force of a solid control surface boundary on the flowing gas, A = the flow cross-sectional area normal to u , q = the heat flow per unit mass flow, c_p = specific heat at constant pressure, and s = entropy per unit mass flow.

The application of Eqs. (1)–(6) to flow in the presence of the simultaneous effects of area-change, heating, and friction (Fig. 1) results in the following set of equations:

Perfect gas: $\frac{dp}{p} - \frac{d\rho}{\rho} - \frac{dT}{T} = 0$ (9)

Stagnation temperature: $\frac{dT}{T} + \frac{[(\gamma - 1)/2]M^2}{1 + [(\gamma - 1)/2]M^2} \times \frac{dM^2}{M^2} = \frac{dT_0}{T_0}$ (10)

Continuity: $\frac{d\rho}{\rho} + \frac{dA}{A} + \frac{du}{u} = 0$ (11)

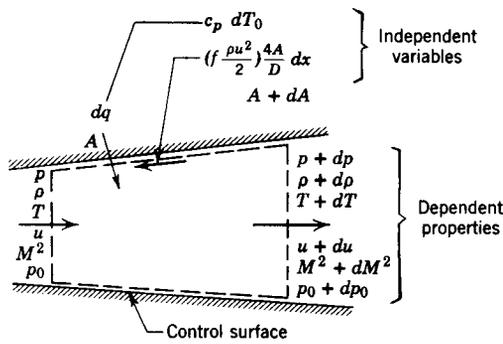

Fig. 1 Independent and dependent variables for generalized one-dimensional flow, where f = friction coefficient, D = hydraulic diameter.

Stagnation pressure:
$$\frac{dp}{p} + \frac{\gamma M^2 / 2}{1 + [(\gamma - 1) / 2] M^2} \frac{dM^2}{M^2} = \frac{dp_0}{p_0} \tag{12}$$

Momentum:
$$\frac{dp}{p} + \gamma M^2 \frac{du}{u} + \frac{\gamma M^2}{2} \frac{4f dx}{D} = 0 \tag{13}$$

Mach number:
$$2 \frac{du}{u} - \frac{dT}{T} = \frac{dM^2}{M^2} \tag{14}$$

In these equations heat effects are measured in terms of the stagnation temperature change according to Eq. (7). The entropy condition of Eq. (8) is also applicable if $dT_0 = 0$. If $dT_0 \neq 0$, then the entropy requirement is $ds \geq (dq/T)$.

The six dependent variables $M^2, u, p, \rho, T,$ and p_0 in this set of six linear algebraic equations may be expressed in terms of the three independent variables, $dA/A, dT_0/T_0,$ and $4f dx/D$. The solution of this set of equations is given in Table 1.

General conclusions can be made relative to the variation of the stream properties of the flow with each of the independent variables by the relations of Table 1.^{1,2} An example of the relation given for (du/u) at the bottom of the table indicates that, in a constant area adiabatic flow friction will increase the stream velocity in subsonic flow and will decrease the velocity in supersonic flow. Similar reasoning may be applied to determine the manner in which any dependent property varies with a single independent variable.

2 SIMPLE FLOWS

A simple flow is defined as one in which all but one of the independent variables in Table 1 are zero. Three types of simple flows are summarized in Fig. 2a by presenting for each simple flow (i) the independent effects present, (ii) a schematic of the flow situation, (iii) the locus on a temperature-entropy diagram of the possible states attained for each flow and (iv) useful functions obtained by integration of the relations of Table 1 or the basic Eqs. (1)–(6). These useful functions are tabulated in Ref. 3.

In the temperature-entropy diagrams of Fig. 2a the path lines of states corresponding to simple area flow, simple heating flow, and simple friction flow, respectively, are shown. These path lines are called the isentrope, Rayleigh, and Fanno lines, respectively.

Table 1 Influence Coefficients for Steady One-Dimensional Flow

Dependent	Independent		
	$\frac{dA}{A}$	$\frac{dT_0}{T_0}$	$\frac{4f dx}{D}$
$\frac{dM^2}{M^2}$	$-\frac{2\{1 + [(\gamma - 1)/2]M^2\}}{1 - M^2}$	$(1 + \gamma M^2)\{1 + [(\gamma - 1)/2]M^2\}$ $1 - M^2$	$\gamma M^2\{1 + [(\gamma - 1)/2]M^2\}$ $1 - M^2$
$\frac{du}{u}$	$-\frac{1}{1 - M^2}$	$\frac{1 + [(\gamma - 1)/2]M^2}{1 - M^2}$	$\frac{\gamma M^2}{2(1 - M^2)}$
$\frac{dp}{p}$	$\frac{\gamma M^2}{1 - M^2}$	$-\frac{\gamma M^2\{1 + [(\gamma - 1)/2]M^2\}}{1 - M^2}$	$-\frac{\gamma M^2[1 + (\gamma - 1)M^2]}{2(1 - M^2)}$
$\frac{d\rho}{\rho}$	$\frac{M^2}{1 - M^2}$	$-\frac{1 + [(\gamma - 1)/2]M^2}{1 - M^2}$	$-\frac{\gamma M^2}{2(1 - M^2)}$
$\frac{dT}{T}$	$\frac{(\gamma - 1)M^2}{1 - M^2}$	$(1 - \gamma M^2)\{1 + [(\gamma - 1)/2]M^2\}$ $1 - M^2$	$-\frac{\gamma(\gamma - 1)M^4}{2(1 - M^2)}$
$\frac{dp_0}{p_0}$	0	$-\frac{\gamma M^2}{2}$	$-\frac{\gamma M^2}{2}$

Table is read:

$$\frac{du}{u} = \left[-\frac{1}{1 - M^2} \right] \frac{dA}{A} + \left[\frac{1 + [(\gamma - 1)/2]M^2}{1 - M^2} \right] \frac{dT_0}{T_0} + \left[\frac{\gamma M^2}{2(1 - M^2)} \right] \frac{4f dx}{D}$$

Fig. 2c (Continued)

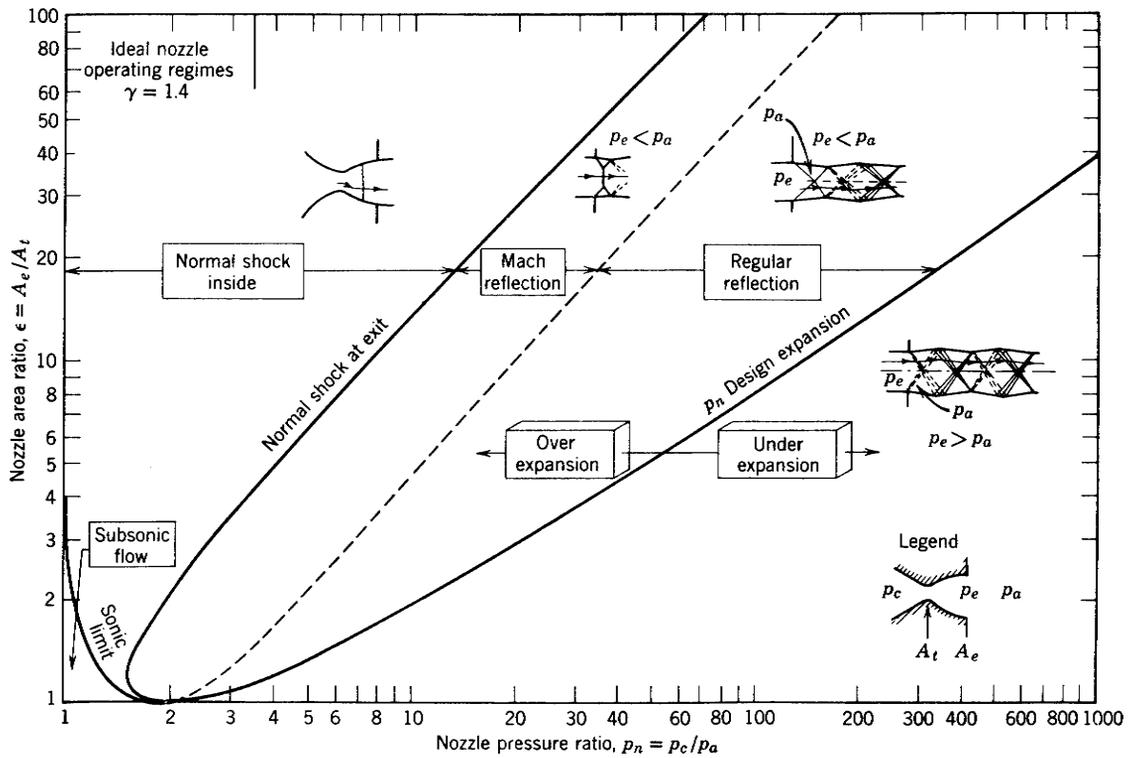

Fig. 3 Nozzle operating diagram (from Ref. 4).

To proceed downward along the *isentropic line* from point *a* of the diagram, the flow area is decreased until the sonic point at *b* is reached. The area must be increased after point *b* in order to continue down to point *c*. By proper adjustments in the flow area and boundary pressure, the flow may be made to proceed through point *b* in either direction along the isentropic line. Point *a* represents the isentropic stagnation condition for all points on the isentropic *ac*.

The *Rayleigh line* shows the series of possible states in a steady, frictionless, constant area flow. Motion along the Rayleigh line is caused by changes in the stagnation temperature produced by heating effects that, in turn, produce entropy changes in the manner indicated on the line. Heating in an initially subsonic flow (point *d*) causes the flow Mach number

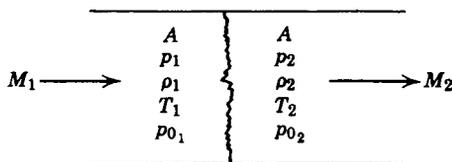

Fig. 4 Normal shock.

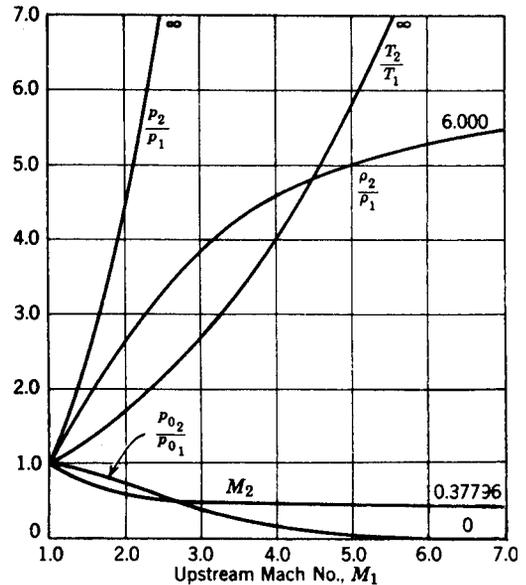

Fig. 5 Property variations across a normal shock.

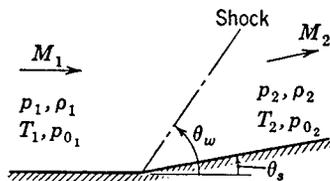

Fig. 7 Plane oblique shock wave.

to approach one (point e). Neither heating nor cooling alone can continuously alter the flow from subsonic to supersonic speeds, or from supersonic to subsonic speeds.

The *Fanno line* represents the possible series of states in a steady, constant area, constant stagnation temperature flow. Frictional effects alone produce motion along the Fanno line. Consequently the flow progression along the line must always be one of increasing entropy toward the sonic point h . The flow is subsonic on the Fanno line above h and supersonic below. Since the entropy decreases along the Fanno line from point h , it is impossible in simple friction flow to proceed by continuous changes through sonic conditions at point h .

3 NOZZLE OPERATING CHARACTERISTICS

The operating characteristics of a nozzle are governed by the ratio of its exit area to throat area (A_e/A_t) and

by the ratio of its reservoir chamber pressure to exhaust region ambient pressure (p_e/p_a). The operating regimes of a nozzle for isentropic (except for shock waves), steady one-dimensional flow of the perfect gas air are depicted in Fig. 3 on a diagram with nozzle pressure ratio and nozzle area ratio as the coordinate axes.

The curve in Fig. 3 with the two branches labeled "design expansion" and "sonic limit" is obtained from the simple area isentropic functions of Fig. 2a by plotting A/A^* versus the reciprocal of p/p_0 . The design expansion line corresponds to sets of values of nozzle pressure ratio and nozzle area ratio for which the flow is shock free with the nozzle exit section Mach number supersonic and with the exit pressure p_e equal to the exhaust region ambient pressure p_a . For any given area ratio the sonic limit line locates the nozzle pressure ratio, which will produce sonic conditions at the throat and subsonic flow elsewhere. Alternatively, the sonic limit branch corresponds to the minimum nozzle pressure ratio that will give the maximum flow through a given area ratio nozzle with specific throat area and reservoir conditions. The flow is subsonic in a nozzle that has its operating point

located below the sonic limit line. In the region to the right of the design expansion line $p_e > p_a$, the nozzle is underexpanded, and the flow expands to ambient conditions in the exhaust jet.

The area between the sonic limit and the design expansion curves is divided into two regions wherein shock waves occur inside the nozzle or in the jet exhaust. The common boundary of these two regions, labeled "normal shock at exit," is the locus of pressure ratios, which will produce a normal shock at the nozzle exit. Between the shock exit line and the sonic limit line, normal shock waves occur inside the nozzle. Between the shock exit and the design expansion lines oblique shocks, as shown, occur in the jet exhaust.

4 NORMAL SHOCK WAVES

A discontinuous change in stream properties can be sustained in a one-dimensional flow. When this phenomenon occurs normal to the flow direction, it is called a normal shock wave (Fig. 4). The process in this case is irreversible adiabatic and, therefore, with increasing entropy. The velocity of the flow entering

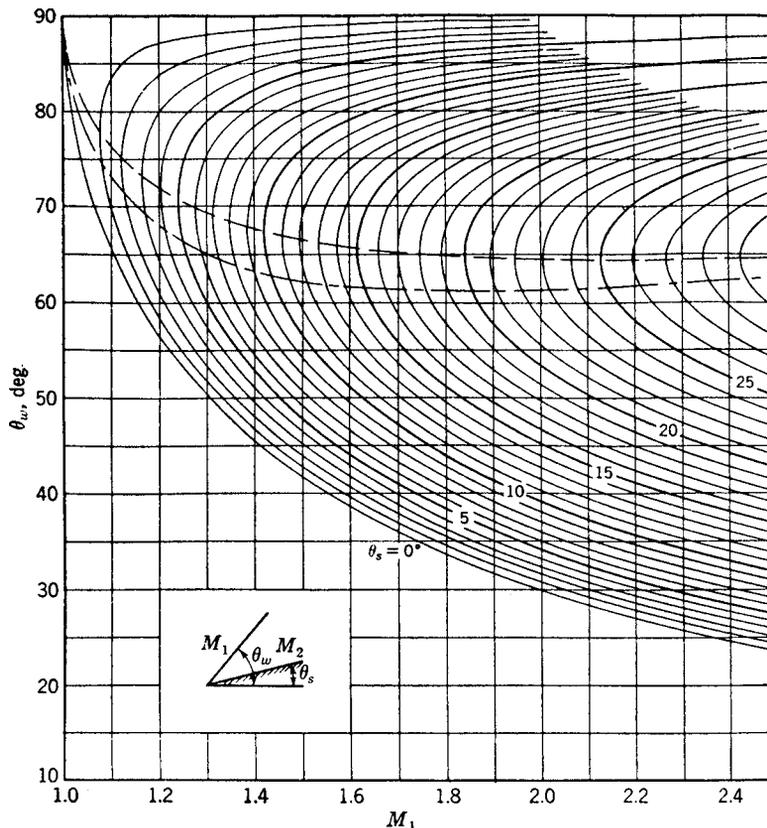

Fig. 8a Wave angle for a plane oblique shock wave ($\gamma = 1.4$).

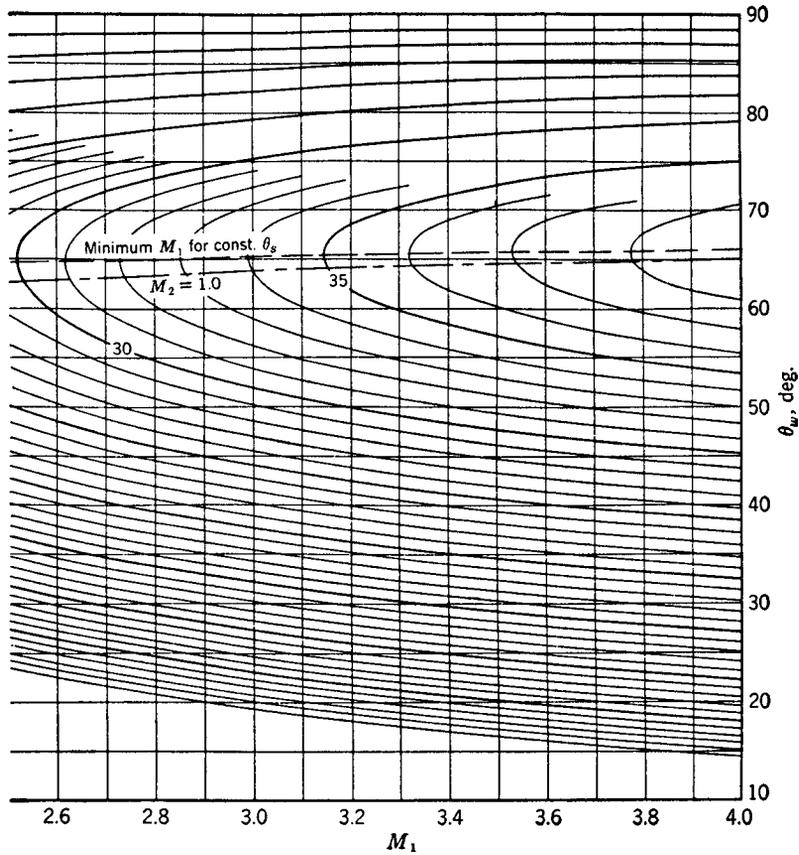

Fig. 8b (Continued)

the shock is supersonic, and that leaving is subsonic. Various important relations are

$$\frac{p_2}{p_1} = \left(\frac{2\gamma}{\gamma+1} \right) M_1^2 - \left(\frac{\gamma-1}{\gamma+1} \right) \quad (15)$$

$$\frac{T_2}{T_1} = \frac{\{ [2\gamma/(\gamma-1)]M_1^2 - 1 \} \{ 1 + [(\gamma-1)/2]M_1^2 \}}{(\gamma+1)^2 M_1^2} \quad (16)$$

$$\frac{\rho_2}{\rho_1} = \frac{u_1}{u_2} = \left[\frac{\gamma-1}{\gamma+1} + \frac{2}{(\gamma+1)M_1^2} \right]^{-1} \quad (17)$$

$$\frac{p_{02}}{p_{01}} = \frac{A_1^*}{A_2^*} = \left[\frac{[(\gamma+1)/2]M_1^2}{1 + [(\gamma-1)/2]M_1^2} \right]^{\gamma/\gamma-1} \times \left[\frac{2\gamma}{\gamma+1} M_1^2 - \frac{\gamma-1}{\gamma+1} \right]^{1/1-\gamma} \quad (18)$$

$$M_2 = \left[\frac{M_1^2 + 2/(\gamma-1)}{[2\gamma/(\gamma-1)]M_1^2 - 1} \right]^{1/2} \quad (19)$$

and the Rayleigh pitot formula,

$$\frac{p_{02}}{p_1} = \left[\frac{\gamma+1}{2} M_1^2 \right]^{\gamma/\gamma-1} \left[\frac{2\gamma}{\gamma+1} M_1^2 - \frac{\gamma-1}{\gamma+1} \right]^{1/1-\gamma} \quad (20)$$

Numerical values for Eqs. (11)–(20) are given in Refs. 3 and 5–7. Equations (7)–(9) are plotted in Fig. 5 and Eq. (20) is shown in Fig. 6.

5 PLANE OBLIQUE SHOCK WAVES

A plane shock wave oblique to the oncoming flow will turn the flow sharply into the oncoming flow. Figure 7 shows an oblique shock wave turning the flow at a sudden change in wall direction. As with a normal shock, the flow process is nonisentropic.

The stream deflection angle θ_s , the wave angle θ_w , and the approach Mach number M_1 of an oblique

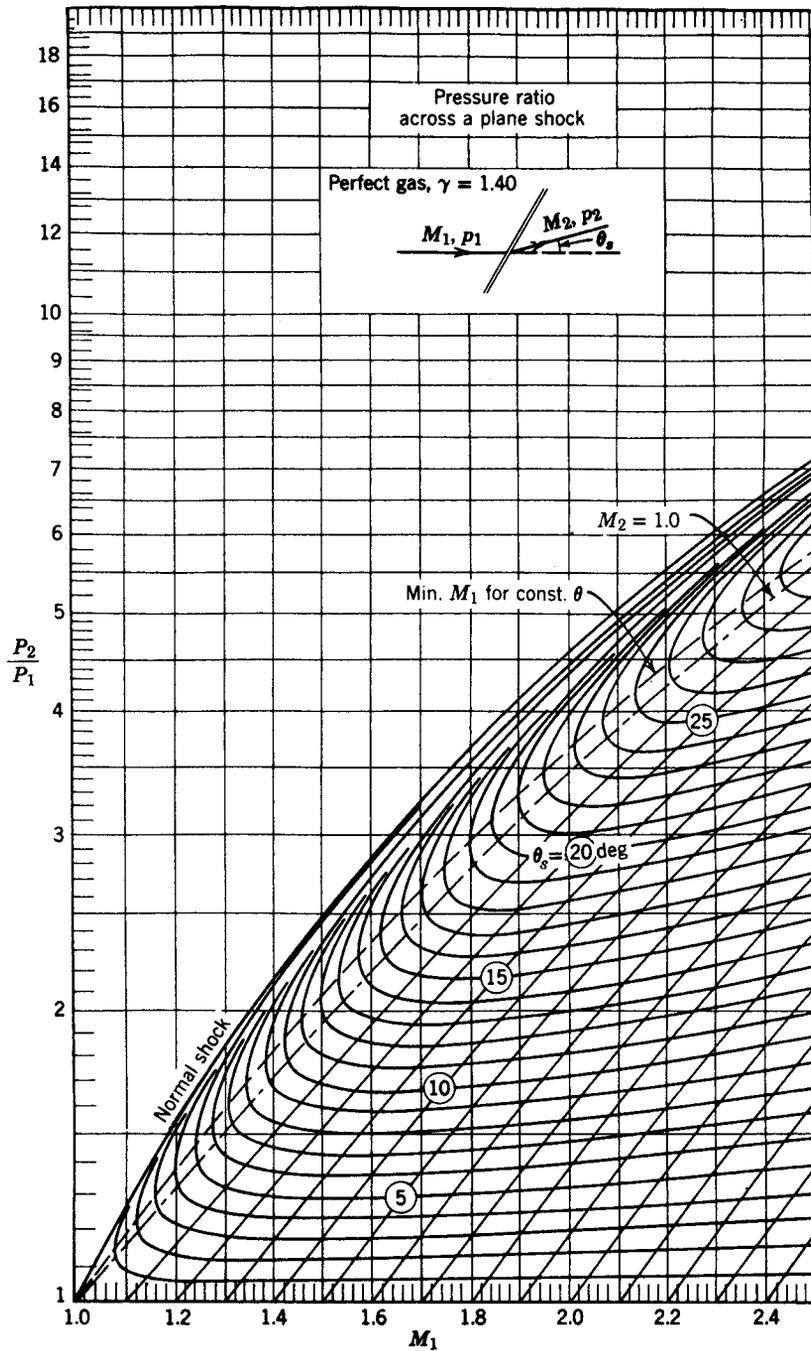

Fig. 9a Variation of pressure ratio and downstream Mach number with flow deflection angle and upstream Mach number M (from Ref. 6).

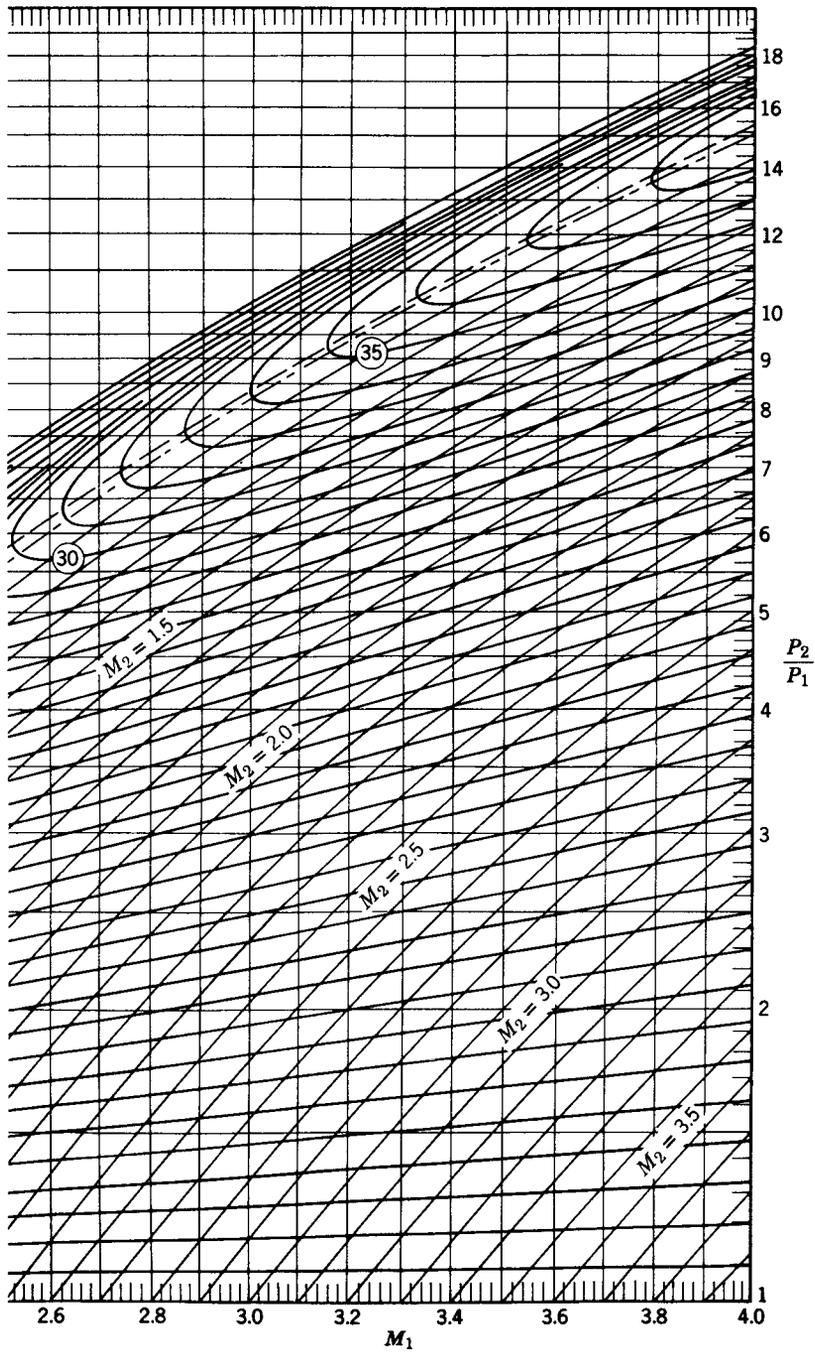

Fig. 9b (Continued)

shock wave are related as follows:

$$\tan(\theta_w - \theta_s) = \frac{2/(\gamma + 1) + [(\gamma - 1)/(\gamma + 1)]M_1^2 \sin^2 \theta_w}{M_1^2 \sin \theta_w \cos \theta_w} \quad (21)$$

This relation is plotted in Fig. 8a. Observe from the figure that two waves are possible. However, when the shock is attached to the corner (Fig. 7), only the wave with the smaller wave angle, the so-called weak wave, can exist. In detached shocks, such as the curved shock in front of a blunt wedge, both solutions, strong and weak, occur. The line of minimum M_1 for constant θ_s is the locus of shock wave detachment.

Relations that relate the pressures, temperatures, densities, stagnation pressures, and Mach numbers before and after plane oblique shocks can be obtained in terms of M_1 and θ_w . In fact, when the products $M_1 \sin \theta_w$ and $M_2 \sin(\theta_w - \theta_s)$ are substituted for M_1 and M_2 , respectively, in the normal shock equations [(15)–(19)], they become directly applicable to flow through plane oblique shocks. Thus by entering the graph of Fig. 5 with $M_1 \sin \theta_w$ (where θ_w may be obtained from Fig. 8a for known values of M_1 and θ_s), the values of the property ratios plotted correspond to those for a plane oblique shock wave. Similarly, the curve labeled M_2 in Fig. 5 gives $M_2 \sin(\theta_w - \theta_s)$ for a plane oblique shock wave. The variation of pressure ratio, downstream Mach number, and total pressure

ratio with flow deflection and upstream Mach number is plotted in Figs. 9 and 10. References 3, 5, 7, and 8 present the oblique shock functions in tabular or graphical form. Reference 8 also contains numerous examples.

6 CONICAL SHOCK WAVES

Conditions on the surface of a cone, Fig. 11, with attached shock wave have been calculated on the basis

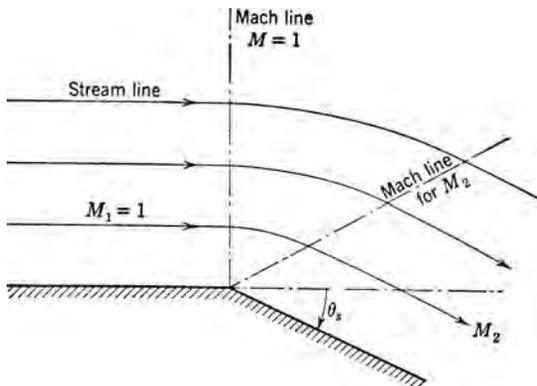

Fig. 14 Prandtl-Meyer expansion at a corner.

of the Taylor-Maccoll theory.⁹ All fluid properties are constant along radial lines through the nose of the cone. Data for the surface stream properties on a cone with an attached conical shock wave are tabulated in Refs. 5 and 10. The shock wave angles and surface pressure coefficient are plotted in Figs. 12 and 13.

7 PRANDTL-MEYER EXPANSION

Supersonic flow turning away from the oncoming flow results in expansion of a gas to a higher Mach number. Figure 14 shows such an expansion around a corner starting with an initial Mach number of unity. The flow is here assumed two dimensional and the process is downward from $M = 1$ along the isentrope line of Fig. 2a.

The angle through which a stream must turn in order to expand from $M_1 = 1$ to M_2 is

$$\theta_s = \sqrt{\frac{\gamma+1}{\gamma-1}} \tan^{-1} \sqrt{\frac{\gamma-1}{\gamma+1}} (M_2^2 - 1) - \tan^{-1} \sqrt{M_2^2 - 1} \quad (22)$$

Numerical values of Eq. (22) are given in Refs. 3 and 5 and Table 2 for air ($\gamma = 1.4$).

Values given in Table 2 can be applied to isentropic flow along any convex curved surface. The downstream Mach number M_2 after expanding M_1 through an angle $\Delta\theta$ can be found by adding $\Delta\theta$ to the θ_s corresponding to M_1 and then finding the M_2 corresponding to $\theta_s + \Delta\theta$ in Table 2.

1 RATIONALE

The design of modern control systems relies on the formulation and analysis of mathematical models of dynamic physical systems. This is simply because a model is more accessible to study than the physical system the model represents. Models typically are less costly and less time consuming to construct and test. Changes in the structure of a model are easier to implement, and changes in the behavior of a model

are easier to isolate and understand. A model often can be used to achieve insight when the corresponding physical system cannot because experimentation with the actual system is too dangerous or too demanding. Indeed, a model can be used to answer “what if” questions about a system that has not yet been realized or actually cannot be realized with current technologies.

The type of model used by the control engineer depends upon the nature of the system the model

represents, the objectives of the engineer in developing the model, and the tools the engineer has at his or her disposal for developing and analyzing the model. A mathematical model is a description of a system in terms of equations. Because the physical systems of primary interest to the control engineer are dynamic in nature, the mathematical models used to represent these systems most often incorporate difference or differential equations. Such equations, based on physical laws and observations, are statements of the fundamental relationships among the important variables that describe the system. Difference and differential equation models are expressions of the way in which the current values assumed by the variables combine to determine the future values of these variables.

Mathematical models are particularly useful because of the large body of mathematical and computational theory that exists for the study and solution of equations. Based on this theory, a wide range of techniques has been developed specifically for the study of control systems. In recent years, computer programs have been written that implement virtually all of these techniques. Computer software packages are now widely available for both simulation and computational assistance in the analysis and design of control systems.

It is important to understand that a variety of models can be realized for any given physical system. The choice of a particular model always represents a trade-off between the fidelity of the model and the effort required in model formulation and analysis. This trade-off is reflected in the nature and extent of simplifying assumptions used to derive the model. In general, the more faithful the model is as a description of the physical system modeled, the more difficult it is to obtain general solutions. In the final analysis, the best engineering model is not necessarily the most accurate or precise. It is, instead, the simplest model that yields the information needed to support a decision. A classification of various types of models commonly encountered by control engineers is given in Section 8.

A large and complicated model is justified if the underlying physical system is itself complex, if the individual relationships among the system variables are well understood, if it is important to understand the system with a great deal of accuracy and precision, and if time and budget exist to support an extensive study. In this case, the assumptions necessary to formulate the model can be minimized. Such complex models cannot be solved analytically, however. The model itself must be studied experimentally, using the techniques of computer simulation. This approach to model analysis is treated in Section 7.

Simpler models frequently can be justified particularly during the initial stages of a control system study. In particular, systems that can be described by linear difference or differential equations permit the use of powerful analysis and design techniques. These include the transform methods of classical control theory and the state-variable methods of modern control

theory. Descriptions of these standard forms for linear systems analysis are presented in Sections 4, 5, and 6.

During the past several decades, a unified approach for developing lumped-parameter models of physical systems has emerged. This approach is based on the idea of idealized system elements, which store, dissipate, or transform energy. Ideal elements apply equally well to the many kinds of physical systems encountered by control engineers. Indeed, because control engineers most frequently deal with systems that are part mechanical, part electrical, part fluid, and/or part thermal, a unified approach to these various physical systems is especially useful and economic. The modeling of physical systems using ideal elements is discussed further in Sections 2, 3, and 4.

Frequently, more than one model is used in the course of a control system study. Simple models that can be solved analytically are used to gain insight into the behavior of the system and to suggest candidate designs for controllers. These designs are then verified and refined in more complex models, using computer simulation. If physical components are developed during the course of a study, it is often practical to incorporate these components directly into the simulation, replacing the corresponding model components. An iterative, evolutionary approach to control systems analysis and design is depicted in Fig. 1.

2 IDEAL ELEMENTS

Differential equations describing the dynamic behavior of a physical system are derived by applying the appropriate physical laws. These laws reflect the ways in which energy can be stored and transferred within the system. Because of the common physical basis provided by the concept of energy, a general approach to deriving differential equation models is possible. This approach applies equally well to mechanical, electrical, fluid, and thermal systems and is particularly useful for systems that are combinations of these physical types.

2.1 Physical Variables

An idealized *two-terminal* or *one-port* element is shown in Fig. 2. Two *primary physical variables* are associated with the element: a through variable $f(t)$ and an across variable $v(t)$. *Through variables* represent quantities that are transmitted through the element, such as the force transmitted through a spring, the current transmitted through a resistor, or the flow of fluid through a pipe. Through variables have the same value at both ends or terminals of the element. *Across variables* represent the difference in state between the terminals of the element, such as the velocity difference across the ends of a spring, the voltage drop across a resistor, or the pressure drop across the ends of a pipe. *Secondary physical variables* are the integrated through variable $h(t)$ and the integrated across variable $x(t)$. These represent the accumulation of quantities within an element as a result of the integration of the

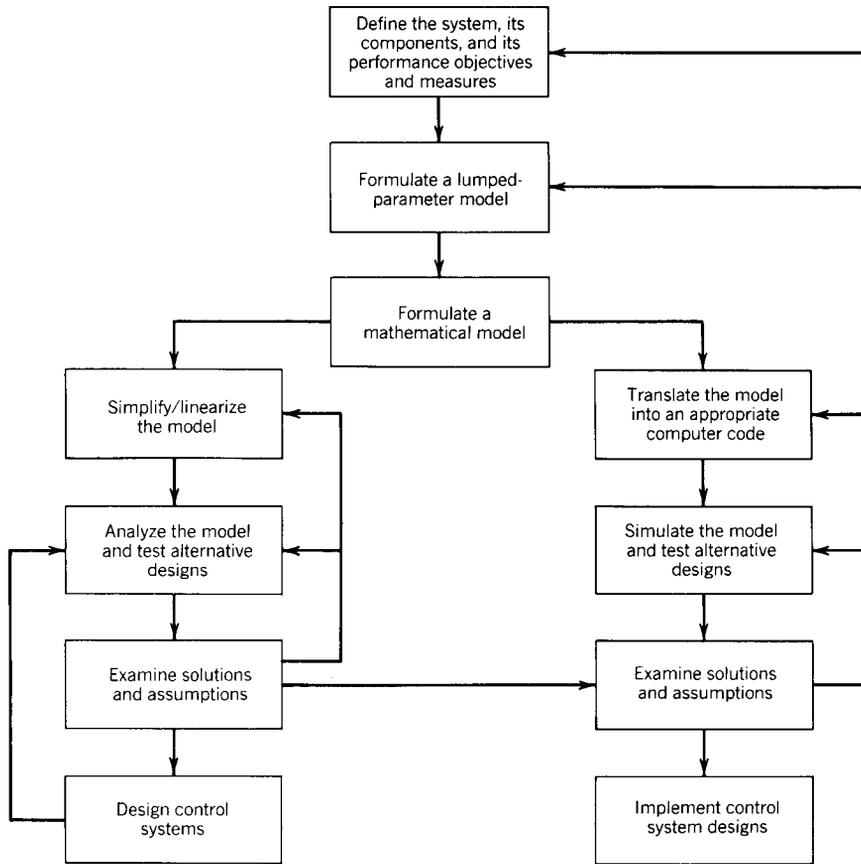

Fig. 1 Iterative approach to control system design, showing the use of mathematical analysis and computer simulation.

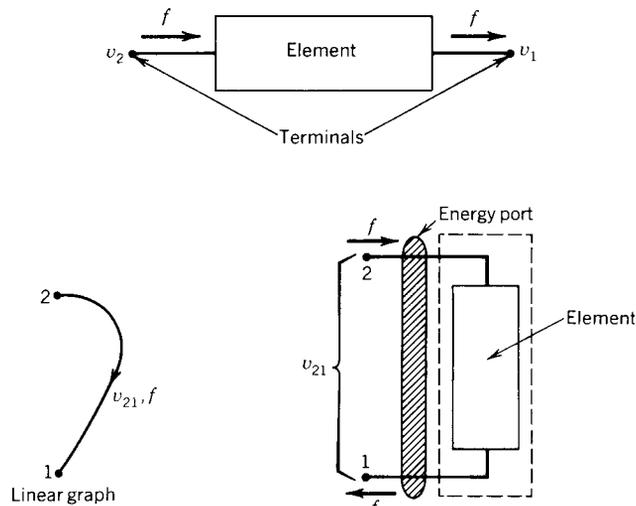

Fig. 2 Two-terminal or one-port element, showing through and across variables.¹

Table 1 Primary and Secondary Physical Variables for Various Systems

System	Through Variable f	Integrated through Variable h	Across Variable v	Integrated across Variable x
Mechanical–translational	Force F	Translational momentum p	Velocity difference v_{21}	Displacement difference x_{21}

associated through and across variables. For example, the momentum of a mass is an integrated through variable, representing the effect of forces on the mass integrated or accumulated over time. Table 1 define the primary and secondary physical variables for various physical systems.

2.2 Power and Energy

The flow of power $P(t)$ into an element through terminals 1 and 2 is the product of the through variable $f(t)$ and the difference between the across variables $v_2(t)$ and $v_1(t)$. Suppressing the notation for time dependence, this may be written as

$$P = f(v_2 - v_1) = f v_{21}$$

A negative value of power indicates that power flow out of the element. The energy $E(t_a, t_b)$ transferred to the element during the time interval from t_a to t_b is the integral of power, that is,

$$E = \int_{t_a}^{t_b} P dt = \int_{t_a}^{t_b} f v_{21} dt$$

A negative value of energy indicates a net transfer of energy out of the element during the corresponding time interval.

Thermal systems are an exception to these generalized energy relationships. For a thermal system, power is identically the through variable $q(t)$, heat flow. Energy is the integrated through variable $\mathcal{H}(t_a, t_b)$, the amount of heat transferred.

By the *first law of thermodynamics*, the net energy stored within a system at any given instant must equal the difference between all energy supplied to the system and all energy dissipated by the system. The generalized classification of elements given in the following sections is based on whether the element stores or dissipates energy within the system, supplies energy to the system, or transforms energy between parts of the system.

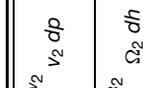

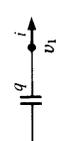

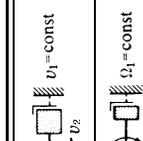

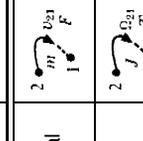

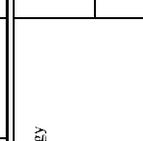

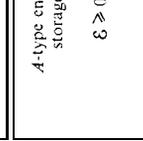

2.3 One-Port Element Laws

Physical devices are represented by idealized system elements, or by combinations of these elements. A physical device that exchanges energy with its environment through one pair of across and through variables is called a *one-port* or *two-terminal* element. The behavior of a one-port element expresses the relationship between the physical variables for that element. This behavior is define mathematically by a *constitutive relationship*. Constitutive relationships are derived empirically, by experimentation, rather than from any more fundamental principles. The *element law*, derived from the corresponding constitutive relationship, describes the behavior of an element in terms of across and through variables and is the form most commonly used to derive mathematical models.

Table 2 summarizes the element laws and constitutive relationships for the one-port elements. Passive elements are classified into three types. *T-type* or *inductive storage* elements are define by a single-valued constitutive relationship between the through variable $f(t)$ and the integrated across-variable difference $x_{21}(t)$. Differentiating the constitutive relationship yields the element law. For a linear (or ideal) *T-type* element, the element law states that the across-variable difference is proportional to the rate of change of the through variable. Pure translational and rotational compliance (springs), pure electrical inductance, and pure fluid inertance are examples of *T-type* storage elements. There is no corresponding thermal element.

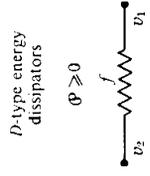

A-type or *capacitive storage elements* are define by a single-valued constitutive relationship between the across-variable difference $v_{21}(t)$ and the integrated through variable $h(t)$. These elements store energy by virtue of the across variable. Differentiating the constitutive relationship yields the element law. For a linear *A-type* element, the element law states that the through variable is proportional to the derivative of the across-variable difference. Pure translational and rotational inertia (masses) and pure electrical, fluid, and thermal capacitance are examples.

Table 2 Element Laws and Constitutive Relationships for Various One-Port Elements

Type of element	Physical element	Linear graph	Diagram	Constitutive relationship	Energy or power function	Ideal elemental equation	Ideal energy or power
F -type energy storage $\epsilon \geq 0$ 	Translational spring			$x_{21} = f(F)$	$\epsilon = \int_0^F f dx_{21}$	$v_{21} = \frac{1}{k} \frac{dF}{dt}$	$\epsilon = \frac{1}{2} \frac{F^2}{k}$
				$\Theta_{21} = f(T)$	$\epsilon = \int_0^T T d\Theta_{21}$	$\Omega_{21} = \frac{1}{K} \frac{dT}{dt}$	$\epsilon = \frac{1}{2} \frac{T^2}{K}$
Pure	Inductance			$\lambda_{21} = f(i)$	$\epsilon = \int_0^i i d\lambda_{21}$	$v_{21} = L \frac{di}{dt}$	$\epsilon = \frac{1}{2} L i^2$
				$\Gamma_{21} = f(Q)$	$\epsilon = \int_0^Q Q d\Gamma_{21}$	$P_{21} = I \frac{dQ}{dt}$	$\epsilon = \frac{1}{2} I Q^2$
A -type energy storage $\epsilon \geq 0$ 	Translational mass			$p = f(v_2)$	$\epsilon = \int_0^{v_2} v_2 dp$	$F = m \frac{dv_2}{dt}$	$\epsilon = \frac{1}{2} m v_2^2$
				$h = f(\Omega_2)$	$\epsilon = \int_0^{\Omega_2} \Omega_2 dh$	$T = J \frac{d\Omega_2}{dt}$	$\epsilon = \frac{1}{2} J \Omega_2^2$
Pure	Electrical capacitance			$q = f(v_{21})$	$\epsilon = \int_0^{v_{21}} v_{21} dq$	$i = C \frac{dv_{21}}{dt}$	$\epsilon = \frac{1}{2} C v_{21}^2$
				$V = f(P_2)$	$\epsilon = \int_0^{P_2} P_2 dV$	$Q = C_f \frac{dP_2}{dt}$	$\epsilon = \frac{1}{2} C_f P_2^2$
$\epsilon \geq 0$ 	Thermal capacitance			$\mathcal{H} = f(\theta_2)$	$\epsilon = \int_0^{\theta_2} q dt = \mathcal{H}$	$q = C_t \frac{d\theta_2}{dt}$	$\epsilon = C_t \theta_2$

Table 2 (Continued)

D -type energy dissipators 									
Pure	Idea								
$f = f(v_{21})$	$f = \frac{1}{R} v_{21}$		$F = f(v_{21})$	$F = bv_{21}$	$\mathcal{P} = Fv_{21}$				$\mathcal{P} = bv_{21}^2$
$\mathcal{P} = v_{21}f(v_{21})$	$\mathcal{P} = \frac{1}{R} v_{21}^2 = Rf^2$		$T = f(\Omega_{21})$	$T = B\Omega_{21}$	$\mathcal{P} = T\Omega_{21}$				$\mathcal{P} = B\Omega_{21}^2$
			$i = f(v_{21})$	$i = \frac{1}{R} v_{21}$	$\mathcal{P} = iv_{21}$				$\mathcal{P} = \frac{1}{R} v_{21}^2$
			$Q = f(p_{21})$	$Q = \frac{1}{R_f} p_{21}$	$\mathcal{P} = QP_{21}$				$\mathcal{P} = \frac{1}{R_f} P_{21}^2$
			$q = f(\theta_{21})$	$q = \frac{1}{R_f} \theta_{21}$	$\mathcal{P} = q$				$\mathcal{P} = \frac{1}{R_f} \theta_{21}^2$
Energy sources			$v_{21} = f(t)$		$\mathcal{P} = fv_{21}$				
$\mathcal{P} \geq 0$									
$\varepsilon \geq 0$			$f = f(t)$		$\mathcal{P} = fv_{21}$				

Nomenclature:

- λ = energy, \mathcal{P} = power
- f = generalized *throughvariable*, F = force, T = torque, i = current, Q = fluid flow rate, q = heat flow rate
- h = generalized integrated through variable, p = translational momentum, h = angular momentum, q = charge, l' = fluid volume displaced, \mathcal{H} = heat
- v = generalized across variable, v = translational velocity, Ω = angular velocity, v = voltage, P = pressure, θ = temperature
- x = generalized integrated across variable, x = translational displacement, θ = angular displacement, λ = flux linkage, Γ = pressure-momentum
- L = generalized ideal inductance, $1/k$ = reciprocal translational stiffness, $1/K$ = reciprocal rotational stiffness, L = inductance, l = fluid inductance
- C = generalized ideal capacitance, m = mass, J = moment of inertia, C = capacitance, C_j = fluid capacitance, C_t = thermal capacitance
- R = generalized ideal resistance, $1/b$ = reciprocal translational damping, $1/B$ = reciprocal rotational damping, R = electrical resistance, R_j = fluid resistance, R_t = thermal resistance

Source: From Ref. 1.

It is important to note that when a nonelectrical capacitance is represented by an *A*-type element, one terminal of the element must have a constant (reference) across variable, usually assumed to be zero. In a mechanical system, for example, this requirement expresses the fact that the velocity of a mass must be measured relative to a noninertial (nonaccelerating) reference frame. The constant-velocity terminal of a pure mass may be thought of as being attached in this sense to the reference frame.

D-type or resistive elements are defined by a single-valued constitutive relationship between the across and the through variables. These elements dissipate energy, generally by converting energy into heat. For this reason, power always flows into a *D*-type element. The element law for a *D*-type energy dissipator is the same as the constitutive relationship. For a linear dissipator, the through variable is proportional to the across-variable difference. Pure translational and rotational friction (dampers or dashpots) and pure electrical, fluid and thermal resistance are examples.

Energy storage and energy-dissipating elements are called *passive* elements because such elements do not supply outside energy to the system. The fourth set of one-port elements are *source elements*, which are examples of *active* or power-supplying elements. Ideal sources describe interactions between the system and its environment. A pure *A*-type source imposes an across-variable difference between its terminals, which is a prescribed function of time, regardless of the values assumed by the through variable. Similarly, a pure *T*-type source imposes a through-variable flow through the source element, which is a prescribed function of time, regardless of the corresponding across variable.

Pure system elements are used to represent physical devices. Such models are called *lumped-element models*. The derivation of lumped-element models typically requires some degree of approximation since (a) there rarely is a one-to-one correspondence between a physical device and a set of pure elements and (b) there

always is a desire to express an element law as simply as possible. For example, a coil spring has both mass and compliance. Depending on the context, the physical spring might be represented by a pure translational mass, or by a pure translational spring, or by some combination of pure springs and masses. In addition, the physical spring undoubtedly will have a nonlinear constitutive relationship over its full range of extension and compression. The compliance of the coil spring may well be represented by an ideal translational spring, however, if the physical spring is approximately linear over the range of extension and compression of concern.

2.4 Multiport Elements

A physical device that exchanges energy with its environment through two or more pairs of through and across variables is called a *multiport element*. The simplest of these, the idealized *four-terminal* or *two-port* element, is shown in Fig. 3. Two-port elements provide for transformations between the physical variables at different energy ports, while maintaining instantaneous continuity of power. In other words, net power flow into a two-port element is always identically zero:

$$P = f_a v_a + f_b v_b = 0$$

The particulars of the transformation between the variables define different categories of two-port elements.

A *pure transformer* is defined by a single-valued constitutive relationship between the integrated across variables or between the integrated through variables at each port:

$$x_b = f(x_a) \quad \text{or} \quad h_b = f(h_a)$$

For a linear (or ideal) transformer, the relationship is proportional, implying the following relationships

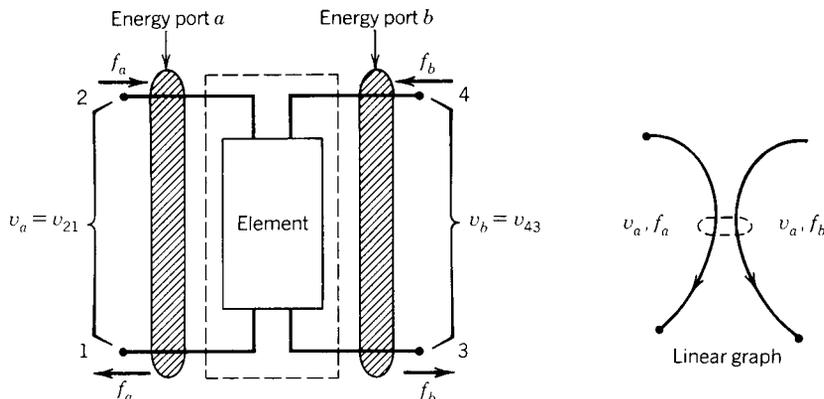

Fig. 3 Four-terminal or two-port element, showing through and across variables.

System	Symbol	Pure transformer	Ideal transformer	Transformation ratio
Mechanical translation (lever)		$x_{41} = f(x_{21})$	$v_{41} = n v_{21}$ $F_b = -\frac{1}{n} F_a$	$n = -\frac{r_b}{r_a}$ Lever ratio
Mechanical rotational (gears)		$\theta_{41} = f(\theta_2)$	$\Omega_{41} = n \Omega_{21}$ $T_b = -\frac{1}{n} T_a$	$n = -\frac{N_a}{N_b}$ Gear ratio
Electrical (magnetic)		$\lambda_{43} = f(\lambda_{21})$	$v_{43} = n v_{21}$ $i_b = -\frac{1}{n} i_a$	$n = \frac{N_b}{N_a}$ Turns ratio
Fluid (differential piston)		$V_b = f(V_a)$	$P_{41} = n P_{21}$ $Q_b = -\frac{1}{n} Q_a$	$n = \frac{A_a}{A_b}$ Area ratio

Fig. 4a Examples of transforms and transducers: (a) pure transformers (Ref. 1); (b) pure mechanical transformers and transforming transducers (Ref. 2).

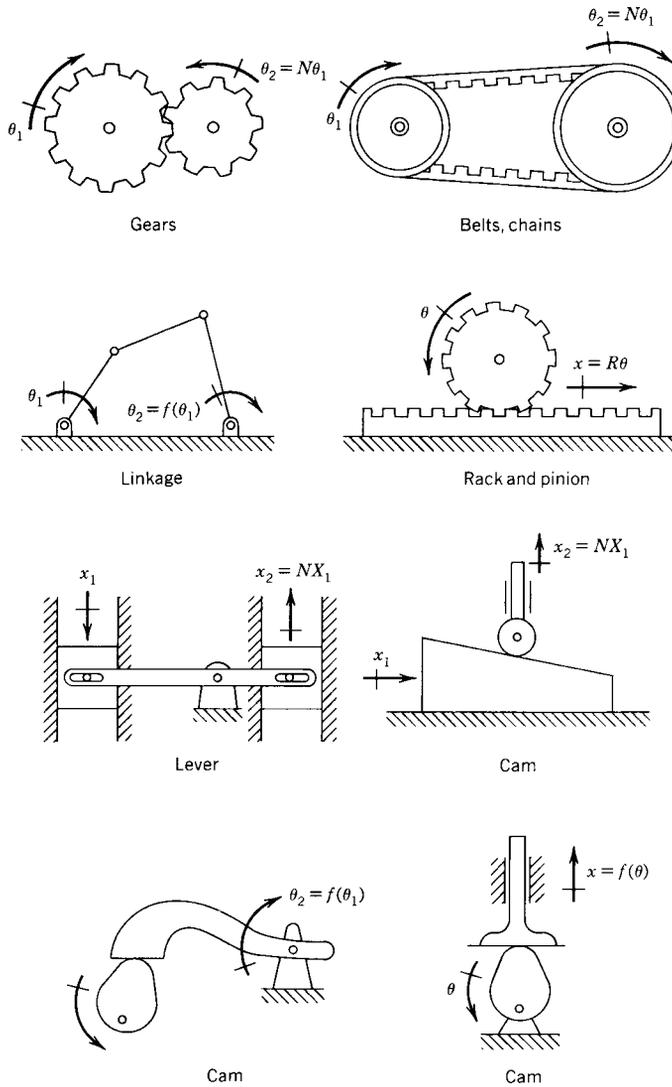

Fig. 4b (Continued)

between the primary variables:

$$v_b = nv_a \quad f_b = -\frac{1}{n} f_a$$

where the constant of proportionality n is called the *transformation ratio*. Levers, mechanical linkages, pulleys, gear trains, electrical transformers, and differential-area fluid pistons are examples of physical devices that typically can be approximated by pure or ideal transformers. Figure 12.4 depicts some examples. *Pure transmitters*, which serve to transmit energy over

a distance, frequently can be thought of as transformers with $n = 1$.

A *pure gyrator* is defined by a single-valued constitutive relationship between the across variable at one energy port and the through variable at the other energy port. For a linear gyrator, the following relations apply:

$$v_b = r f_a \quad f_b = \frac{-1}{r} v_a$$

where the constant of proportionality is called the *gyration ratio* or *gyrational resistance*. Physical devices that perform pure gyration are not as common as

those performing pure transformation. A mechanical gyroscope is one example of a system that might be modeled as a gyrator.

In the preceding discussion of two-port elements, it has been assumed that the type of energy is the same at both energy ports. A *pure transducer*, on the other hand, changes energy from one physical medium to another. This change may be accomplished as either a transformation or a gyration. Examples of *transforming transducers* are gears with racks (mechanical rotation to mechanical translation) and electric motors and electric generators (electrical to mechanical rotation and vice versa). Examples of *gyrating transducers* are the piston-and-cylinder (fluid to mechanical) and piezoelectric crystals (mechanical to electrical).

More complex systems may have a large number of energy ports. A common *six-terminal* or *three-port element* called a *modulator* is depicted in Fig. 5. The flow of energy between ports *a* and *b* is controlled by the energy input at the modulating port *c*. Such devices inherently dissipate energy, since

$$P_a + P_c \geq P_b$$

although most often the modulating power P_c is much smaller than the power input P_a or the power output P_b . When port *a* is connected to a pure source element, the combination of source and modulator is called a *pure dependent source*. When the modulating power P_c is considered the input and the modulated power P_b is considered the output, the modulator is called an *amplifier*. Physical devices that often can be modeled as modulators include clutches, fluid valves and couplings, switches, relays, transistors, and variable resistors.

3 SYSTEM STRUCTURE AND INTERCONNECTION LAWS

3.1 A Simple Example

Physical systems are represented by connecting the terminals of pure elements in patterns that approximate

the relationships among the properties of component devices. As an example, consider the mechanical-translational system depicted in Fig. 6a, which might represent an idealized automobile suspension system. The inertial properties associated with the masses of the chassis, passenger compartment, engine, and so on, all have been lumped together as the pure mass m_1 . The inertial properties of the unsprung components (wheels, axles, etc.) have been lumped into the pure mass m_2 . The compliance of the suspension is modeled as a pure spring with stiffness k_1 and the frictional effects (principally from the shock absorbers) as a pure damper with damping coefficient b . The road is represented as an input or source of vertical velocity, which is transmitted to the system through a spring of stiffness k_2 , representing the compliance of the tires.

3.2 Structure and Graphs

The *pattern of interconnections* among elements is called the *structure* of the system. For a one-dimensional system, structure is conveniently represented by a *system graph*. The system graph for the idealized automobile suspension system of Fig. 6a is shown in Fig. 6b. Note that each distinct across variable (velocity) becomes a distinct *node* in the graph. Each distinct through variable (force) becomes a *branch* in the graph. Nodes coincide with the terminals of elements and branches coincide with the elements themselves. One node always represents *ground* (the constant velocity of the inertial reference frame v_g), and this is usually assumed to be zero for convenience. For nonelectrical systems, all the *A*-type elements (masses) have one terminal connection to the reference node. Because the masses are not physically connected to ground, however, the convention is to represent the corresponding branches in the graph by dashed lines.

System graphs are oriented by placing arrows on the branches. The orientation is arbitrary and serves to assign reference directions for both the

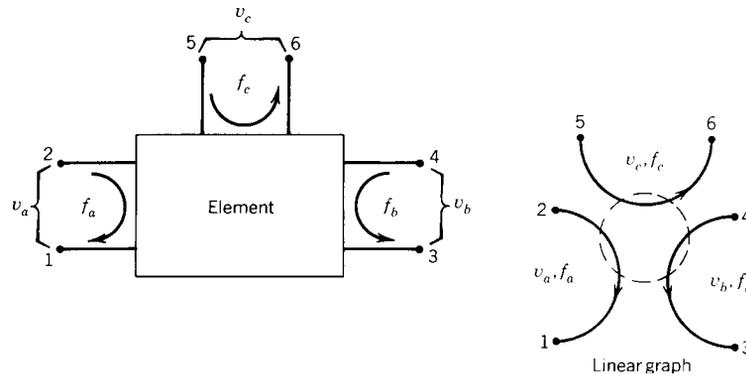

Fig. 5 Six-terminal or three-port element, showing through and across variables.

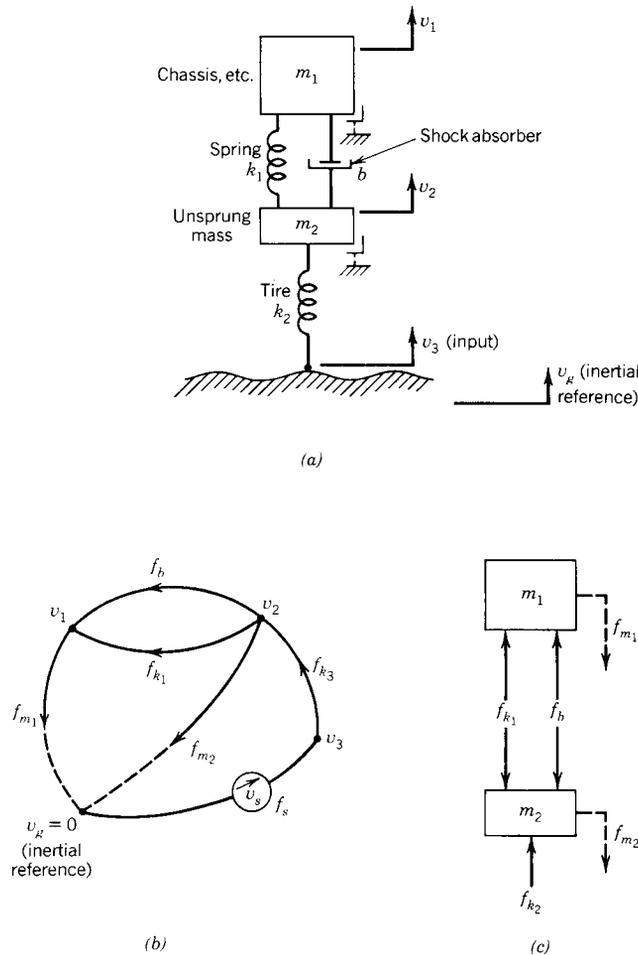

Fig. 6 Idealized model of automobile suspension system: (a) lumped-element model, (b) system graph, (c) free-body diagram.

through-variable and the across-variable difference. For example, the branch representing the damper in Fig. 6b is directed from node 2 (tail) to node 1 (head). This assigns $v_b = v_{21} = v_2 - v_1$ as the across-variable difference to be used in writing the damper elemental equation

$$f_b = bv_b = bv_{21}$$

The reference direction for the through variable is determined by the convention that power flow $P_b = f_b v_b$ into an element is positive. Referring to Fig. 6a, when v_{21} is positive, the damper is in compression. Therefore, f_b must be positive for compressive forces in order to obey the sign convention for power. By similar reasoning, tensile forces will be negative.

3.3 System Relations

The structure of a system gives rise to two sets of *interconnection laws* or *system relations*. Continuity relations apply to through variables and compatibility relations apply to across variables. The interpretation of system relations for various physical systems is given in Table 3.

Continuity is a general expression of dynamic equilibrium. In terms of the system graph, continuity states that the algebraic sum of all through variables entering a given node must be zero. Continuity applies at each node in the graph. For a graph with n nodes, continuity gives rise to n continuity equations, $n - 1$ of which are independent. For node i , the continuity equation is

$$\sum_j f_{ij} = 0$$

Table 3 System Relations for Various Systems

System	Continuity	Compatibility
Mechanical	Newton's first and third laws (conservation of momentum)	Geometrical constraints (distance is a scalar)
Electrical	Kirchhoff's current law (conservation of charge)	Kirchhoff's voltage law (potential is a scalar)
Fluid	Conservation of matter	Pressure is a scalar
Thermal	Conservation of energy	Temperature is a scalar

where the sum is taken over all branches (i, j) incident on i .

For the system graph depicted in Fig. 6b, the four continuity equations are

$$\begin{aligned} \text{Node 1:} & \quad f_{k_1} + f_b - f_{m_1} = 0 \\ \text{Node 2:} & \quad f_{k_2} - f_{k_1} + f_b - f_{m_2} = 0 \\ \text{Node 3:} & \quad f_s - f_{k_2} = 0 \\ \text{Node g:} & \quad f_{m_1} + f_{m_2} - f_s = 0 \end{aligned}$$

Only three of these four equations are independent. Note, also, that the equations for nodes 1–3 could have been obtained from the conventional *free-body diagrams* shown in Fig. 6c, where f_{m_1} and f_{m_2} are the *D'Alembert forces* associated with the pure masses. Continuity relations are also known as *vertex, node, flow, and equilibrium relations*.

Compatibility expresses the fact that the magnitudes of all across variables are scalar quantities. In terms of the system graph, compatibility states that the algebraic sum of the across-variable differences around any closed path in the graph must be zero. Compatibility applies to any closed path in the system. For convenience and to ensure the independence of the resulting equations, continuity is usually applied to the *meshes* or “windows” of the graph. A one-part graph with n nodes and b branches will have $b - n + 1$ meshes, each mesh yielding one independent compatibility equation. A planar graph with p separate parts (resulting from multipoint elements) will have $b - n + p$ independent compatibility equations. For a closed path q , the compatibility equation is

$$\sum_q v_{ij} = 0$$

where the summation is taken over all branches (i, j) on the path.

For the system graph depicted in Fig. 6b, the three compatibility equations based on the meshes are

$$\begin{aligned} \text{Path 1} \rightarrow 2 \rightarrow g \rightarrow 1: & \quad -v_b + v_{m_2} - v_{m_1} = 0 \\ \text{Path 1} \rightarrow 2 \rightarrow 1: & \quad -v_{k_1} + v_b = 0 \\ \text{Path 2} \rightarrow 3 \rightarrow g \rightarrow 2: & \quad -v_{k_2} - v_s - v_{m_2} = 0 \end{aligned}$$

These equations are all mutually independent and express apparent geometric identities. The first equation, for example, states that the velocity difference between the ends of the damper is identically the difference between the velocities of the masses it connects. Compatibility relations are also known as *path, loop, and connectedness* relations.

3.4 Analogs and Duals

Taken together, the element laws and system relations are a complete mathematical model of a system. When expressed in terms of generalized through and across variables, the model applies not only to the physical system for which it was derived, but also to any physical system with the same generalized system graph. Different physical systems with the same generalized model are called *analogs*. The mechanical rotational, electrical, and fluid analogs of the mechanical translational system of Fig. 6a are shown in Fig. 7. Note that because the original system contains an inductive storage element, there is no thermal analog.

Systems of the same physical type but in which the roles of the through variables and the across variables have been interchanged are called *duals*. The analog of a dual—or, equivalently, the dual of an analog—is sometimes called a *dualog*. The concepts of analogy and duality can be exploited in many different ways.

4 STANDARD FORMS FOR LINEAR MODELS

The element laws and system relations together constitute a complete mathematical description of a physical system. For a system graph with n nodes, b branches, and s sources, there will be $b - s$ element laws, $n - 1$ continuity equations, and $b - n + 1$ compatibility equations. This is a total of $2b - s$ differential and algebraic equations. For systems composed entirely of linear elements, it is always possible to reduce these $2b - s$ equations to either of two standard forms. The *input/output*, or *I/O*, form is the basis for *transform* or so-called *classical linear systems analysis*. The *state-variable form* is the basis for *state-variable* or so-called *modern linear systems analysis*.

4.1 I/O Form

The classical representation of a system is the “black-box,” depicted in Fig. 8. The system has a set of p *inputs* (also called *excitations* or *forcing functions*), $u_j(t)$, $j = 1, 2, \dots, p$. The system also has a set of

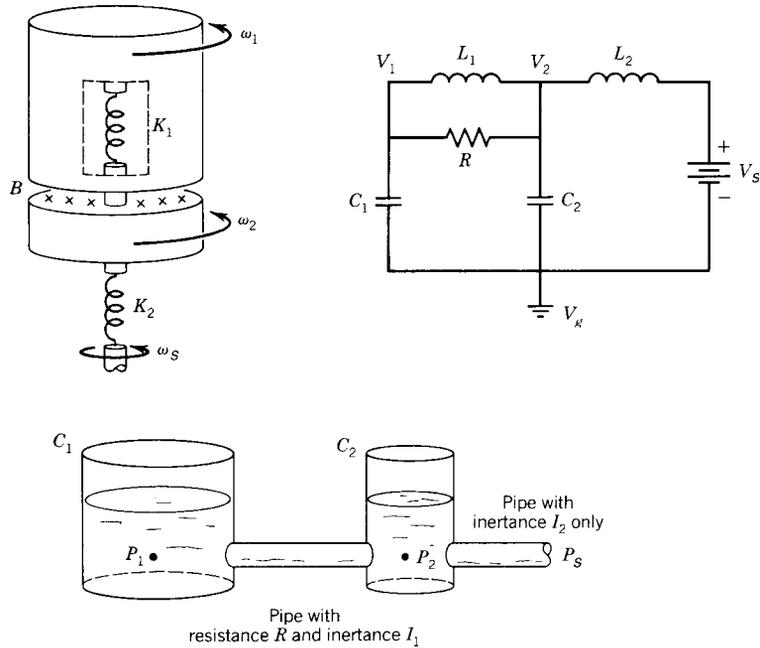

Fig. 7 Analogs of the idealized automobile suspension system depicted in Fig. 6.

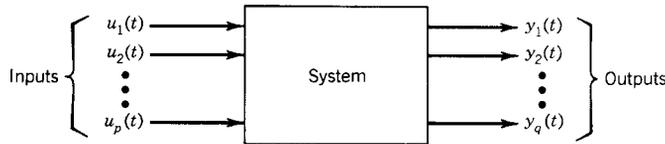

Fig. 8 Input/output (I/O), or blackbox, representation of a dynamic system.

q outputs (also called *response variables*), $y_k(t)$, $k = 1, 2, \dots, q$. Inputs correspond to sources and are assumed to be known functions of time. Outputs correspond to physical variables that are to be measured or calculated.

Linear systems represented in I/O form can be modeled mathematically by *I/O differential equations*. Denoting as $y_{kj}(t)$ that part of the k th output $y_k(t)$ that is attributable to the j th input $u_j(t)$, there are $(p \times q)$ I/O equations of the form

$$\begin{aligned} \frac{d^n y_{kj}}{dt^n} + a_{n-1} \frac{d^{n-1} y_{kj}}{dt^{n-1}} + \dots + a_1 \frac{dy_{kj}}{dt} + a_0 y_{kj}(t) \\ = b_m \frac{d^m u_j}{dt^m} + b_{m-1} \frac{d^{m-1} u_j}{dt^{m-1}} + \dots + b_1 \frac{du_j}{dt} + b_0 u_j(t) \end{aligned}$$

where $j = 1, 2, \dots, p$ and $k = 1, 2, \dots, q$. Each equation represents the dependence of one output and its derivatives on one input and its derivatives. By the

principle of superposition, the k th output in response to all of the inputs acting simultaneously is

$$y_k(t) = \sum_{j=1}^p y_{kj}(t)$$

A system represented by n th-order I/O equations is called an *n th-order system*. In general, the order of a system is determined by the number of *independent* energy storage elements within the system, that is, by the combined number of *T*-type and *A*-type elements for which the initial energy stored can be independently specified

The coefficients a_0, a_1, \dots, a_{n-1} and b_0, b_1, \dots, b_m are parameter groups made up of algebraic combinations of the system physical parameters. For a system with constant parameters, therefore, these coefficients are also constant. Systems with constant parameters are called *time-invariant* systems and are the basis for classical analysis.

4.2 Deriving I/O Form: Example

I/O differential equations are obtained by combining element laws and continuity and compatibility equations in order to eliminate all variables except the input and the output. As an example, consider the mechanical system depicted in Fig. 9a, which might represent an idealized milling machine. A rotational motor is used to position the table of the machine tool through a rack and pinion. The motor is represented as a torque source T with inertia J and internal friction B . A flexible shaft, represented as a torsional spring K , is connected to a pinion gear of radius R . The pinion meshes with a rack, which is rigidly attached to the table of mass m . Damper b represents the friction opposing the motion of the table. The problem is to determine the I/O equation that expresses the relationship between the input torque T and the position of the table x .

The corresponding system graph is depicted in Fig. 9b. Applying continuity at nodes 1, 2, and 3 yields

$$\begin{aligned} \text{Node 1: } & T - T_J - T_B - T_K = 0 \\ \text{Node 2: } & T_K - T_p = 0 \\ \text{Node 3: } & -f_r - f_m - f_b = 0 \end{aligned}$$

Substituting the elemental equation for each of the one-port elements into the continuity equations and assuming zero ground velocities yield

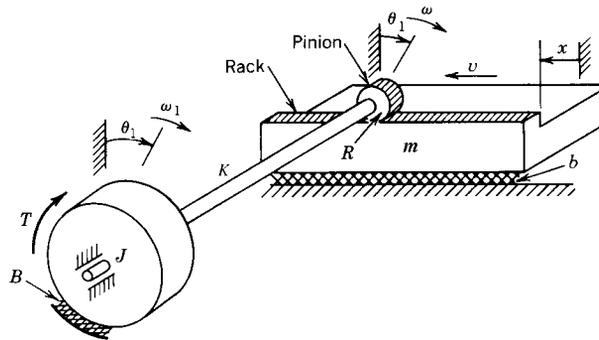

$$\begin{aligned} \text{Node 1: } & T - J\dot{\omega}_1 - B\omega_1 - K \int (\omega_1 - \omega_2) dt = 0 \\ \text{Node 2: } & K \int (\omega_1 - \omega_2) dt - T_p = 0 \\ \text{Node 3: } & -f_r - m\dot{v} - bv = 0 \end{aligned}$$

Note that the definition of the across variables for each element in terms of the node variables, as above, guarantees that the compatibility equations are satisfied. With the addition of the constitutive relationships for the rack and pinion

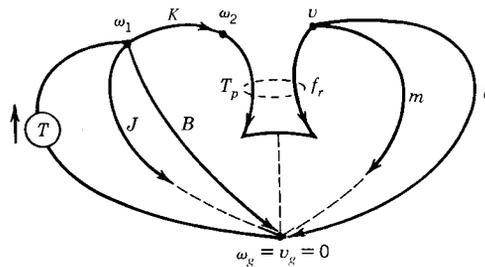

$$\omega_2 = \frac{1}{R}v \quad \text{and} \quad T_p = -Rf_r$$

there are now five equations in the five unknowns $\omega_1, \omega_2, v, T_p,$ and f_r . Combining these equations to eliminate all of the unknowns except v yields, after some manipulation,

$$a_3 \frac{d^3v}{dt^3} + a_2 \frac{d^2v}{dt^2} + a_1 \frac{dv}{dt} + a_0v = b_1T$$

(a)

(b)

Fig. 9 Idealized model of milling machine: (a) lumped-element model (Ref. 3), (b) system graph.

where

$$a_3 = Jm \quad a_1 = \frac{JK}{R^2} + Bb + mK \quad b_1 = \frac{K}{R}$$

$$a_2 = Jb + mB \quad a_0 = \frac{BK}{R^2} + Kb$$

Differentiating yields the desired I/O equation

$$a_3 \frac{d^3x}{dt^3} + a_2 \frac{d^2x}{dt^2} + a_1 \frac{dx}{dt} + a_0x = b_1 \frac{dT}{dt}$$

where the coefficient are unchanged.

For many systems, combining element laws and system relations can best be achieved by ad hoc procedures. For more complicated systems, formal methods are available for the orderly combination and reduction of equations. These are the so-called *loop method* and *node method* and correspond to procedures of the same names originally developed in connection with electrical networks. The interested reader should consult Ref. 1.

4.3 State-Variable Form

For systems with multiple inputs and outputs, the I/O model form can become unwieldy. In addition, important aspects of system behavior can be suppressed in deriving I/O equations. The "modern" representation of dynamic systems, called the *state-variable form*, largely eliminates these problems. A state-variable model is the maximum reduction of the original element laws and system relations that can be achieved without the loss of any information concerning the behavior of a system. State-variable models also provide a convenient representation for systems with multiple inputs and outputs and for systems analysis using computer simulation.

State variables are a set of variables $x_1(t)$, $x_2(t)$, \dots , $x_n(t)$ internal to the system from which any set of outputs can be derived, as depicted schematically in Fig. 10. A set of state variables is the minimum number of independent variables such that by knowing the values of these variables at any time t_0 and by knowing the values of the inputs for all time $t \geq t_0$, the

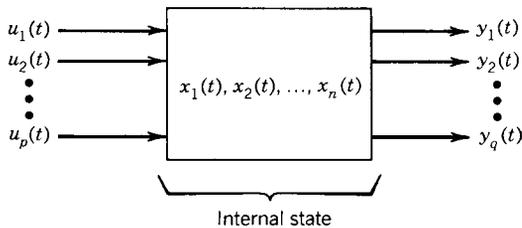

Fig. 10 State-variable representation of a dynamic system.

values of the state variables for all future time $t \geq t_0$ can be calculated. For a given system, the number n of state variables is unique and is equal to the order of the system. The definition of the state variables is not unique, however, and various combinations of one set of state variables can be used to generate alternative sets of state variables. For a physical system, the state variables summarize the *energy state* of the system at any given time.

A complete state-variable model consists of two sets of equations, the *state* or *plant equations* and the *output equations*. For the most general case, the state equations have the form

$$\dot{x}_1(t) = f_1[x_1(t), x_2(t), \dots, x_n(t), u_1(t), u_2(t), \dots, u_p(t)]$$

$$\dot{x}_2(t) = f_2[x_1(t), x_2(t), \dots, x_n(t), u_1(t), u_2(t), \dots, u_p(t)]$$

⋮

$$\dot{x}_n(t) = f_n[x_1(t), x_2(t), \dots, x_n(t), u_1(t), u_2(t), \dots, u_p(t)]$$

and the output equations have the form

$$y_1(t) = g_1[x_1(t), x_2(t), \dots, x_n(t), u_1(t), u_2(t), \dots, u_p(t)]$$

$$y_2(t) = g_2[x_1(t), x_2(t), \dots, x_n(t), u_1(t), u_2(t), \dots, u_p(t)]$$

⋮

$$y_q(t) = g_q[x_1(t), x_2(t), \dots, x_n(t), u_1(t), u_2(t), \dots, u_p(t)]$$

These equations are expressed more compactly as the two vector equations

$$\dot{x}(t) = f[x(t), u(t)] \quad y(t) = g[x(t), u(t)]$$

where

$$\dot{x}(t) = n \times 1 \text{ state vector}$$

$$u(t) = p \times 1 \text{ input or control vector}$$

$$y(t) = q \times 1 \text{ output or response vector}$$

and f and g are vector-valued functions.

For linear systems, the state equations have the form

$$\dot{x}_1(t) = a_{11}(t)x_1(t) + \dots + a_{1n}(t)x_n(t) + b_{11}(t)u_1(t) + \dots + b_{1p}(t)u_p(t)$$

$$\dot{x}_2(t) = a_{21}(t)x_1(t) + \dots + a_{2n}(t)x_n(t) + b_{21}(t)u_1(t) + \dots + b_{2p}(t)u_p(t)$$

⋮

$$\dot{x}_n(t) = a_{n1}(t)x_1(t) + \dots + a_{nn}(t)x_n(t) + b_{n1}(t)u_1(t) + \dots + b_{np}(t)u_p(t)$$

and the output equations have the form

$$\begin{aligned}
 y_1(t) &= c_{11}(t)x_1(t) + \cdots + c_{1n}(t)x_n(t) \\
 &\quad + d_{11}(t)u_1(t) + \cdots + d_{1p}(t)u_p(t) \\
 y_2(t) &= c_{21}(t)x_1(t) + \cdots + c_{2n}(t)x_n(t) \\
 &\quad + d_{21}(t)u_1(t) + \cdots + d_{2p}(t)u_p(t) \\
 &\quad \vdots \\
 y_n(t) &= c_{q1}(t)x_1(t) + \cdots + c_{qn}(t)x_n(t) \\
 &\quad + d_{q1}(t)u_1(t) + \cdots + d_{qp}(t)u_p(t)
 \end{aligned}$$

where the coefficient are groups of parameters. The linear model is expressed more compactly as the two linear vector equations

$$\begin{aligned}
 \dot{x}(t) &= A(t)x(t) + B(t)u(t) \\
 y(t) &= C(t)x(t) + D(t)u(t)
 \end{aligned}$$

where the vectors x , u , and y are the same as the general case and the matrices are define as

- $A = [a_{ij}]$ is the $n \times n$ system matrix
- $B = [b_{jk}]$ is the $n \times p$ control, input, or distribution matrix
- $C = [c_{lj}]$ is the $q \times n$ output matrix
- $D = [d_{lk}]$ is the $q \times p$ output distribution matrix

For a time-invariant linear system, all of these matrices are constant.

4.4 Deriving “Natural” State Variables

Procedure Because the state variables for a system are not unique, there are an unlimited number of alternative (but equivalent) state-variable models for the system. Since energy is stored only in generalized system storage elements, however, a natural choice for the state variables is the set of through and across variables corresponding to the independent T -type and A -type elements, respectively. This definitio is sometimes called the set of *natural state variables* for the system.

For linear systems, the following procedure can be used to reduce the set of element laws and system relations to the natural state-variable model.

Step 1. For each independent T -type storage, write the element law with the derivative of the through variable isolated on the left-hand side, that is, $\dot{f} = L^{-1}v$.

Step 2. For each independent A -type storage, write the element law with the derivative of the across variable isolated on the left-hand side, that is, $\dot{v} = C^{-1}f$.

Step 3. Solve the compatibility equations, together with the element laws for the appropriate D -type and multiport elements, to obtain each of the across variables of the independent T -type elements in terms of the natural state variables and specific sources.

Step 4. Solve the continuity equations, together with the element laws for the appropriate D -type and multiport elements, to obtain the through variables of the A -type elements in terms of the natural state variables and specific sources.

Step 5. Substitute the results of step 3 into the results of step 1; substitute the results of step 4 into the results of step 2.

Step 6. Collect terms on the right-hand side and write in vector form.

Example The six-step process for deriving a natural state-variable representation, outlined in the preceding section, is demonstrated for the idealized automobile suspension depicted in Fig. 6:

Step 1

$$\dot{f}_{k_1} = k_1 v_{k_1} \quad \dot{f}_{k_2} = k_2 v_{k_2}$$

Step 2

$$\dot{v}_{m_1} = m_1^{-1} f_{m_1} \quad \dot{v}_{m_2} = m_2^{-1} f_{m_2}$$

Step 3

$$v_{k_1} = v_b = v_{m_2} - v_{m_1} \quad v_{k_2} = -v_{m_2} - v_s$$

Step 4

$$\begin{aligned}
 f_{m_1} &= f_{k_1} + f_b = f_{k_1} + b^{-1}(v_{m_2} - v_{m_1}) \\
 f_{m_2} &= f_{k_2} - f_{k_1} - f_b = f_{k_2} - f_{k_1} - b^{-1}(v_{m_2} - v_{m_1})
 \end{aligned}$$

Step 5

$$\begin{aligned}
 \dot{f}_{k_1} &= k_1(v_{m_2} - v_{m_1}) \\
 \dot{v}_{m_1} &= m_1^{-1}[f_{k_1} + b^{-1}(v_{m_2} - v_{m_1})] \\
 \dot{f}_{k_2} &= k_2(-v_{m_2} - v_s) \\
 \dot{v}_{m_2} &= m_2^{-1}[f_{k_2} - f_{k_1} - b^{-1}(v_{m_2} - v_{m_1})]
 \end{aligned}$$

Step 6

$$\frac{d}{dt} \begin{bmatrix} f_{k_1} \\ f_{k_2} \\ v_{m_1} \\ v_{m_2} \end{bmatrix} = \begin{bmatrix} 0 & 0 & -k_1 & k_1 \\ 0 & 0 & 0 & -k_2 \\ 1/m_1 & 0 & -1/m_1 b & 1/m_1 b \\ -1/m_2 & 1/m_2 & 1/m_2 b & -1/m_2 b \end{bmatrix} \times \begin{bmatrix} f_{k_1} \\ f_{k_2} \\ v_{m_1} \\ v_{m_2} \end{bmatrix} + \begin{bmatrix} 0 \\ -k_2 \\ 0 \\ 0 \end{bmatrix} v_s$$

4.5 Converting from I/O to Phase-Variable Form

Frequently, it is desired to determine a state-variable model for a dynamic system for which the I/O equation is already known. Although an unlimited number of such models is possible, the easiest to determine uses a special set of state variables called the *phase variables*. The phase variables are defined in terms of the output and its derivatives as follows:

$$\begin{aligned} x_1(t) &= y(t) \\ x_2(t) &= \dot{x}_1(t) = \frac{d}{dt} y(t) \\ x_3(t) &= \dot{x}_2(t) = \frac{d^2}{dt^2} y(t) \\ &\vdots \\ x_n(t) &= \dot{x}_{n-1}(t) = \frac{d^{n-1}}{dt^{n-1}} y(t) \end{aligned}$$

This definition of the phase variables, together with the I/O equation of Section 4.1, can be shown to result in a state equation of the form

$$\frac{d}{dt} \begin{bmatrix} x_1(t) \\ x_2(t) \\ \vdots \\ x_{n-1}(t) \\ x_n(t) \end{bmatrix} = \begin{bmatrix} 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & 1 \\ -a_0 & -a_1 & -a_2 & \cdots & -a_{n-1} \end{bmatrix} \times \begin{bmatrix} x_1(t) \\ x_2(t) \\ \vdots \\ x_{n-1}(t) \\ x_n(t) \end{bmatrix} + \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 0 \\ 1 \end{bmatrix} u(t)$$

and an output equation of the form

$$y(t) = [b_0 \ b_1 \ \cdots \ b_m] \begin{bmatrix} x_1(t) \\ x_2(t) \\ \vdots \\ x_n(t) \end{bmatrix}$$

This special form of the system matrix, with 1's along the upper off-diagonal and 0's elsewhere except for the bottom row, is called a *companion matrix*.

5 APPROACHES TO LINEAR SYSTEMS ANALYSIS

There are two fundamental approaches to the analysis of linear, time-invariant systems. *Transform methods* use rational functions obtained from the Laplace transformation of the system I/O equations. Transform methods provide a particularly convenient algebra for combining the component submodels of a system and form the basis of so-called *classical control theory*. *State-variable methods* use the vector state and output equations directly. State-variable methods permit the adaptation of important ideas from linear algebra and form the basis for so-called *modern control theory*. Despite the deceiving names of "classical" and "modern," the two approaches are complementary. Both approaches are widely used in current practice and the control engineer must be conversant with both.

5.1 Transform Methods

A *transformation* converts a given mathematical problem into an equivalent problem, according to some well-defined rule called a *transform*. Prudent selection of a transform frequently results in an equivalent problem that is easier to solve than the original. If the solution to the original problem can be recovered by an inverse transformation, the three-step process of (a) transformation, (b) solution in the *transform domain*, and (c) inverse transformation may prove more attractive than direct solution of the problem in the original problem domain. This is true for fixed linear dynamic systems under the *Laplace transform*, which converts differential equations into equivalent algebraic equations.

Laplace Transforms: Definition The one-sided Laplace transform is defined as

$$F(s) = \mathcal{L}[f(t)] = \int_0^{\infty} f(t)e^{-st} dt$$

and the inverse transform as

$$f(t) = \mathcal{L}^{-1}[F(s)] = \frac{1}{2\pi j} \int_{\sigma-j\omega}^{\sigma+j\omega} F(s)e^{-st} ds$$

The Laplace transform converts the function $f(t)$ into the transformed function $F(s)$; the inverse transform recovers $f(t)$ from $F(s)$. The symbol \mathcal{L} stands for the "Laplace transform of"; the symbol \mathcal{L}^{-1} stands for "the inverse Laplace transform of."

The Laplace transform takes a problem given in the *time domain*, where all physical variables are functions

of the *real variable* t , into the *complex-frequency domain*, where all physical variables are functions of the complex frequency $s = \sigma + j\omega$, where $j = \sqrt{-1}$ is the imaginary operator. Laplace transform pairs consist of the function $f(t)$ and its transform $F(s)$. Transform pairs can be calculated by substituting $f(t)$ into the definin equation and then evaluating the integral with s held constant. For a transform pair to exist, the corresponding integral must converge, that is,

$$\int_0^\infty |f(t)|e^{-\sigma^*t} dt < \infty$$

for some real $\sigma^* > 0$. Signals that are physically realizable always have a Laplace transform.

Tables of Transform Pairs and Transform Properties Transform pairs for functions commonly encountered in the analysis of dynamic systems rarely need to be calculated. Instead, pairs are determined by reference to a *table of transforms* such as that given in Table 4. In addition, the Laplace transform has a number of properties that are useful in determining the transforms and inverse transforms of functions in terms of the tabulated pairs. The most important of these are given in a *table of transform properties* such as that given in Table 5.

Table 4 Laplace Transform Pairs

$F(s)$	$f(t), t \geq 0$
1. 1	$\delta(t)$, the unit impulse at $t = 0$
2. $\frac{1}{s}$	1, the unit step
3. $\frac{n!}{s^{n+1}}$	t^n
4. $\frac{1}{s+a}$	e^{-at}
5. $\frac{1}{(s+a)^n}$	$\frac{1}{(n-1)!}t^{n-1}e^{-at}$
6. $\frac{a}{s(s+a)}$	$1 - e^{-at}$
7. $\frac{1}{(s+a)(s+b)}$	$\frac{1}{b-a}(e^{-at} - e^{-bt})$
8. $\frac{s+p}{(s+a)(s+b)}$	$\frac{1}{b-a}[(p-a)e^{-at} - (p-b)e^{-bt}]$
9. $\frac{1}{(s+a)(s+b)(s+c)}$	$\frac{e^{-at}}{(b-a)(c-a)} + \frac{e^{-bt}}{(c-b)(a-b)} + \frac{e^{-ct}}{(a-c)(b-c)}$
10. $\frac{s+p}{(s+a)(s+b)(s+c)}$	$\frac{(p-a)e^{-at}}{(b-a)(c-a)} + \frac{(p-b)e^{-bt}}{(c-b)(a-b)} + \frac{(p-c)e^{-ct}}{(a-c)(b-c)}$
11. $\frac{b}{s^2+b^2}$	$\sin bt$
12. $\frac{s}{s^2+b^2}$	$\cos bt$
13. $\frac{b}{(s+a)^2+b^2}$	$e^{-at} \sin bt$
14. $\frac{s+a}{(s+a)^2+b^2}$	$e^{-at} \cos bt$
15. $\frac{\omega_n^2}{s^2+2\zeta\omega_n s+\omega_n^2}$	$\frac{\omega_n}{\sqrt{1-\zeta^2}}e^{-\zeta\omega_n t} \sin \omega_n \sqrt{1-\zeta^2}t, \quad \zeta < 1$
16. $\frac{\omega_n^2}{s(s^2+2\zeta\omega_n s+\omega_n^2)}$	$1 + \frac{1}{\sqrt{1-\zeta^2}}e^{-\zeta\omega_n t} \sin(\omega_n \sqrt{1-\zeta^2}t + \phi)$ $\phi = \tan^{-1} \frac{\sqrt{1-\zeta^2}}{\zeta} + \pi$ (third quadrant)

Table 5 Laplace Transform Properties

$f(t)$	$F(s) = \int_0^{\infty} f(t)e^{-st} dt$
1. $af_1(t) + bf_2(t)$	$aF_1(s) + bF_2(s)$
2. $\frac{df}{dt}$	$sF(s) - f(0)$
3. $\frac{d^2f}{dt^2}$	$s^2F(s) - sf(0) - \left. \frac{df}{dt} \right _{t=0}$
4. $\frac{d^nf}{dt^n}$	$s^nF(s) - \sum_{k=1}^n s^{n-k}g_{k-1}$ $g_{k-1} = \left. \frac{d^{k-1}f}{dt^{k-1}} \right _{t=0}$
5. $\int_0^t f(t) dt$	$\frac{F(s)}{s} + \frac{h(0)}{s}$ $h(0) = \int f(t) dt \Big _{t=0}$
6. $\begin{cases} 0 & t < D \\ f(t-D) & t \geq D \end{cases}$	$e^{-sD}F(s)$
7. $e^{-at}f(t)$	$F(s+a)$
8. $f\left(\frac{t}{a}\right)$	$aF(as)$
9. $f(t) = \int_0^t x(t-\tau)y(\tau) d\tau$ $= \int_0^t y(t-\tau)x(\tau) d\tau$	$F(s) = X(s)Y(s)$
10. $f(\infty) = \lim_{s \rightarrow 0} sF(s)$	
11. $f(0+) = \lim_{s \rightarrow \infty} sF(s)$	

Poles and Zeros The response of a dynamic system most often assumes the following form in the complex-frequency domain:

$$F(s) = \frac{N(s)}{D(s)} = \frac{b_m s^m + b_{m-1} s^{m-1} + \cdots + b_1 s + b_0}{s^n + a_{n-1} s^{n-1} + \cdots + a_1 s + a_0} \quad (1)$$

Functions of this form are called *rational functions* because these are the ratio of two polynomials $N(s)$ and $D(s)$. If $n \geq m$, then $F(s)$ is a *proper rational function*; if $n > m$, then $F(s)$ is a *strictly proper rational function*.

In factored form, the rational function $F(s)$ can be written as

$$F(s) = \frac{N(s)}{D(s)} = \frac{b_m (s - z_1)(s - z_2) \cdots (s - z_m)}{(s - p_1)(s - p_2) \cdots (s - p_n)} \quad (2)$$

The roots of the numerator polynomial $N(s)$ are denoted by z_j , $j = 1, 2, \dots, m$. These numbers are

called the *zeros* of $F(s)$, since $F(z_j) = 0$. The roots of the denominator polynomial are denoted by p_i , $1, 2, \dots, n$. These numbers are called the *poles* of $F(s)$ since $\lim_{s \rightarrow p_i} F(s) = \pm\infty$.

Inversion by Partial-Fraction Expansion The *partial-fraction expansion theorem* states that a strictly proper rational function $F(s)$ with *distinct (nonrepeated) poles* p_i , $i = 1, 2, \dots, n$, can be written as the sum

$$F(s) = \frac{A_1}{s - p_1} + \frac{A_2}{s - p_2} + \cdots + \frac{A_n}{s - p_n} = \sum_{i=1}^n A_i \left(\frac{1}{s - p_i} \right) \quad (3)$$

where the A_i , $i = 1, 2, \dots, n$, are constants called *residues*. The inverse transform of $F(s)$ has the simple form

$$f(t) = A_1 e^{p_1 t} + A_2 e^{p_2 t} + \cdots + A_n e^{p_n t} = \sum_{i=1}^n A_i e^{p_i t}$$

The *Heaviside expansion theorem* gives the following expression for calculating the residue at the pole p_i ,

$$A_i = (s - p_i)F(s)|_{s=p_i} \quad \text{for } i = 1, 2, \dots, n$$

These values can be checked by substituting into Eq. (3), combining the terms on the right-hand side of Eq. (3), and showing that the result yields the values for all the coefficients b_j , $j = 1, 2, \dots, m$, originally specified in the form of Eq. (3).

Repeated Poles When two or more poles of a strictly proper rational function are identical, the poles are said to be *repeated* or *nondistinct*. If a pole is repeated q times, that is, if $p_i = p_{i+1} = \dots = p_{i+q-1}$, then the pole is said to be of *multiplicity* q . A strictly proper rational function with a pole of multiplicity q will contain q terms of the form

$$\frac{A_{i1}}{(s - p_i)^q} + \frac{A_{i2}}{(s - p_i)^{q-1}} + \dots + \frac{A_{iq}}{s - p_i}$$

in addition to the terms associated with the distinct poles. The corresponding terms in the inverse transform are

$$\left(\frac{1}{(q-1)!} A_{i1} t^{(q-1)} + \frac{1}{(q-2)!} A_{i2} t^{(q-2)} + \dots + A_{iq} \right) e^{p_i t}$$

The corresponding residues are

$$A_{i1} = (s - p_i)^q F(s)|_{s=p_i}$$

$$A_{i2} = \left(\frac{d}{ds} [(s - p_i)^q F(s)] \right) \Big|_{s=p_i}$$

⋮

$$A_{iq} = \frac{1}{(q-1)!} \left(\frac{d^{(q-1)}}{ds^{(q-1)}} [(s - p_i)^q F(s)] \right) \Big|_{s=p_i}$$

Complex Poles A strictly proper rational function with complex-conjugate poles can be inverted using partial-fraction expansion. Using a method called *completing the square*, however, is almost always easier. Consider the function

$$\begin{aligned} F(s) &= \frac{B_1 s + B_2}{(s + \sigma - j\omega)(s + \sigma + j\omega)} \\ &= \frac{B_1 s + B_2}{s^2 + 2\sigma s + \sigma^2 + \omega^2} \\ &= \frac{B_1 s + B_2}{(s + \sigma)^2 + \omega^2} \end{aligned}$$

From the transform tables the Laplace inverse is

$$\begin{aligned} f(t) &= e^{-\sigma t} [B_1 \cos \omega t + B_3 \sin \omega t] \\ &= K e^{-\sigma t} \cos(\omega t + \phi) \end{aligned}$$

where

$$\begin{aligned} B_3 &= \left(\frac{1}{\omega} \right) (B_2 - a B_1) \quad K = \sqrt{B_1^2 + B_3^2} \\ \phi &= -\tan^{-1} \left(\frac{B_3}{B_1} \right) \end{aligned}$$

Proper and Improper Rational Functions If $F(s)$ is not a strictly proper rational function, then $N(s)$ must be divided by $D(s)$ using *synthetic division*. The result is

$$F(s) = \frac{N(s)}{D(s)} = P(s) + \frac{N^*(s)}{D(s)}$$

where $P(s)$ is a polynomial of degree $m - n$ and $N^*(s)$ is a polynomial of degree $n - 1$. Each term of $P(s)$ may be inverted directly using the transform tables. The strictly proper rational function $N^*(s)/D(s)$ may be inverted using partial-fraction expansion.

Initial-Value and Final-Value Theorems The limits of $f(t)$ as time approaches zero or infinity can be determined directly from the transform $F(s)$ without inverting. The *initial-value theorem* states that

$$f(0_+) = \lim_{s \rightarrow \infty} s F(s)$$

where the limit exists. If the limit does not exist (i.e., is infinite) the value of $f(0_+)$ is undefined. The *final-value theorem* states that

$$f(\infty) = \lim_{s \rightarrow 0} s F(s)$$

provided that (with the possible exception of a single pole at $s = 0$) $F(s)$ has no poles with nonnegative real parts.

Transfer Functions The Laplace transform of the system I/O equation may be written in terms of the transform $Y(s)$ of the system response $y(t)$ as

$$\begin{aligned} Y(s) &= \frac{G(s)N(s) + F(s)D(s)}{P(s)D(s)} \\ &= \left(\frac{G(s)}{P(s)} \right) \left(\frac{N(s)}{D(s)} \right) + \frac{F(s)}{P(s)} \end{aligned}$$

- where (a) $P(s) = a_n s^n + a_{n-1} + \dots + a_1 s + a_0$ is the characteristic polynomial of the system
- (b) $G(s) = b_m s^m + b_{m-1} s^{m-1} + \dots + b_1 s + b_0$ represents the numerator dynamics of the system
- (c) $U(s) = N(s)/D(s)$ is the transform of the input to the system, $u(t)$, assumed to be a rational function
- (d) $F(s) = a_n y(0) s^{n-1} + \left(a_n \frac{dy}{dt}(0) + a_{n-1} y(0) \right) s^{n-2} + \dots + \left(a_n \frac{d^{n-1}y}{dt^{n-1}}(0) + a_{n-1} \frac{d^{n-2}y}{dt}(0) + \dots + a_1 y(0) \right)$

reflect the initial system state [i.e., the initial conditions on $y(t)$ and its first $n - 1$ derivatives]

The transformed response can be thought of as the sum of two components,

$$Y(s) = Y_{zs}(s) + Y_{zi}(s)$$

- where (e) $Y_{zs}(s) = [G(s)/P(s)][N(s)/D(s)] = H(s)U(s)$ is the transform of the zero-state response, that is, the response of the system to the input alone
- (f) $Y_{zi}(s) = F(s)/P(s)$ is the transform of the zero-input response, that is, the response of the system to the initial state alone

The rational function

- (g) $H(s) = Y_{zs}(s)/U(s) = G(s)/P(s)$ is the transfer function of the system, define as the Laplace transform of the ratio of the system response to the system input, assuming zero initial conditions

The transfer function plays a crucial role in the analysis of fixed linear systems using transforms and can be written directly from knowledge of the system I/O equation as

$$H(s) = \frac{b_m s^m + \dots + b_0}{a_n s^n + a_{n-1} s^{n-1} + \dots + a_1 s + a_0}$$

Impulse Response Since $U(s) = 1$ for a unit impulse function, the transform of the zero-state response to a unit impulse input is given by the relation

(g) as

$$Y_{zs}(s) = H(s)$$

that is, the system transfer function. In the time domain, therefore, the unit impulse response is

$$h(t) = \begin{cases} 0 & \text{for } t \leq 0 \\ \mathcal{L}^{-1}[H(s)] & \text{for } t > 0 \end{cases}$$

This simple relationship is profound for several reasons. First, this provides for a direct characterization of time domain response $h(t)$ in terms of the properties (poles and zeros) of the rational function $H(s)$ in the complex-frequency domain. Second, applying the convolution-transform pair (Table 5) to relation (e) above yields

$$Y_{zs}(t) = \int_0^t h(\tau)u(t - \tau) d\tau$$

In words, the zero-state output corresponding to an arbitrary input $u(t)$ can be determined by convolution with the impulse response $h(t)$. In other words, the impulse response completely characterizes the system. The impulse response is also called the system *weighting function*.

Block Diagrams Block diagrams are an important conceptual tool for the analysis and design of dynamic systems because block diagrams provide a graphic means for depicting the relationships among system variables and components. A block diagram consists of unidirectional blocks representing specific system components or subsystems interconnected by arrows representing system variables. Causality follows in the direction of the arrows, as in Fig. 11, indicating that the output is caused by the input acting on the system defined in the block.

Combining transform variables, transfer functions, and block diagrams provides a powerful graphical means for determining the overall transfer function of a system when the transfer functions of its component subsystems are known. The basic blocks in such diagrams are given in Fig. 12. A block diagram

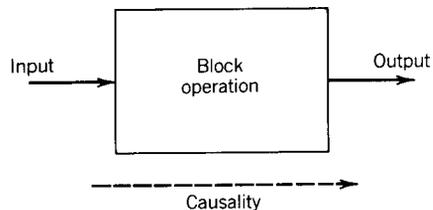

Fig. 11 Basic block diagram, showing assumed direction of causality or loading.

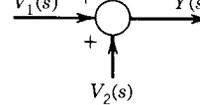

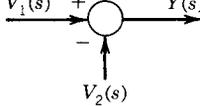

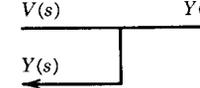

Type	Input-Output Relations		Symbol
	Time Domain	Transform Domain	
(a) Multiplier	$y(t) = Kv(t)$	$Y(s) = KV(s)$	
(b) General transfer function	$y(t) = \mathcal{L}^{-1}[T(s)V(s)]$	$Y(s) = T(s)V(s)$	
(c) Summer	$y(t) = v_1(t) + v_2(t)$	$Y(s) = V_1(s) + V_2(s)$	
(d) Comparator	$y(t) = v_1(t) - v_2(t)$	$Y(s) = V_1(s) - V_2(s)$	
(e) Takeoff point	$y(t) = v(t)$	$Y(s) = V(s)$	

Fig. 12 Basic block diagram elements (Ref. 4).

comprising many blocks and summers can be reduced to a single transfer function block by using the diagram transformations given in Fig. 13.

5.2 Transient Analysis Using Transform Methods

Basic to the study of dynamic systems are the concepts and terminology used to characterize system behavior or performance. These ideas are aids in *defining* behavior in order to consider for a given context those features of behavior that are desirable and undesirable; in *describing* behavior in order to communicate concisely and unambiguously various behavioral attributes of a given system; and in *specifying* behavior in order to formulate desired behavioral norms for system design. Characterization of dynamic behavior in terms of standard concepts also leads in many cases to analytical shortcuts since key features of the system response frequently can be determined without actually solving the system model.

Parts of the Complete Response A variety of names are used to identify terms in the response of a fixed linear system. The complete response of a system may be thought of alternatively as the sum of the following:

1. The *free response* (or complementary or homogeneous solution) and the *forced response* (or

particular solution). The free response represents the natural response of a system when inputs are removed and the system responds to some initial stored energy. The forced response of the system depends on the form of the input only.

2. The *transient response* and the *steady-state response*. The transient response is that part of the output that decays to zero as time progresses. The steady-state response is that part of the output that remains after all the transients disappear.
3. The *zero-state response* and the *zero-input response*. The zero-state response is the complete response (both free and forced responses) to the input when the initial state is zero. The zero-input response is the complete response of the system to the initial state when the input is zero.

Test Inputs or Singularity Functions For a stable system, the response to a specific input signal will provide several measures of system performance. Since the actual inputs to a system are not usually known a priori, characterization of the system behavior is generally given in terms of the response to one of a standard set of *test input signals*. This approach provides a common basis for the comparison of different systems. In addition, many inputs actually encountered can be approximated by some combination of standard inputs.

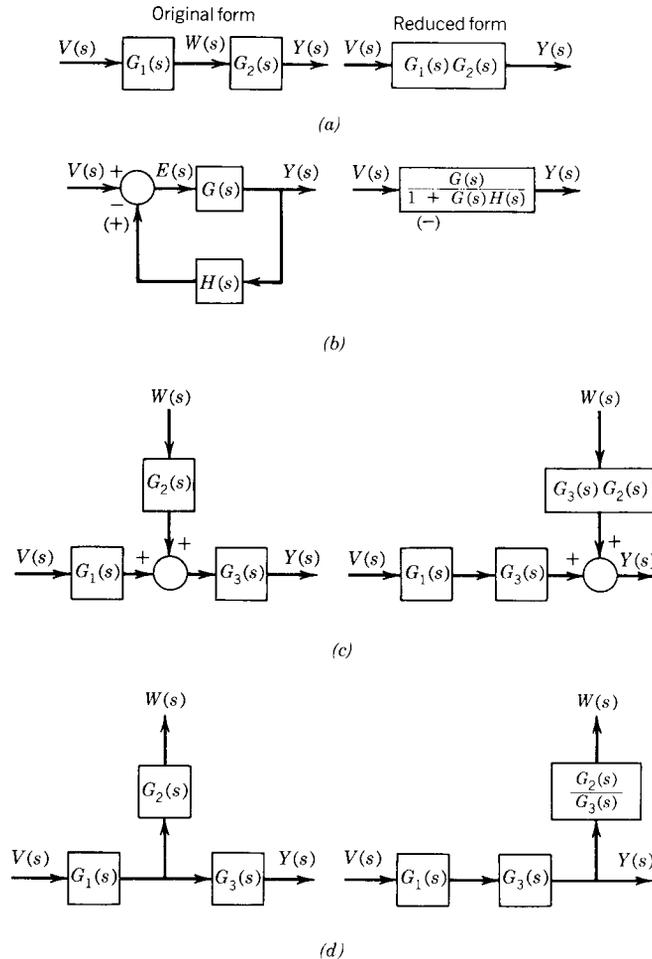

Fig. 13 Representative block diagram transformations: (a) series or cascaded elements, (b) feedback loop, (c) relocated summer, (d) relocated takeoff point (Ref. 4).

The most commonly used test inputs are members of the family of *singularity functions*, depicted in Fig. 14.

First-Order Transient Response The standard form of the I/O equation for a first-order system is

$$\frac{dy}{dt} + \frac{1}{\tau}y(t) = \frac{1}{\tau}u(t)$$

where the parameter τ is called the system *time constant*. The response of this standard first-order system to three test inputs is depicted in Fig. 15, assuming zero initial conditions on the output $y(t)$. For all inputs, it is clear that the response approaches its steady state monotonically (i.e., without oscillations) and that the *speed of response* is completely characterized by the

time constant τ . The transfer function of the system is

$$H(s) = \frac{Y(s)}{U(s)} = \frac{1/\tau}{s + 1/\tau}$$

and therefore $\tau = -p^{-1}$, where p is the system pole. As the absolute value of p increases, τ decreases and the response becomes faster.

The response of the standard first-order system to a step input of magnitude u for arbitrary initial condition $y(0) = y_0$ is

$$y(t) = y_{ss} - [y_{ss} - y_0]e^{-t/\tau}$$

where $y_{ss} = u$ is the steady-state response. Table 6 and Fig. 16 record the values of $y(t)$ and $\dot{y}(t)$ for

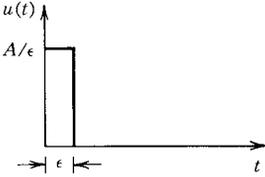

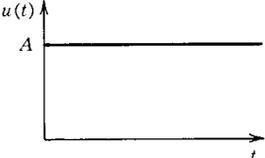

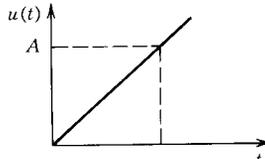

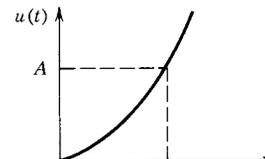

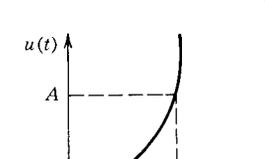

Function	Graph	$u(t)$	$U(s)$
Impulse		$u(t) = \begin{cases} \lim_{\epsilon \rightarrow 0} A/\epsilon, & 0_+ < t < \epsilon \\ 0, & \text{otherwise} \end{cases}$	$U(s) = A$
Step		$u(t) = \begin{cases} A, & 0_+ < t \\ 0, & \text{otherwise} \end{cases}$	$U(s) = \frac{A}{s}$
Ramp		$u(t) = \begin{cases} At, & 0_+ < t \\ 0, & \text{otherwise} \end{cases}$	$U(s) = \frac{A}{s^2}$
Parabolic		$u(t) = \begin{cases} At^2, & 0_+ < t \\ 0, & \text{otherwise} \end{cases}$	$U(s) = \frac{2A}{s^3}$
General		$u(t) = \begin{cases} At^n, & 0_+ < t \\ 0, & \text{otherwise} \end{cases}$	$U(s) = \frac{n!A}{s^{n+1}}$

Fig. 14 Family of singularity functions commonly used as test inputs.

$t = k\tau, k = 0, 1, \dots, 6$. Note that over any time interval of duration τ , the response increases approximately 63% of the difference between the steady-state value and the value at the beginning of the time interval, that is,

$$y(t + \tau) - y(t) \approx 0.63212[y_{ss} - y(t)]$$

Note also that the slope of the response at the beginning of any time interval of duration τ intersects the steady-state value y_{ss} at the end of the interval, that is,

$$\frac{dy}{dt}(t) = \frac{y_{ss} - y(t)}{\tau}$$

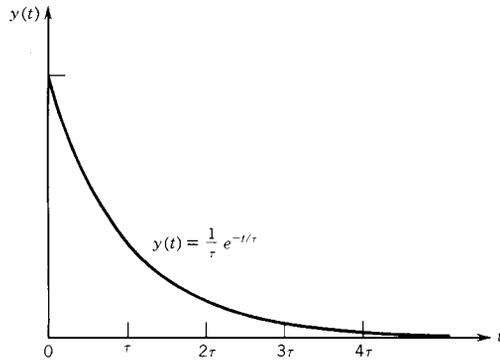

Finally, note that after an interval of four time constants, the response is within 98% of the steady-state value, that is,

$$y(4\tau) \approx 0.98168(y_{ss} - y_0)$$

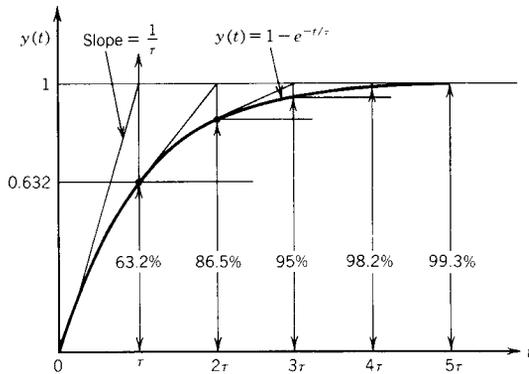

For this reason, $T_s = 4\tau$ is called the (2%) *setting time*.

Second-Order Transient Response The standard form of the I/O equation for a second-order system is

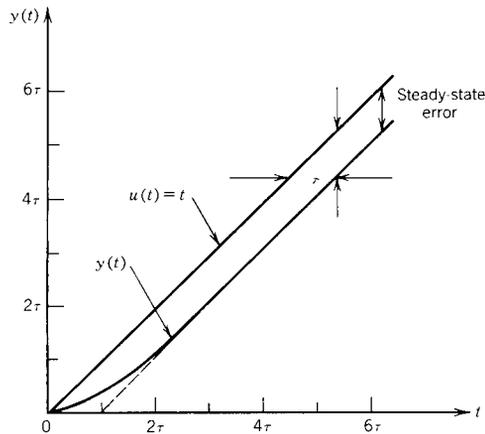

$$\frac{d^2y}{dt^2} + 2\zeta\omega_n \frac{dy}{dt} + \omega_n^2 y(t) = \omega_n^2 u(t)$$

(a)

(b)

(c)

Table 6 Tabulated Values of the Response of a First-Order System to a Unit Step Input

t	$y(t)$	$\dot{y}(t)$
0	0	τ^{-1}
τ	0.632	$0.368\tau^{-1}$
2τ	0.865	$0.135\tau^{-1}$
3τ	0.950	$0.050\tau^{-1}$
4τ	0.982	$0.018\tau^{-1}$
5τ	0.993	$0.007\tau^{-1}$
6τ	0.998	$0.002\tau^{-1}$

with transfer function

$$H(s) = \frac{Y(s)}{U(s)} = \frac{\omega_n^2}{s^2 + 2\zeta\omega_n s + \omega_n^2}$$

The system poles are obtained by applying the quadratic formula to the characteristic equation as

$$p_{1,2} = -\zeta\omega_n \pm j\omega_n\sqrt{1 - \zeta^2}$$

where the following parameters are defined ζ is the *damping ratio*, ω_n is the *natural frequency*, and $\omega_d = \omega_n\sqrt{1 - \zeta^2}$ is the *damped natural frequency*.

The nature of the response of the standard second-order system to a step input depends on the value of the damping ratio, as depicted in Fig. 17. For a stable system, four classes of response are defined

1. *Overdamped Response* ($\zeta > 1$). The system poles are real and distinct. The response of the second-order system can be decomposed into the response of two cascaded first-order systems, as shown in Fig. 18.
2. *Critically Damped Response* ($\zeta = 1$). The system poles are real and repeated. This is the limiting case of overdamped response, where the response is as fast as possible without overshoot.
3. *Underdamped Response* ($1 > \zeta > 0$). The system poles are complex conjugates. The response oscillates at the damped frequency ω_d . The magnitude of the oscillations and the speed with which the oscillations decay depend on the damping ratio ζ .
4. *Harmonic Oscillation* ($\zeta = 0$). The system poles are pure imaginary numbers. The response oscillates at the natural frequency ω_n and the oscillations are undamped (i.e., the oscillations are sustained and do not decay).

Complex s Plane The location of the system poles (roots of the characteristic equation) in the *complex s plane* reveals the nature of the system response to test inputs. Figure 19 shows the relationship between the location of the poles in the complex plane and the parameters of the standard second-order system.

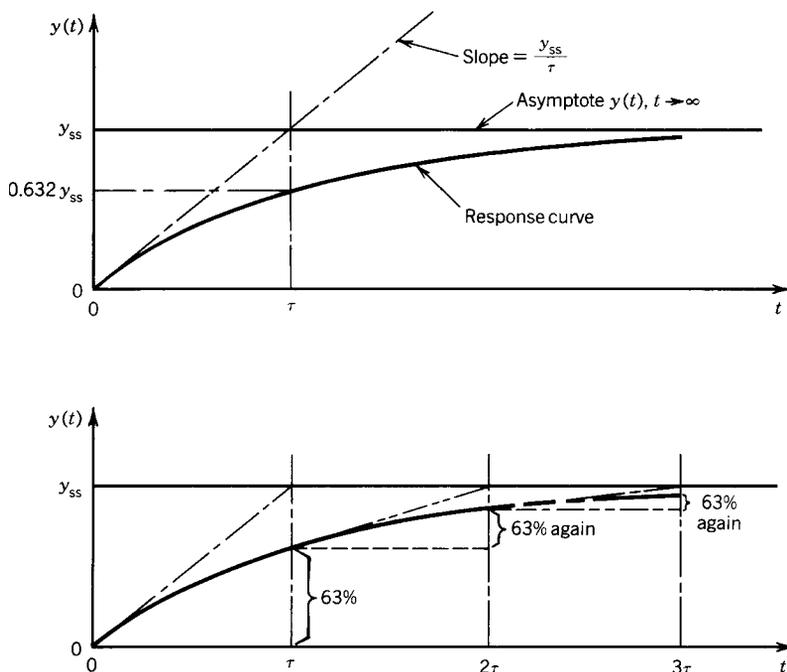

Fig. 16 Response of a first-order system to a unit step input, showing the relationship to the time constant.

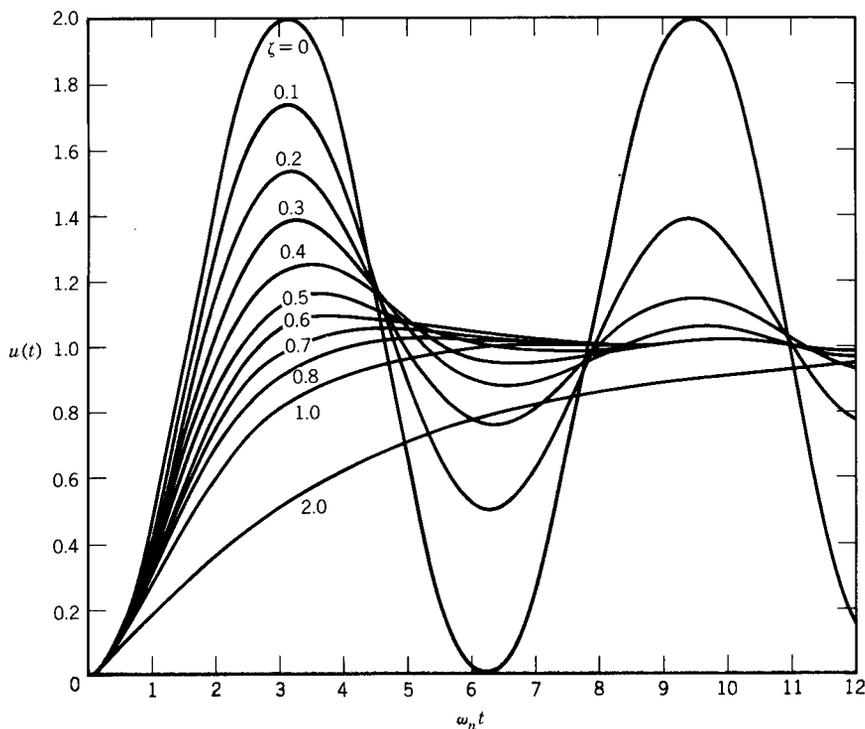

Fig. 17 Response of a second-order system to a unit step input for selected values of the damping ratio.

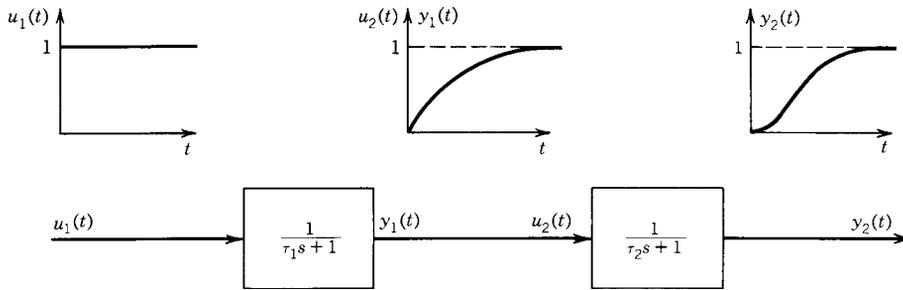

Fig. 18 Overdamped response of a second-order system decomposed into the responses of two first-order systems.

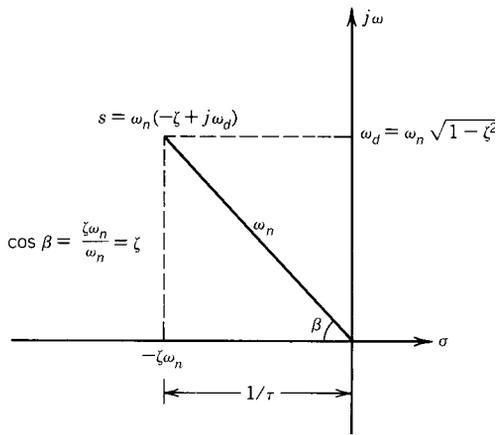

Fig. 19 Location of the upper complex pole in the s plane in terms of the parameters of the standard second-order system.

Figure 20 shows the unit impulse response of a second-order system corresponding to various pole locations in the complex plane.

Transient Response of Higher Order Systems

The response of third- and higher order systems to test inputs is simply the sum of terms representing component first and second-order responses. This is because the system poles must either be real, resulting in first-order terms, or complex, resulting in second-order underdamped terms. Furthermore, because the transients associated with those system poles having the largest real part decay the most slowly, these transients tend to dominate the output. The response of higher order systems therefore tends to have the same form as the response to the *dominant poles*, with the response to the *subdominant poles* superimposed over it. Note that the larger the relative difference between the real parts of the dominant and subdominant poles, the more the output tends to resemble the dominant mode of response.

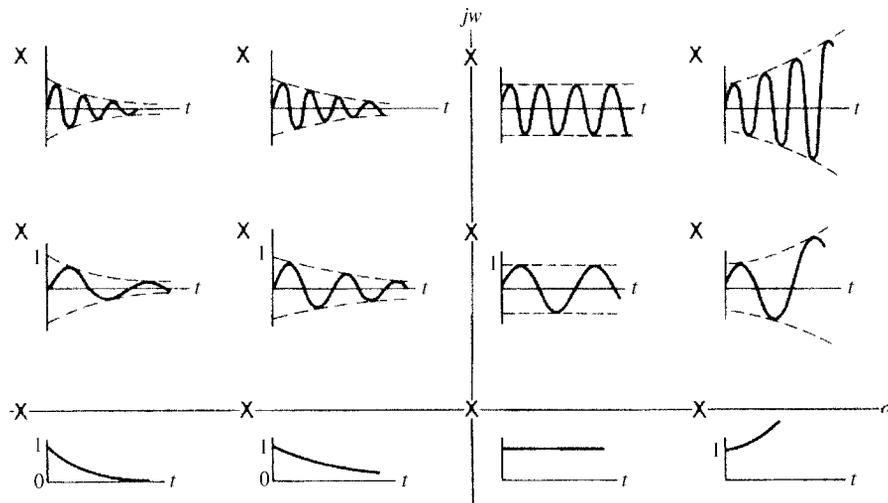

Fig. 20 Unit impulse response for selected upper complex pole locations in the s plane.

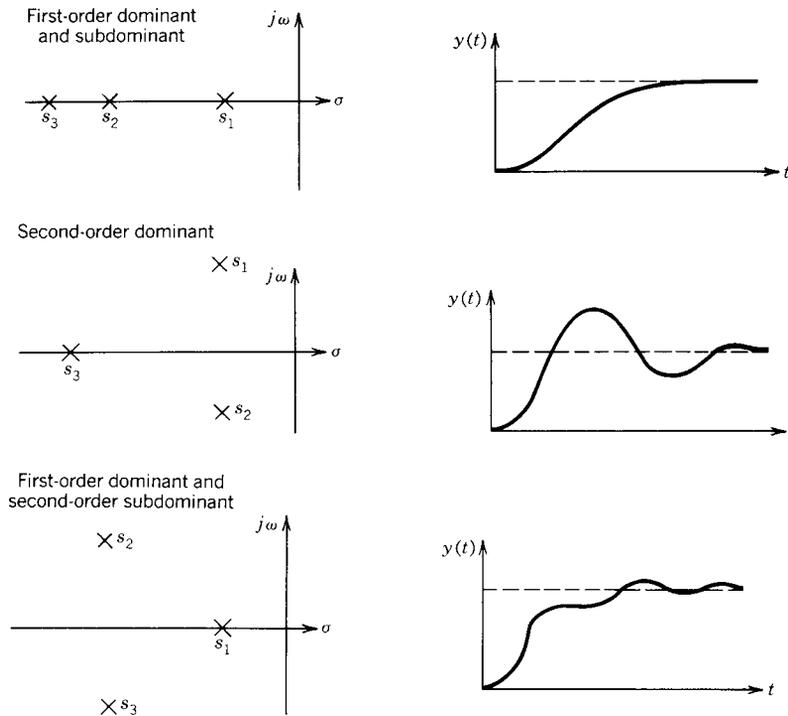

Fig. 21 Step response of a third-order system for alternative upper complex pole locations in the s plane.

For example, consider a fixed linear third-order system. The system has three poles. Either the poles may all be real or one may be real while the other pair is complex conjugate. This leads to the three forms of step response shown in Fig. 21, depending on the relative locations of the poles in the complex plane.

Transient Performance Measures The transient response of a system is commonly described in terms of the measures define in Table 7 and shown in Fig. 22. While these measures apply to any output, for a second-order system these can be calculated exactly in terms of the damping ratio and natural frequency, as shown in column 3 of the table. A common practice in control system design is to determine an initial design with dominant second-order poles that satisfy the performance specifications. Such a design can easily be calculated and then modified as necessary to achieve the desired performance.

Effect of Zeros on Transient Response Zeros arise in a system transfer function through the inclusion of one or more derivatives of $u(t)$ among the inputs to the system. By sensing the rate(s) of change of $u(t)$, the system in effect *anticipates* the future values of $u(t)$. This tends to increase the speed of response of the system relative to the input $u(t)$.

The effect of a zero is greatest on the modes of response associated with neighboring poles. For example, consider the second-order system represented by the transfer function

$$H(s) = K \frac{s - z}{(s - p_1)(s - p_2)}$$

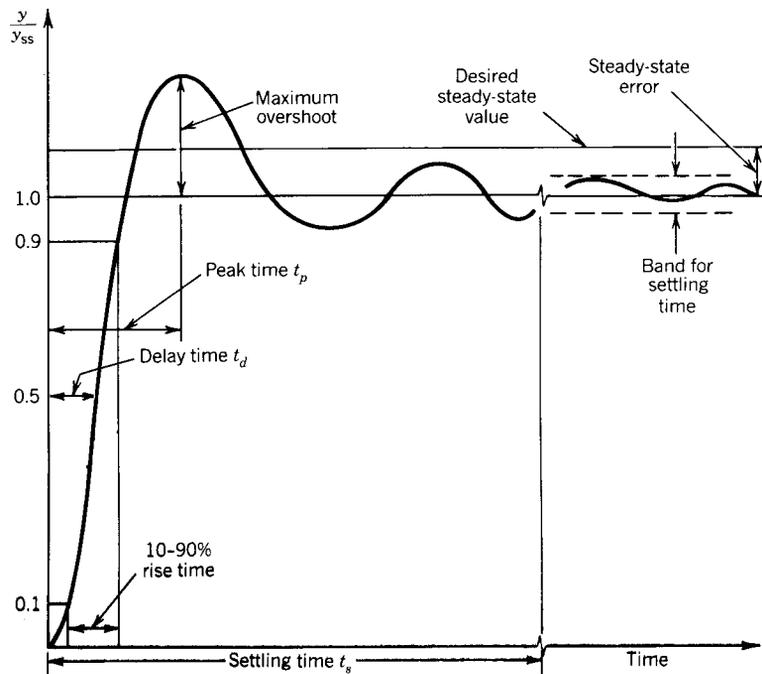

If $z = p_1$, then the system responds as a first-order system with $\tau = -p_2^{-1}$; whereas if $z = p_2$, then the system responds as a first-order system with $\tau = -p_1^{-1}$. Such *pole-zero cancellation* can only be achieved mathematically, but it can be approximated in physical systems. Note that by diminishing the residue associated with the response mode having the larger time constant, the system responds more quickly to changes in the input, confirming our earlier observation.

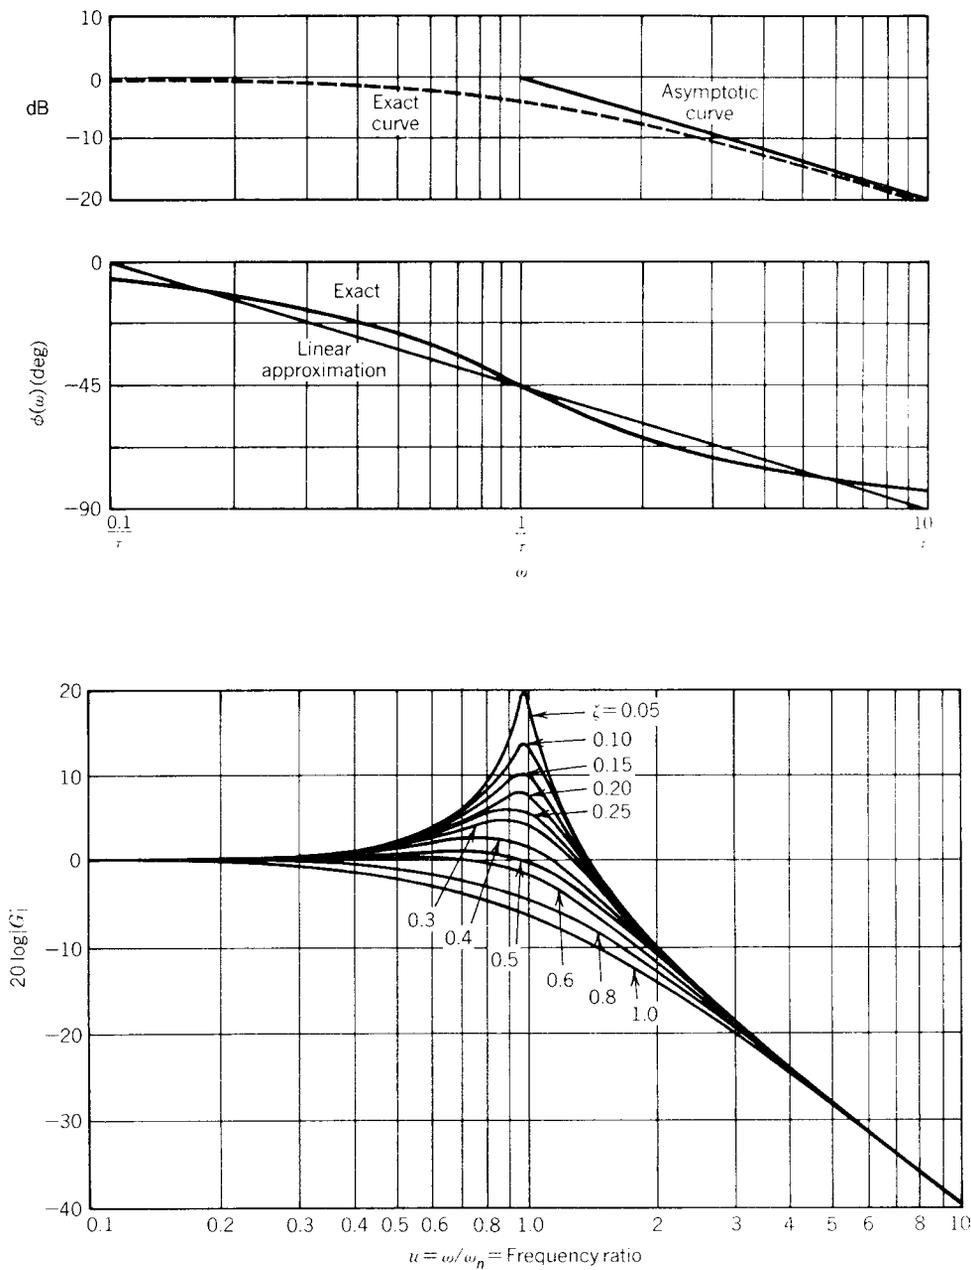

5.3 Response to Periodic Inputs Using Transform Methods

The response of a dynamic system to periodic inputs can be a critical concern to the control engineer. An input $u(t)$ is *periodic* if $u(t + T) = u(t)$ for all time t , where T is a constant called the period. Periodic inputs are important because these are ubiquitous: rotating unbalanced machinery, reciprocating pumps

Table 7 Transient Performance Measures Based on Step Response

Performance Measure	Definition	Formula for a Second-Order System
Delay time, t_d	Time required for the response to reach half the final value for the first time	
10–90% rise time, t_r	Time required for the response to rise from 10 to 90% of the final response (used for overdamped responses)	
0–100% rise time, t_r	Time required for the response to rise from 0 to 100% of the final response (used for underdamped responses)	$t_r = \frac{\pi - \beta}{\omega_d}$ where $\beta = \cos^{-1} \zeta$
Peak time, t_p	Time required for the response to reach the first peak of the overshoot	$t_p = \frac{\pi}{\omega_d}$
Maximum overshoot, M_p	The difference in the response between the first peak of the overshoot and the final response	$M_p = e^{-\zeta\pi/\sqrt{1-\zeta^2}}$
Percent overshoot (PO)	The ratio of maximum overshoot to the final response expressed as a percentage	$PO = 100e^{-\zeta\pi/\sqrt{1-\zeta^2}}$
Setting time, t_s	The time required for the response to reach and stay within a specified band centered on the final response (usually 2 or 5% of final response band)	$t_s = \frac{4}{\zeta\omega_n} \text{ (2% band)}$ $t_s = \frac{3}{\zeta\omega_n} \text{ (5% band)}$

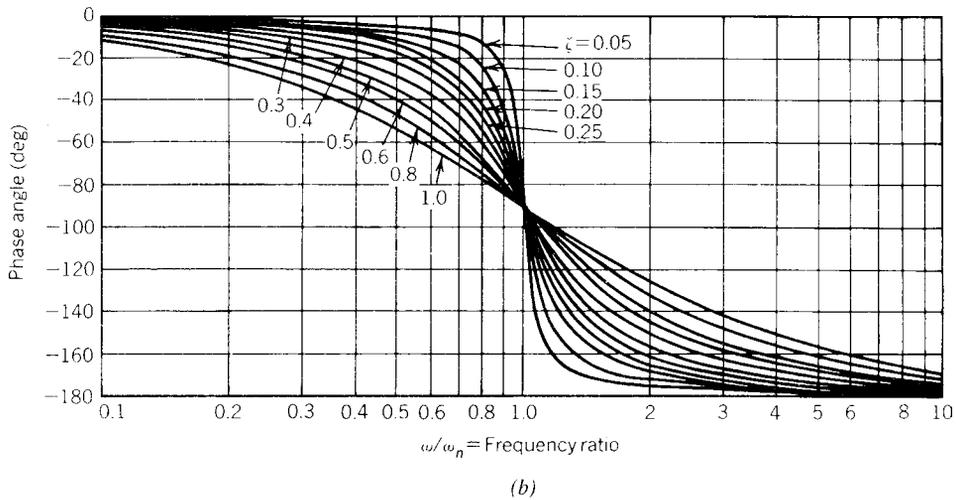

Fig. 23b (Continued)

and engines, alternating current (ac) electrical power, and a legion of noise and disturbance inputs can be approximated by periodic inputs. Sinusoids are the most important category of periodic inputs, because these are frequently occurring and easily analyzed and form the basis for analysis of general periodic inputs.

Frequency Response The *frequency response* of a system is the steady-state response of the system to a sinusoidal input. For a linear system, the frequency response has the unique property that the response is a sinusoid of the same frequency as the input sinusoid, differing only in amplitude and phase. In addition, it is easy to show that the amplitude and phase of the response are functions of the input frequency, which are readily obtained from the system transfer function.

Consider a system defined by the transfer function $H(s)$. For an input

$$u(t) = A \sin \omega t$$

the corresponding steady-state output is

$$y_{ss}(t) = AM(\omega) \sin[\omega t + \phi(\omega)]$$

where $M(\omega) = |H(j\omega)|$ is the *magnitude ratio*

$\phi(\omega) = \angle H(j\omega)$ is the *phase angle*

$H(j\omega) = H(s)|_{s=j\omega}$ is the *frequency transfer function*

The frequency transfer function is obtained by substituting $j\omega$ for s in the transfer function $H(s)$. If the complex quantity $H(j\omega)$ is written in terms

of its real and imaginary parts as $H(j\omega) = \text{Re}(\omega) + j \text{Im}(\omega)$, then

$$M(\omega) = [\text{Re}(\omega)^2 + \text{Im}(\omega)^2]^{1/2}$$

$$\phi(\omega) = \tan^{-1} \left[\frac{\text{Im}(\omega)}{\text{Re}(\omega)} \right]$$

and in polar form

$$H(j\omega) = M(\omega)e^{j\phi(\omega)}$$

Frequency Response Plots The frequency response of a fixed linear system is typically represented graphically using one of three types of frequency response plots. A *polar plot* is simply a plot of the vector $H(j\omega)$ in the complex plane, where $\text{Re}(\omega)$ is the abscissa and $\text{Im}(\omega)$ is the ordinate. A *logarithmic plot* or *Bode diagram* consists of two displays: (a) the magnitude ratio in decibels $M_{dB}(\omega)$ [where $M_{dB}(\omega) = 20 \log M(\omega)$] versus $\log \omega$ and (b) the phase angle in degrees $\phi(\omega)$ versus $\log \omega$. Bode diagrams for normalized first and second-order systems are given in Fig. 23a. Bode diagrams for higher order systems are obtained by adding these first- and second-order terms, appropriately scaled. A *Nichols diagram* can be obtained by cross plotting the Bode magnitude and phase diagrams, eliminating $\log \omega$. Polar plots and Bode and Nichols diagrams for common transfer functions are given in Table 8.

Frequency Response Performance Measures

Frequency response plots show that dynamic systems tend to behave like *filters*, “passing” or even amplifying certain ranges of input frequencies while blocking

or attenuating other frequency ranges. The range of frequencies for which the amplitude ratio is no less than 3 dB of its maximum value is called the *bandwidth* of the system. The bandwidth is defined by upper and lower *cutoff frequencies* ω_c , or by $\omega = 0$ and an upper cutoff frequency if $M(0)$ is the maximum amplitude ratio. Although the choice of “down 3 dB” used to define the cutoff frequencies is somewhat arbitrary, the bandwidth is usually taken to be a measure of the range of frequencies for which a significant portion of the input is felt in the system output. The bandwidth is also taken to be a measure of the system speed of response since attenuation of inputs in the higher frequency ranges generally results from the inability of the system to “follow” rapid changes in amplitude. Thus, a narrow bandwidth generally indicates a sluggish system response.

Response to General Periodic Inputs The *Fourier series* provides a means for representing a general periodic input as the sum of a constant and terms containing sine and cosine. For this reason the *Fourier series*, together with the superposition principle for linear systems, extends the results of frequency response analysis to the general case of arbitrary periodic inputs. The Fourier series representation of a periodic function $f(t)$ with period $2T$ on the interval $t^* + 2T \geq t \geq t^*$ is

$$f(t) = \frac{a_0}{2} + \sum_{n=1}^{\infty} \left(a_n \cos \frac{n\pi t}{T} + b_n \sin \frac{n\pi t}{T} \right)$$

where

$$a_n = \frac{1}{T} \int_{t^*}^{t^*+2T} f(t) \cos \frac{n\pi t}{T} dt$$

$$b_n = \frac{1}{T} \int_{t^*}^{t^*+2T} f(t) \sin \frac{n\pi t}{T} dt$$

If $f(t)$ is defined outside the specific interval by a periodic extension of period $2T$ and if $f(t)$ and its first derivative are piecewise continuous, then the series converges to $f(t)$ if t is a point of continuity or to $1/2[f(t_+) + f(t_-)]$ if t is a point of discontinuity. Note that while the Fourier series in general is infinite, the notion of bandwidth can be used to reduce the number of terms required for a reasonable approximation.

6 STATE-VARIABLE METHODS

State-variable methods use the vector state and output equations introduced in Section 4 for analysis of dynamic systems directly in the time domain. These methods have several advantages over transform methods. First, state-variable methods are particularly advantageous for the study of multivariable (multiple-input/multiple-output) systems. Second, state-variable

methods are more naturally extended for the study of linear time-varying and nonlinear systems. Finally, state-variable methods are readily adapted to computer simulation studies.

6.1 Solution of State Equation

Consider the vector equation of state for a fixed linear system:

$$\dot{x}(t) = Ax(t) + Bu(t)$$

The solution to this system is

$$x(t) = \Phi(t)x(0) + \int_0^t \Phi(t - \tau)Bu(\tau) d\tau$$

where the matrix $\Phi(t)$ is called the *state transition matrix*. The state transition matrix represents the free response of the system and is defined by the matrix exponential series

$$\Phi(t) = e^{At} = I + At + \frac{1}{2!}A^2t^2 + \dots = \sum_{k=0}^{\infty} \frac{1}{k!}A^k t^k$$

where I is the identity matrix. The state transition matrix has the following useful properties:

$$\Phi(0) = I$$

$$\Phi^{-1}(t) = \Phi(-t)$$

$$\Phi^k(t) = \Phi(kt)$$

$$\Phi(t_1 + t_2) = \Phi(t_1)\Phi(t_2)$$

$$\Phi(t_2 - t_1)\Phi(t_1 - t_0) = \Phi(t_2 - t_0)$$

$$\Phi(t) = A\Phi(t)$$

The Laplace transform of the state equation is

$$sX(s) - x(0) = AX(s) + BU(s)$$

The solution to the fixed linear system therefore can be written as

$$x(t) = \mathcal{L}^{-1}[X(s)]$$

$$= \mathcal{L}^{-1}[\Phi(s)]x(0) + \mathcal{L}^{-1}[\Phi(s)BU(s)]$$

where $\Phi(s)$ is called the *resolvent matrix* and

$$\Phi(t) = \mathcal{L}^{-1}[\Phi(s)] = \mathcal{L}^{-1}[sI - A]^{-1}$$

6.2 Eigenstructure

The internal structure of a system (and therefore its free response) is defined entirely by the system matrix A . The concept of matrix *eigenstructure*, as defined by the eigenvalues and eigenvectors of the system

matrix, can provide a great deal of insight into the fundamental behavior of a system. In particular, the system eigenvectors can be shown to define a special set of first-order subsystems embedded within the system. These subsystems behave independently of one another, a fact that greatly simplifies analysis.

System Eigenvalues and Eigenvectors For a system with system matrix A , the system *eigenvectors* v_i and associated *eigenvalues* λ_i are defined by the equation

$$Av_i = \lambda_i v_i$$

Note that the eigenvectors represent a set of special directions in the state space. If the state vector is aligned in one of these directions, then the homogeneous state equation becomes $\dot{v}_i = Av_i = \lambda_i v_i$, implying that each of the state variables changes at the *same* rate determined by the eigenvalue λ_i . This further implies that, in the absence of inputs to the system, a state vector that becomes aligned with an eigenvector will remain aligned with that eigenvector. The system eigenvalues are calculated by solving the n th-order polynomial equation

$$|\lambda I - A| = \lambda^n + a_{n-1}\lambda^{n-1} + \dots + a_1\lambda + a_0 = 0$$

This equation is called the *characteristic equation*. Thus the system eigenvalues are the roots of the characteristic equation, that is, the system eigenvalues are identically the system poles defined in transform analysis.

Each system eigenvector is determined by substituting the corresponding eigenvalue into the defining equation and then solving the resulting set of simultaneous linear equations. Only $n - 1$ of the n components of any eigenvector are independently defined however. In other words, the magnitude of an eigenvector is arbitrary, and the eigenvector describes a direction in the state space.

Diagonalized Canonical Form There will be one linearly independent eigenvector for each distinct (non-repeated) eigenvalue. If all of the eigenvalues of an n th-order system are distinct, then the n independent eigenvectors form a new basis for the state space. This basis represents new coordinate axes defining a set of state variables $z_i(t)$, $i = 1, 2, \dots, n$, called the *diagonalized canonical variables*. In terms of the diagonalized variables, the homogeneous state equation is

$$\dot{z}(t) = \Lambda z$$

where Λ is a diagonal system matrix of the eigenvectors, that is,

$$\Lambda = \begin{bmatrix} \lambda_1 & 0 & \dots & 0 \\ 0 & \lambda_2 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \vdots & \lambda_n \end{bmatrix}$$

The solution to the diagonalized homogeneous system is

$$z(t) = e^{\Lambda t} z(0)$$

where $e^{\Lambda t}$ is the diagonal state transition matrix

$$e^{\Lambda t} = \begin{bmatrix} e^{\lambda_1 t} & 0 & \dots & 0 \\ 0 & e^{\lambda_2 t} & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & e^{\lambda_n t} \end{bmatrix}$$

Modal Matrix Consider the state equation of the n th-order system

$$\dot{x}(t) = Ax(t) + Bu(t)$$

which has real, distinct eigenvalues. Since the system has a full set of eigenvectors, the state vector $x(t)$ can be expressed in terms of the canonical state variables as

$$x(t) = v_1 z_1(t) + v_2 z_2(t) + \dots + v_n z_n(t) = Mz(t)$$

where M is the $n \times n$ matrix whose columns are the eigenvectors of A , called the *modal matrix*. Using the modal matrix, the state transition matrix for the original system can be written as

$$\Phi(t) = e^{\Lambda t} = M e^{\Lambda t} M^{-1}$$

where $e^{\Lambda t}$ is the diagonal state transition matrix. This frequently proves to be an attractive method for determining the state transition matrix of a system with real, distinct eigenvalues.

Jordan Canonical Form For a system with one or more repeated eigenvalues, there is not in general a full set of eigenvectors. In this case, it is not possible to determine a diagonal representation for the system. Instead, the simplest representation that can be achieved is block diagonal. Let $L_k(\lambda)$ be the $k \times k$ matrix

$$L_k(\lambda) = \begin{bmatrix} \lambda & 1 & 0 & \dots & 0 \\ 0 & \lambda & 1 & \dots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \vdots & \vdots & \vdots & \vdots & \ddots \\ 0 & 0 & 0 & 0 & \lambda \end{bmatrix}$$

Then for any $n \times n$ system matrix A there is certain to exist a nonsingular matrix T such that

$$T^{-1}AT = \begin{bmatrix} L_{k_1}(\lambda_1) & & & \\ & L_{k_2}(\lambda_2) & & \\ & & \ddots & \\ & & & L_{k_r}(\lambda_r) \end{bmatrix}$$

where $k_1 + k_2 + \dots + k_r = n$ and $\lambda_i, i = 1, 2, \dots, r$, are the (not necessarily distinct) eigenvalues of A . The matrix $T^{-1}AT$ is called the *Jordan canonical form*.

7 SIMULATION

7.1 Experimental Analysis of Model Behavior

Closed-form solutions for nonlinear or time-varying systems are rarely available. In addition, while explicit solutions for time-invariant linear systems can always be found, for high-order systems this is often impractical. In such cases it may be convenient to study the dynamic behavior of the system using *simulation*.

Simulation is the *experimental* analysis of model behavior. A *simulation run* is a controlled experiment in which a specific realization of the model is manipulated in order to determine the response associated with that realization. A *simulation study* comprises *multiple runs*, each run for a different combination of model parameter values and/or initial conditions. The generalized solution of the model must then be inferred from a finite number of simulated data points.

Simulation is almost always carried out with the assistance of computing equipment. *Digital simulation* involves the *numerical solution* of model equations using a digital computer. *Analog simulation* involves solving model equations by analogy with the behavior of a physical system using an analog computer. *Hybrid simulation* employs digital and analog simulation together using a hybrid (part digital and part analog) computer.

7.2 Digital Simulation

Digital continuous-system simulation involves the approximate solution of a state-variable model over successive time steps. Consider the general state-variable equation

$$\dot{x}(t) = f[x(t), u(t)]$$

to be simulated over the time interval $t_0 \leq t \leq t_K$. The solution to this problem is based on the repeated solution of the single-variable, single-step subproblem depicted in Fig. 24. The subproblem may be stated formally as follows:

Given:

1. $\Delta t(k) = t_k - t_{k-1}$, the length of the k th time step.
2. $x_i(t) = f_i[x(t), u(t)]$ for $t_{k-1} \leq t \leq t_k$, the i th equation of state define for the state variable $x_i(t)$ over the k th time step.
3. $u(t)$ for $t_{k-1} \leq t \leq t_k$, the input vector define for the k th time step.
4. $\tilde{x}(k-1) \simeq x(t_{k-1})$, an initial approximation for the state vector at the beginning of the time step.

Find:

5. $\tilde{x}_i(k) \simeq x_i(t_k)$, a final approximation for the state variable $x_i(t)$ at the end of the k th time step.

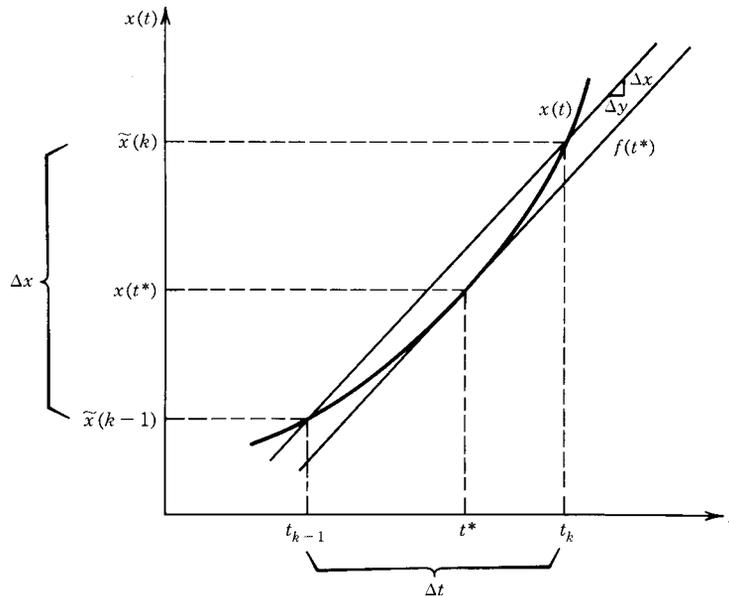

Fig. 24 Numerical approximation of a single variable over a single time step.

Solving this single-variable, single-step subproblem for each of the state variables $x_i(t)$, $i = 1, 2, \dots, n$, yields a final approximation for the state vector $\tilde{x}(k) \simeq x(t_k)$ at the end of the k th time step. Solving the complete single-step problem K times over K time steps, beginning with the initial condition $\tilde{x}(0) = x(t_0)$ and using the final value of $\tilde{x}(t_k)$ from the k th time step as the initial value of the state for the $(k + 1)$ st time step, yields a discrete succession of approximations $\tilde{x}(1) \simeq x(t_1)$, $\tilde{x}(2) \simeq x(t_2)$, \dots , $\tilde{x}(K) \simeq x(t_K)$ spanning the solution time interval.

The basic procedure for completing the single-variable, single-step problem is the same regardless of the particular integration method chosen. It consists of two parts: (a) calculation of the average value of the i th derivative over the time step as

$$\dot{x}_i(t^*) = f_i[x(t^*), u(t^*)] = \frac{\Delta x_i(k)}{\Delta t(k)} \simeq \tilde{f}_i(k)$$

and (b) calculation of the final value of the simulated variable at the end of the time step as

$$\begin{aligned} \tilde{x}_i(k) &= \tilde{x}_i(k-1) + \Delta x_i(k) \\ &\simeq \tilde{x}_i(k-1) + \Delta t(k) \tilde{f}_i(k) \end{aligned}$$

If the function $f_i[x(t), u(t)]$ is continuous, then t^* is guaranteed to be on the time step, that is, $t_{k-1} \leq t^* \leq t_k$. Since the value of t^* is otherwise unknown, however, the value of $x(t^*)$ can only be approximated as $\tilde{f}(k)$.

Different *numerical integration* methods are distinguished by the means used to calculate the approximation $f_i(k)$. A wide variety of such methods is available for digital simulation of dynamic systems. The choice of a particular method depends on the nature of the model being simulated, the accuracy required in the simulated data, and the computing effort available for the simulation study. Several popular classes of integration methods are outlined in the following sections.

Euler Method The simplest procedure for numerical integration is the Euler method. The standard Euler method approximates the average value of the i th derivative over the k th time step using the derivative evaluated at the beginning of the time step, that is,

$$\tilde{f}_i(k) = f_i[\tilde{x}(k-1), u(t_{k-1})] \simeq f_i(t_{k-1})$$

$i = 1, 2, \dots, n$ and $k = 1, 2, \dots, K$. This is shown geometrically in Fig. 25 for the scalar single-step case. A modification of this method uses the newly calculated state variables in the derivative calculation as these new values become available. Assuming the state

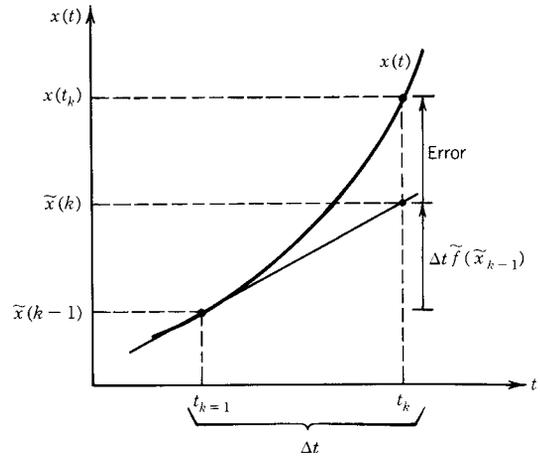

Fig. 25 Geometric interpretation of the Euler method for numerical integration.

variables are computed in numerical order according to the subscripts, this implies

$$\begin{aligned} \tilde{f}_i(k) &= f_i[\tilde{x}_1(k), \dots, \tilde{x}_{i-1}(k), \\ &\quad \tilde{x}_i(k-1), \dots, \tilde{x}_n(k-1), u(t_{k-1})] \end{aligned}$$

The modified Euler method is modestly more efficient than the standard procedure and, frequently, is more accurate. In addition, since the input vector $u(t)$ is usually known for the entire time step, using an average value of the input, such as

$$u(k) = \frac{1}{\Delta t(k)} \int_{t_{k-1}}^{t_k} u(\tau) d\tau$$

frequently leads to a superior approximation of $\tilde{f}_i(k)$.

The Euler method requires the least amount of computational effort per time step of any numerical integration scheme. Local truncation error is proportional to Δt^2 , however, which means that the error within each time step is highly sensitive to step size. Because the accuracy of the method demands very small time steps, the number of time steps required to implement the method successfully can be large relative to other methods. This can imply a large computational overhead and can lead to inaccuracies through the accumulation of round-off error at each step.

Runge-Kutta Methods Runge-Kutta methods precompute two or more values of $f_i[x(t), u(t)]$ in the time step $t_{k-1} \leq t \leq t_k$ and use some weighted average of these values to calculate $\tilde{f}_i(k)$. The order of a

Runge–Kutta method refers to the number of derivative terms (or *derivative calls*) used in the scalar single-step calculation. A Runge–Kutta routine of order N therefore uses the approximation

$$\tilde{f}_i(k) = \sum_{j=1}^N w_j f_{ij}(k)$$

where the N approximations to the derivative are

$$f_{i1}(k) = f_i[\tilde{x}(k-1), u(t_{k-1})]$$

(the Euler approximation) and

$$f_{ij} = f_i \left[\tilde{x}(k-1) + \Delta t \sum_{l=1}^{j-1} I b_{jl} f_{il}, u \left(t_{k-1} + \Delta t \sum_{l=1}^{j-1} b_{jl} \right) \right]$$

where I is the identity matrix. The weighting coefficients w_j and b_{jl} are not unique, but are selected such that the error in the approximation is zero when $x_i(t)$ is some specific N th-degree polynomial in t . Coefficient commonly used for Runge–Kutta integration are given in Table 9.

Among the most popular of the Runge–Kutta methods is fourth-order Runge–Kutta. Using the defining equations for $N = 4$ and the weighting coefficients from Table 9 yields the derivative approximation

$$\tilde{f}_i(k) = \frac{1}{6} [f_{i1}(k) + 2f_{i2}(k) + 2f_{i3}(k) + f_{i4}(k)]$$

based on the four derivative calls

$$f_{i1}(k) = f_i[\tilde{x}(k-1), u(t_{k-1})]$$

$$f_{i2}(k) = f_i \left[\tilde{x}(k-1) + \frac{\Delta t}{2} I f_{i1}, u \left(t_{k-1} + \frac{\Delta t}{2} \right) \right]$$

$$f_{i3}(k) = f_i \left[\tilde{x}(k-1) + \frac{\Delta t}{2} I f_{i2}, u \left(t_{k-1} + \frac{\Delta t}{2} \right) \right]$$

$$f_{i4}(k) = f_i[\tilde{x}(k-1) + \Delta t I f_{i3}, u(t_k)]$$

where I is the identity matrix.

Because Runge–Kutta formulas are designed to be exact for a polynomial of order N , local truncation error is of the order Δt^{N+1} . This considerable improvement over the Euler method means that comparable accuracy can be achieved for larger step sizes. The penalty is that N derivative calls are required for each scalar evaluation within each time step.

Euler and Runge–Kutta methods are examples of *single-step methods* for numerical integration, so-called because the state $x(k)$ is calculated from knowledge of the state $x(k-1)$, without requiring knowledge of the state at any time prior to the beginning of the current time step. These methods are also referred to as *self-starting methods* since calculations may proceed from any known state.

Multistep Methods *Multistep methods* differ from the single-step methods previously described in that multistep methods use the stored values of two or more previously computed states and/or derivatives in order to compute the derivative approximation $\tilde{f}_i(k)$ for the current time step. The advantage of multistep methods over Runge–Kutta methods is that these

Table 9 Coefficients Commonly Used for Runge–Kutta Numerical Integration

Common name	N	b_{jl}	w_j
Open or explicit Euler	1	All zero	$w_1 = 1$
Improved polygon	2	$b_{21} = \frac{1}{2}$	$w_1 = 0$ $w_2 = 1$
Modified Euler or Heun's method	2	$b_{21} = 1$	$w_1 = \frac{1}{2}$ $w_2 = \frac{1}{2}$
Third-order Runge–Kutta	3	$b_{21} = \frac{1}{2}$ $b_{31} = -1$ $b_{32} = 2$	$w_1 = \frac{1}{6}$ $w_2 = \frac{2}{3}$ $w_3 = \frac{1}{6}$
Fourth-order Runge–Kutta	4	$b_{21} = \frac{1}{2}$ $b_{31} = 0$ $b_{32} = \frac{1}{2}$ $b_{43} = 1$	$w_1 = \frac{1}{8}$ $w_2 = \frac{1}{3}$ $w_3 = \frac{1}{3}$ $w_4 = \frac{1}{6}$

Source: From Ref. 6.

require only one derivative call for each state variable at each time step for comparable accuracy. The disadvantage is that multistep methods are not self-starting since calculations cannot proceed from the initial state alone. Multistep methods must be started, or restarted in the case of discontinuous derivatives, using a single-step method to calculate the first several steps.

The most popular of the multistep methods are the *Adams–Bashforth predictor methods* and the *Adams–Moulton corrector methods*. These methods use the derivative approximation

$$\tilde{f}_i(k) = \sum_{j=0}^N b_j f_i[\tilde{x}(k-j), u(k-j)]$$

where the b_j are weighting coefficients. These coefficients are selected such that the error in the approximation is zero when $x_i(t)$ is a specific polynomial. Table 10 gives the values of the weighting coefficients for several Adams–Bashforth–Moulton rules. Note that the predictor methods employ an *open* or *explicit rule* since for these methods $b_0 = 0$ and a prior estimate of $x_i(k)$ is not required. The corrector methods use a *closed* or *implicit rule* since for these methods $b_i \neq 0$ and a prior estimate of $x_i(k)$ is required. Note also that for all of these methods $\sum_{j=0}^N b_j = 1$, ensuring unity gain for the integration of a constant.

Predictor–Corrector Methods Predictor–corrector methods use one of the multistep predictor equations to provide an initial estimate (or “prediction”) of $x(k)$. This initial estimate is then used with one of the multistep corrector equations to provide a second and improved (or “corrected”) estimate of $x(k)$ before proceeding to the next step. A popular choice is the four-point Adams–Bashforth predictor together with the four-point Adams–Moulton corrector, resulting in a prediction of

$$\begin{aligned} \tilde{x}_i(k) = \tilde{x}_i(k-1) + \frac{\Delta t}{24} [55\tilde{f}_i(k-1) - 59\tilde{f}_i(k-2) \\ + 37\tilde{f}_i(k-3) - 9\tilde{f}_i(k-4)] \end{aligned}$$

for $i = 1, 2, \dots, n$ and a correction of

$$\begin{aligned} \tilde{x}_i(k) = \tilde{x}_i(k-1) + \frac{\Delta t}{24} \{9f_i[\tilde{x}(k), u(k)] \\ + 19\tilde{f}_i(k-1) - 5\tilde{f}_i(k-2) + \tilde{f}_i(k-3)\} \end{aligned}$$

Predictor–corrector methods generally incorporate a strategy for increasing or decreasing the size of the time step depending on the difference between the predicted and corrected $x(k)$ values. Such *variable time-step methods* are particularly useful if the simulated system possesses local time constants that differ by several orders of magnitude or if there is little a priori knowledge about the system response.

Numerical Integration Errors An inherent characteristic of digital simulation is that the discrete data points generated by the simulation $x(k)$ are only approximations to the exact solution $x(t_k)$ at the corresponding point in time. This results from two types of errors that are unavoidable in the numerical solutions. *Round-off errors* occur because numbers stored in a digital computer have finite word length (i.e., a finite number of bits per word) and therefore limited precision. Because the results of calculations cannot be stored exactly, round-off error tends to increase with the number of calculations performed. For a given total solution interval $t_0 \leq t \leq t_K$, therefore, round-off error tends to increase (a) with increasing integration rule order (since more calculations must be performed at each time step) and (b) with decreasing step size Δt (since more time steps are required).

Truncation errors or *numerical approximation errors* occur because of the inherent limitations in the numerical integration methods themselves. Such

Table 10 Coefficients Commonly Used for Adams–Bashforth–Moulton Numerical Integration

errors would arise even if the digital computer had infinite precision. *Local or per-step truncation error* is defined as

$$e(k) = x(k) - x(t_k)$$

given that $x(k - 1) = x(t_{k-1})$ and that the calculation at the k th time step is infinitely precise. For many integration methods, local truncation errors can be approximated at each step. *Global or total truncation error* is defined as

$$e(K) = x(K) - x(t_K)$$

given that $x(0) = x(t_0)$ and the calculations for all K time steps are infinitely precise. Global truncation error usually cannot be estimated, neither can efforts to reduce local truncation errors be guaranteed to yield acceptable global errors. In general, however, truncation errors can be decreased by using more sophisticated integration methods and by decreasing the step size Δt .

Time Constants and Time Steps As a general rule, the step size Δt for simulation must be less than the smallest local time constant of the model simulated. This can be illustrated by considering the simple first order system

$$\dot{x}(t) = \lambda x(t)$$

and the difference equation defining the corresponding Euler integration

$$x(k) = x(k - 1) + \Delta t \lambda x(k - 1)$$

The continuous system is stable for $\lambda < 0$, while the discrete approximation is stable for $|1 + \lambda \Delta t| < 1$. If the original system is stable, therefore, the simulated response will be stable for

$$\Delta t \leq 2 \left| \frac{1}{\lambda} \right|$$

where the equality defines the *critical step size*. For larger step sizes, the simulation will exhibit *numerical instability*. In general, while higher order integration methods will provide greater per-step accuracy, the critical step size itself will not be greatly reduced.

A major problem arises when the simulated model has one or more time constants $|1/\lambda_i|$ that are small when compared to the total solution time interval $t_0 \leq t \leq t_K$. Numerical stability will then require very small Δt , even though the transient response associated with the higher frequency (larger λ_i) subsystems may contribute little to the particular solution. Such problems can be addressed either by neglecting the higher frequency components where appropriate or by adopting special numerical integration methods for *stiff systems*.

Selecting an Integration Method The best numerical integration method for a specific simulation is the method that yields an acceptable global approximation error with the minimum amount of round-off error and computing effort. No single method is best for all applications. The selection of an integration method depends on the model simulated, the purpose of the simulation study, and the availability of computing hardware and software.

In general, for well-behaved problems with continuous derivatives and no stiffness, a lower order Adams predictor is often a good choice. Multistep methods also facilitate estimating local truncation error. Multistep methods should be avoided for systems with discontinuities, however, because of the need for frequent restarts. Runge-Kutta methods have the advantage that these are self-starting and provide fair stability. For stiff systems where high-frequency modes have little influence on the global response, special stiff-system methods enable the use of economically large step sizes. Variable-step rules are useful when little is known a priori about solutions. Variable-step rules often make a good choice as general-purpose integration methods.

Round-off error usually is not a major concern in the selection of an integration method, since the goal of minimizing computing effort typically obviates such problems. Double-precision simulation can be used where round-off is a potential concern. An upper bound on step size often exists because of discontinuities in derivative functions or because of the need for response output at closely spaced time intervals.

Continuous-System Simulation Languages

Digital simulation can be implemented for a specific model in any high-level language such as FORTRAN or C. The general process for implementing a simulation is shown in Fig. 26. In addition, many special-purpose continuous-system simulation languages are commonly available across a wide range of platforms. Such languages greatly simplify programming tasks and typically provide for good graphical output.

8 MODEL CLASSIFICATIONS

Mathematical models of dynamic systems are distinguished by several criteria that describe fundamental properties of model variables and equations. These criteria in turn prescribe the theory and mathematical techniques that can be used to study different models. Table 11 summarizes these distinguishing criteria. In the following sections, the approaches adopted for the analysis of important classes of systems are briefly outlined.

8.1 Stochastic Systems

Systems in which some of the dependent variables (input, state, output) contain random components are called *stochastic systems*. Randomness may result from

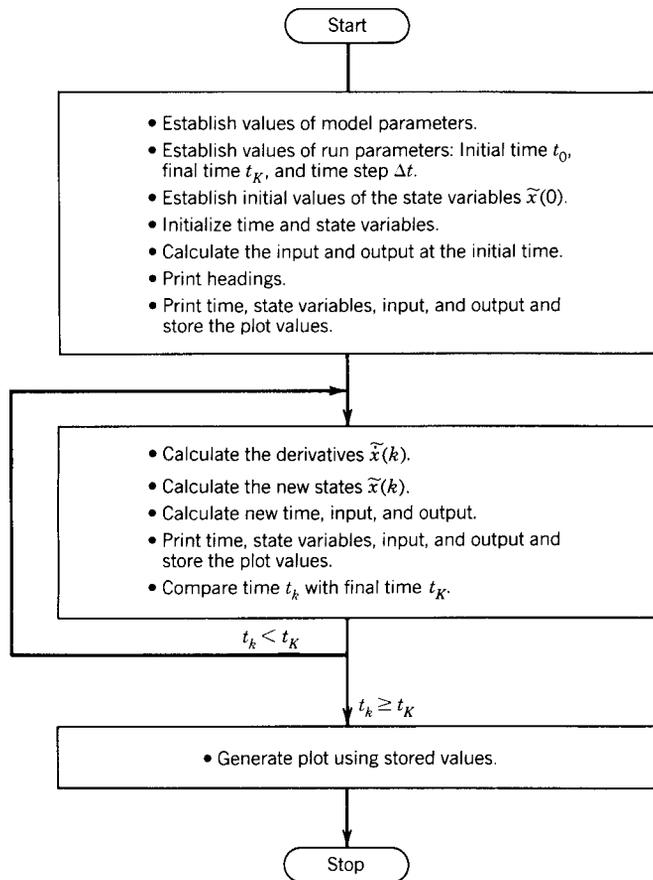

Fig. 26 General process for implementing digital simulation. (Adapted from Ref. 3.)

environmental factors, such as wind gusts or electrical noise, or simply from a lack of precise knowledge of the system model, such as when a human operator is included within a control system. If the randomness in the system can be described by some rule, then it is often possible to derive a model in terms of probability distributions involving, for example, the means and variances of model variables or parameters.

State-Variable Formulation A common formulation is the fixed linear model with additive noise

$$\begin{aligned}\dot{x}(t) &= Ax(t) + Bu(t) + w(t) \\ y(t) &= Cx(t) + v(t)\end{aligned}$$

where $w(t)$ is a zero-mean Gaussian disturbance and $v(t)$ is a zero-mean Gaussian measurement noise. This formulation is the basis for many *estimation problems*, including the problem of *optimal filtering*. Estimation

essentially involves the development of a rule or algorithm for determining the best estimate of the past, current, or future values of measured variables in the presence of disturbances or noise.

Random Variables In the following, important concepts for characterizing random signals are developed. A *random variable* x is a variable that assumes values that cannot be precisely predicted a priori. The likelihood that a random variable will assume a particular value is measured as the *probability* of that value. The *probability distribution function* $F(x)$ of a continuous random variable x is defined as the probability that x assumes a value no greater than x , that is,

$$F(x) = \Pr(X \leq x) = \int_{-\infty}^x f(x) dx$$

The *probability density function* $f(x)$ is defined as the derivative of $F(x)$.

Table 11 Classification of Mathematical Models of Dynamic Systems

Criterion	Classification	Description
Certainty	Deterministic	Model parameters and variables can be known with certainty. Common approximation when uncertainties are small.
	Stochastic	Uncertainty exists in the values of some parameters and/or variables. Model parameters and variables are expressed as random numbers or processes and are characterized by the parameters of probability distributions.
Spatial characteristics	Lumped	State of the system can be described by a finite set of state variables. Model is expressed as a discrete set of point functions described by ordinary differential or difference equations.
	Distributed	State depends on both time and spatial location. Model is usually described by variables that are continuous in time and space, resulting in partial differential equations. Frequently approximated by lumped elements. Typical in the study of structures and mass and heat transport.
Parameter variation	Fixed or time invariant	Model parameters are constant. Model described by differential or difference equations with constant coefficients. Model with same initial conditions and input delayed by t_d has the same response delayed by t_d .
	Time varying	Model parameters are time dependent.
Superposition property	Linear	Superposition applies. Model can be expressed as a system of linear difference or differential equations.
	Nonlinear	Superposition does not apply. Model is expressed as a system of nonlinear difference or differential equations. Frequently approximated by linear systems for analytical ease.
Continuity of independent variable (time)	Continuous	Dependent variables (input, output, state) are defined over a continuous range of the independent variable (time), even though the dependence is not necessarily described by a mathematically continuous function. Model is expressed as differential equations. Typical of physical systems.
	Discrete	Dependent variables are defined only at distinct instants of time. Model is expressed as difference equations. Typical of digital and nonphysical systems.
	Hybrid	System with continuous and discrete subsystems, most common in computer control and communication systems. Sampling and quantization typical in A/D (analog-to-digital) conversion; signal reconstruction for D/A conversion. Model frequently approximated as entirely continuous or entirely discrete.
Quantization of dependent variables	Nonquantized	Dependent variables are continuously variable over a range of values. Typical of physical systems at macroscopic resolution.
	Quantized	Dependent variables assume only a countable number of different values. Typical of computer control and communication systems (sample data systems).

The *mean* or *expected value* of a probability distribution is define as

$$E(X) = \int_{-\infty}^{\infty} x f(x) dx = \bar{X}$$

The mean is the first moment of the distribution. The *n*th *moment* of the distribution is define as

$$E(X^n) = \int_{-\infty}^{\infty} x^n f(x) dx$$

The mean square of the difference between the random variable and its mean is the *variance* or *second central*

moment of the distribution,

$$\begin{aligned} \sigma^2(X) &= E(X - \bar{X})^2 = \int_{-\infty}^{\infty} (x - \bar{X})^2 f(x) dx \\ &= E(X^2) - [E(X)]^2 \end{aligned}$$

The square root of the variance is the *standard deviation* of the distribution:

$$\sigma(X) = \sqrt{E(X^2) - [E(X)]^2}$$

The mean of the distribution therefore is a measure of the average magnitude of the random variable, while

the variance and standard deviation are measures of the variability or dispersion of this magnitude.

The concepts of probability can be extended to more than one random variable. The *joint distribution* function of two random variables x and y is defined as

$$F(x, y) = \Pr(X < x \text{ and } Y < y) \\ = \int_{-\infty}^x \int_{-\infty}^y f(x, y) dy dx$$

where $f(x, y)$ is the joint distribution. The ij th moment of the joint distribution is

$$E(X^i Y^j) = \int_{-\infty}^{\infty} x^i \int_{-\infty}^{\infty} y^j f(x, y) dy dx$$

The *covariance* of x and y is defined to be

$$E[(X - \bar{X})(Y - \bar{Y})]$$

and the normalized covariance or *correlation coefficient* as

$$\rho = \frac{E[(X - \bar{X})(Y - \bar{Y})]}{\sqrt{\sigma^2(X)\sigma^2(Y)}}$$

Although many distribution functions have proven useful in control engineering, far and away the most useful is the *Gaussian* or *normal distribution*

$$F(x) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left[-\frac{(x - \mu)^2}{2\sigma^2}\right]$$

where μ is the mean of the distribution and σ is the standard deviation. The Gaussian distribution has a number of important properties. First, if the input to a linear system is Gaussian, the output also will be Gaussian. Second, if the input to a linear system is only approximately Gaussian, the output will tend to approximate a Gaussian distribution even more closely. Finally, a Gaussian distribution can be completely specified by two parameters, μ and σ , and therefore a zero-mean Gaussian variable is completely specified by its variance.

Random Processes A *random process* is a set of random variables with time-dependent elements. If the statistical parameters of the process (such as σ for the zero-mean Gaussian process) do not vary with time, the process is *stationary*. The *autocorrelation function* of a stationary random variable $x(t)$ is defined by

$$\phi_{xx}(\tau) = \lim_{T \rightarrow \infty} \frac{1}{2T} \int_{-T}^T x(t)x(t + \tau) dt$$

a function of the fixed time interval τ . The autocorrelation function is a quantitative measure of the sequential dependence or time correlation of the random variable, that is, the relative effect of prior values of the variable on the present or future values of the variable. The autocorrelation function also gives information regarding how rapidly the variable is changing and about whether the signal is in part deterministic (specifically periodic). The autocorrelation function of a zero-mean variable has the properties

$$\sigma^2 = \phi_{xx}(0) \geq \phi_{xx}(\tau) \quad \phi_{xx}(\tau) = \phi_{xx}(-\tau)$$

In other words, the autocorrelation function for $\tau = 0$ is identically the variance and the variance is the maximum value of the autocorrelation function. From the definition of the function, it is clear that (a) for a purely random variable with zero mean, $\phi_{xx}(\tau) = 0$ for $\tau \neq 0$, and (b) for a deterministic variable, which is periodic with period T , $\phi_{xx}(k2\pi T) = \sigma^2$ for k integer. The concept of time correlation is readily extended to more than one random variable. The *cross-correlation function* between the random variables $x(t)$ and $y(t)$ is

$$\phi_{xy}(\tau) = \lim_{T \rightarrow \infty} \int_{-T}^T x(t)y(t + \tau) dt$$

For $\tau = 0$, the cross correlation between two zero-mean variables is identically the covariance. A final characterization of a random variable is its *power spectrum*, defined as

$$G(\omega, x) = \lim_{T \rightarrow \infty} \frac{1}{2\pi T} \left| \int_{-T}^T x(t)e^{-j\omega t} dt \right|^2$$

For a stationary random process, the power spectrum function is identically the Fourier transform of the autocorrelation function

$$G(\omega, x) = \frac{1}{\pi} \int_{-\infty}^{\infty} \phi_{xx}(\tau)e^{-j\omega\tau} d\tau$$

with

$$\phi_{xx}(0) = \int_{-\infty}^{\infty} G(\omega, x) d\omega$$

8.2 Distributed-Parameter Models

There are many important applications in which the state of a system cannot be defined at a finite number of points in space. Instead, the system state is a continuously varying function of both time and location. When continuous spatial dependence is explicitly accounted for in a model, the independent variables

must include spatial coordinates as well as time. The resulting *distributed-parameter model* is described in terms of *partial differential equations*, containing partial derivatives with respect to each of the independent variables.

Distributed-parameter models commonly arise in the study of mass and heat transport, the mechanics of structures and structural components, and electrical transmission. Consider as a simple example the unidirectional flow of heat through a wall, as depicted in Fig. 27. The temperature of the wall is not in general uniform but depends on both the time t and position within the wall x , that is, $\theta = \theta(x, t)$. A distributed-parameter model for this case might be the first-order partial differential equation

$$\frac{d}{dt}\theta(x, t) = \frac{1}{C_t} \frac{\partial}{\partial x} \left[\frac{1}{R_t} \frac{\partial}{\partial x} \theta(x, t) \right]$$

where C_t is the thermal capacitance and R_t is the thermal resistance of the wall (assumed uniform).

The complexity of distributed-parameter models is typically such that these models are avoided in the analysis and design of control systems. Instead, distributed-parameter systems are approximated by a finite number of spatial "lumps," each lump being characterized by some average value of the state. By eliminating the independent spatial variables, the result is a *lumped-parameter (or lumped-element) model* described by coupled ordinary differential equations. If a sufficiently fine-grained representation of the lumped microstructure can be achieved, a lumped model can be derived that will approximate the distributed model to any desired degree of accuracy. Consider, for example, the three temperature lumps shown in Fig. 28, used to approximate the wall of Fig. 27. The corresponding

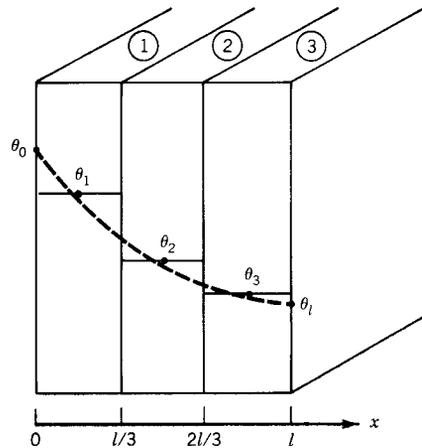

Fig. 28 Lumped-parameter model for uniform heat transfer through a wall.

third-order lumped approximation is

$$\frac{d}{dt} \begin{bmatrix} \theta_1(t) \\ \theta_2(t) \\ \theta_3(t) \end{bmatrix} = \begin{bmatrix} -\frac{9}{C_t R_t} & \frac{3}{C_t R_t} & 0 \\ \frac{3}{C_t R_t} & \frac{6}{C_t R_t} & \frac{3}{C_t R_t} \\ 0 & \frac{3}{C_t R_t} & \frac{6}{C_t R_t} \end{bmatrix} \begin{bmatrix} \theta_1(t) \\ \theta_2(t) \\ \theta_3(t) \end{bmatrix} + \begin{bmatrix} \frac{6}{C_t R_t} \\ 0 \\ 0 \end{bmatrix} \theta_0(t)$$

If a more detailed approximation is required, this can always be achieved at the expense of adding additional, smaller lumps.

8.3 Time-Varying Systems

Time-varying systems are those with characteristics that change as a function of time. Such variation may result from environmental factors, such as temperature or radiation, or from factors related to the operation of the system, such as fuel consumption. While in general a model with variable parameters can be either linear or nonlinear, the name time varying is most frequently associated with linear systems described by the following state equation:

$$\dot{x}(t) = A(t)x(t) + B(t)u(t)$$

For this linear time-varying model, the superposition principle still applies. Superposition is a great aid in

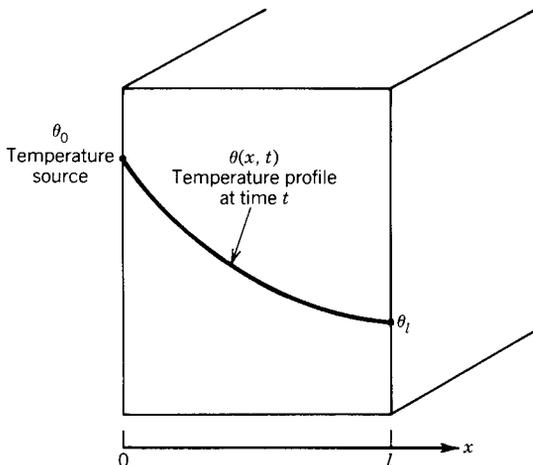

Fig. 27 Uniform heat transfer through a wall.

model formulation but unfortunately does not prove to be much help in determining the model solution.

Paradoxically, the form of the solution to the linear time-varying equation is well known⁷:

$$x(t) = \Phi(t, t_0)x(t_0) + \int_{t_0}^t \Phi(t, \tau)B(\tau)u(\tau) dt$$

where $\Phi(t, t_0)$ is the time-varying state transition matrix. This knowledge is typically of little value, however, since it is not usually possible to determine the state transition matrix by any straightforward method. By analogy with the first-order case, the relationship

$$\Phi(t, t_0) = \exp\left(\int_{t_0}^t A(\tau) d\tau\right)$$

can be proven valid *if and only if*

$$A(t) \int_{t_0}^t A(\tau) d\tau = \int_{t_0}^t A(\tau) d\tau A(t)$$

that is, if and only if $A(t)$ and its integral commute. This is a very stringent condition for all but a first-order system and, as a rule, it is usually easiest to obtain the solution using simulation.

Most of the properties of the fixed transition matrix extend to the time-varying case:

$$\Phi(t, t_0) = I$$

$$\Phi^{-1}(t, t_0) = \Phi(t_0, t)$$

$$\Phi(t_2, t_1)\Phi(t_1, t_0) = \Phi(t_2, t_0)$$

$$\Phi(t, t_0) = A(t)\Phi(t, t_0)$$

8.4 Nonlinear Systems

The theory of fixed, linear, lumped-parameter systems is highly developed and provides a powerful set of techniques for control system analysis and design. In practice, however, all physical systems are nonlinear to some greater or lesser degree. The linearity of a physical system is usually only a convenient approximation, restricted to a certain range of operation. In addition, nonlinearities such as dead zones, saturation, or on-off action are sometimes introduced into control systems intentionally, either to obtain some advantageous performance characteristic or to compensate for the effects of other (undesirable) nonlinearities.

Unfortunately, while nonlinear systems are important, ubiquitous, and potentially useful, the theory of nonlinear differential equations is comparatively meager. Except for specific cases, closed-form solutions to nonlinear systems are generally unavailable. The only universally applicable method for the study of nonlinear systems is *simulation*. As described in

Section 7, however, simulation is an experimental approach, embodying all of the attending limitations of experimentation.

A number of special techniques are available for the analysis of nonlinear systems. All of these techniques are in some sense approximate, assuming, for example, either a restricted range of operation over which nonlinearities are mild or the relative isolation of lower order subsystems. When used in conjunction with more complex simulation models, however, these techniques often provide insights and design concepts that would be difficult to discover through the use of simulation alone.⁸

Linear versus Nonlinear Behaviors There are several fundamental differences between the behavior of linear and nonlinear systems that are especially important. These differences not only account for the increased difficulty encountered in the analysis and design of nonlinear systems, but also imply entirely new types of behavior for nonlinear systems that are not possible for linear systems.

The fundamental property of linear systems is *superposition*. This property states that if $y_1(t)$ is the response of the system to $u_1(t)$ and $y_2(t)$ is the response of the system to $u_2(t)$, then the response of the system to the linear combination $a_1u_1(t) + a_2u_2(t)$ is the linear combination $a_1y_1(t) + a_2y_2(t)$. An immediate consequence of superposition is that the responses of a linear system to inputs differing only in amplitude is qualitatively the same. Since superposition does not apply to nonlinear systems, the responses of a nonlinear system to large and small changes may be fundamentally different.

This fundamental difference in linear and nonlinear behaviors has a second consequence. For a linear system, interchanging two elements connected in series does not affect the overall system behavior. Clearly, this cannot be true in general for nonlinear systems.

A third property peculiar to nonlinear systems is the potential existence of *limit cycles*. A linear oscillator oscillates at an amplitude that depends on its initial state. A limit cycle is an oscillation of fixed amplitude and period, independent of the initial state, that is unique to the nonlinear system.

A fourth property concerns the response of nonlinear systems to sinusoidal inputs. For a linear system, the response to sinusoidal input is a sinusoid of the same frequency, potentially differing only in magnitude and phase. For a nonlinear system, the output will in general contain other frequency components, including possibly harmonics, subharmonics, and aperiodic terms. Indeed, the response need not contain the input frequency at all.

Linearizing Approximations Perhaps the most useful technique for analyzing nonlinear systems is to approximate these with linear systems. While many linearizing approximations are possible, linearization can frequently be achieved by considering small

excursions of the system state about a reference trajectory. Consider the nonlinear state equation

$$\dot{x}(t) = f[x(t), u(t)]$$

together with a reference trajectory $x^0(t)$ and reference input $u^0(t)$ that together satisfy the state equation

$$\dot{x}^0(t) = f[x^0(t), u^0(t)]$$

Note that the simplest case is to choose a static equilibrium or *operating point* \bar{x} as the reference “trajectory” such that $0 = f(\bar{x}, 0)$. The actual trajectory is then related to the reference trajectory by the relationships

$$x(t) = x^0(t) + \delta x(t)$$

$$u(t) = u^0(t) + \delta u(t)$$

where $\delta x(t)$ is some small perturbation about the reference state and $\delta u(t)$ is some small perturbation about the reference input. If these perturbations are indeed small, then applying Taylor’s series expansion about the reference trajectory yields the linearized approximation

$$\delta \dot{x}(t) = A(t) \delta x(t) + B(t) \delta u(t)$$

where the state and distribution matrices are the *Jacobian matrices*

$$A(t) = \begin{bmatrix} \frac{\partial f_1}{\partial x_1} & \frac{\partial f_1}{\partial x_2} & \cdots & \frac{\partial f_1}{\partial x_n} \\ \frac{\partial f_2}{\partial x_1} & \frac{\partial f_2}{\partial x_2} & \cdots & \frac{\partial f_2}{\partial x_n} \\ \vdots & \vdots & \ddots & \vdots \\ \frac{\partial f_n}{\partial x_1} & \frac{\partial f_n}{\partial x_2} & \cdots & \frac{\partial f_n}{\partial x_n} \end{bmatrix}_{x(t)=x^0(t); u(t)=u^0(t)}$$

$$B(t) = \begin{bmatrix} \frac{\partial f_1}{\partial u_1} & \frac{\partial f_1}{\partial u_2} & \cdots & \frac{\partial f_1}{\partial u_m} \\ \frac{\partial f_2}{\partial u_1} & \frac{\partial f_2}{\partial u_2} & \cdots & \frac{\partial f_2}{\partial u_m} \\ \vdots & \vdots & \ddots & \vdots \\ \frac{\partial f_n}{\partial u_1} & \frac{\partial f_n}{\partial u_2} & \cdots & \frac{\partial f_n}{\partial u_m} \end{bmatrix}_{x(t)=x^0(t); u(t)=u^0(t)}$$

If the reference trajectory is a fixed operating point \bar{x} , then the resulting linearized system is time invariant and can be solved analytically. If the reference trajectory is a function of time, however, then the resulting system is linear but time varying.

Describing Functions The describing function method is an extension of the frequency transfer function approach of linear systems, most often used to determine the stability of limit cycles of systems containing nonlinearities. The approach is approximate and its usefulness depends on two major assumptions:

1. All the nonlinearities within the system can be aggregated mathematically into a single block, denoted as $N(M)$ in Fig. 29, such that the equivalent gain and phase associated with this block depend only on the amplitude M_d of the sinusoidal input $m(\omega t) = M \sin(\omega t)$ and are independent of the input frequency ω .
2. All the harmonics, subharmonics, and any direct current (dc) component of the output of the nonlinear block are filtered out by the linear portion of the system such that the effective output of the nonlinear block is well approximated by a periodic response having the same fundamental period as the input.

Although these assumptions appear to be rather limiting, the technique gives reasonable results for a large class of control systems. In particular, the second assumption is generally satisfied by higher order control systems with symmetric nonlinearities, since (a) symmetric nonlinearities do not generate dc terms, (b) the amplitudes of harmonics are generally small when compared with the fundamental term and subharmonics are uncommon, and (c) feedback within a control system typically provides low-pass filtering to further attenuate harmonics, especially for higher order systems. Because the method is relatively simple and can be used for systems of any order, describing functions have enjoyed wide practical application.

The describing function of a nonlinear block is defined as the ratio of the fundamental component of the output to the amplitude of a sinusoidal input. In general, the response of the nonlinearity to the input

$$m(\omega t) = M \sin \omega t$$

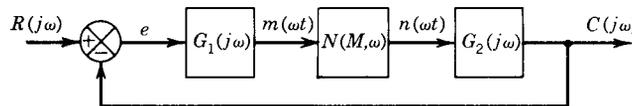

Fig. 29 General nonlinear system for describing function analysis.

is the output

$$n(\omega t) = N_1 \sin(\omega t + \phi_1) + N_2 \sin(2\omega t + \phi_2) \\ + N_3 \sin(3\omega t + \phi_3) + \dots$$

and, hence, the describing function for the nonlinearity is defined as the complex quantity

$$N(M) = \frac{N_1}{M} e^{j\phi_1}$$

Derivation of the approximating function typically proceeds by representing the fundamental frequency by the Fourier series coefficients

$$A_1(M) = \frac{2}{T} \int_{-T/2}^{T/2} n(\omega t) \cos \omega t \, d(\omega t) \\ B_1(M) = \frac{2}{T} \int_{-T/2}^{T/2} n(\omega t) \sin \omega t \, d(\omega t)$$

The describing function is then written in terms of these coefficients as

$$N(M) = \frac{B_1(M)}{M} + j \frac{A_1(M)}{M} = \left[\left(\frac{B_1(M)}{M} \right)^2 \right. \\ \left. + \left(\frac{A_1(M)}{M} \right)^2 \right]^{1/2} \exp \left[j \tan^{-1} \left(\frac{A_1(M)}{B_1(M)} \right) \right]$$

Note that if $n(\omega t) = -n(-\omega t)$, then the describing function is odd, $A_1(M) = 0$, and there is no phase shift between the input and output. If $n(\omega t) = n(-\omega t)$, then the function is even, $B_1(M) = 0$, and the phase shift is $\pi/2$.

The describing functions for a number of typical nonlinearities are given in Fig. 12.30. Reference 9 contains an extensive catalog. The following derivation for a dead-zone nonlinearity demonstrates the general procedure for deriving a describing function. For the saturation element depicted in Fig. 12.30a, the relationship between the input $m(\omega t)$ and output $n(\omega t)$ can be written as

$$n(\omega t) = \begin{cases} 0 & \text{for } -D < m < D \\ K_1 M (\sin \omega t - \sin \omega_1 t) & \text{for } m > D \\ K_1 M (\sin \omega t + \sin \omega_1 t) & \text{for } m < -D \end{cases}$$

Since the function is odd, $A_1 = 0$. By the symmetry over the four quarters of the response period,

$$B_1 = 4 \left[\frac{2}{\pi/2} \int_0^{\pi/2} n(\omega t) \sin \omega t \, d(\omega t) \right] \\ = \frac{4}{\pi} \left[\int_0^{\omega t_1} (0) \sin \omega t \, d(\omega t) \right. \\ \left. + \int_{\omega t_1}^{\pi/2} K_1 M (\sin \omega t - \sin \omega_1 t) \sin \omega t \, d(\omega t) \right]$$

where $\omega t_1 = \sin^{-1}(D/M)$. Evaluating the integrals and dividing by M yields the describing function listed in Fig. 12.30.

Phase-Plane Method The *phase-plane method* is a graphical application of the state-space approach used to characterize the free response of second-order nonlinear systems. While any convenient pair of state variables can be used, the *phase variables* originally were taken to be the displacement and velocity of the mass of a second-order mechanical system. Using the two state variables as the coordinate axis, the transient response of a system is captured on the *phase plane* as the plot of one variable against the other, with time implicit on the resulting curve. The curve for a specific initial condition is called a *trajectory* in the phase plane; a representative sample of trajectories is called the *phase portrait* of the system. The phase portrait is a compact and readily interpreted summary of the system response. Phase portraits for a sample of typical nonlinearities are shown in Fig. 12.31.

Four methods can be used to construct a phase portrait: (a) direct solution of the differential equation, (b) the graphical *method of isoclines*, (c) transformation of the second-order system (with time as the independent variable) into an equivalent first-order system (with one of the phase variables as the independent variable), and (d) numerical solution using simulation. The first and second methods are usually impractical; the third and fourth methods are frequently used in combination. For example, consider the second-order model

$$\frac{dx_1}{dt} = f_1(x_1, x_2) \quad \frac{dx_2}{dt} = f_2(x_1, x_2)$$

Dividing the second equation by the first and eliminating the dt terms yield

$$\frac{dx_2}{dx_1} = \frac{f_2(x_1, x_2)}{f_1(x_1, x_2)}$$

This first-order equation describes the phase-plane trajectories. In many cases it can be solved analytically. If not, it always can be simulated.

The phase-plane method complements the describing-function approach. A describing function is an approximate representation of the sinusoidal response for systems of any order, while the phase

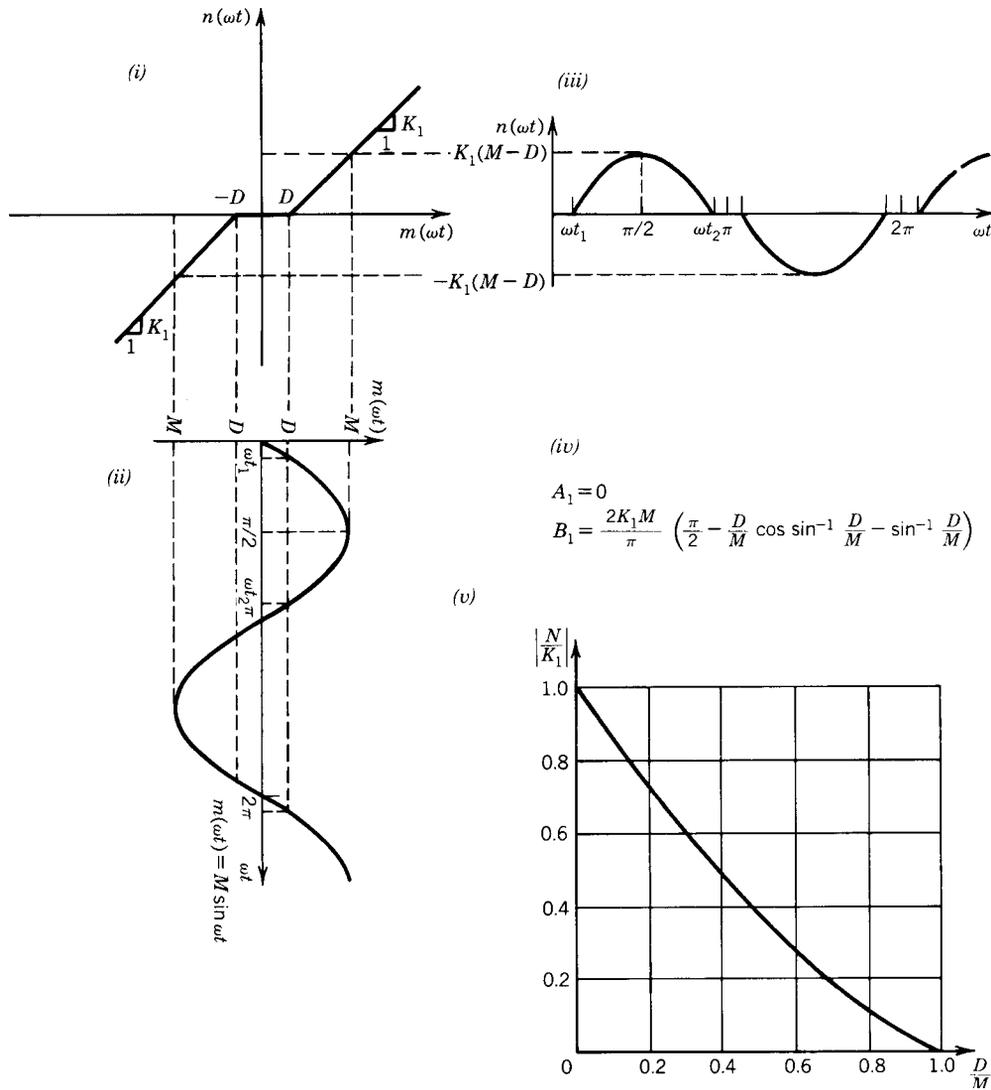

Fig. 30a Describing functions for typical nonlinearities (after Refs. 9 and 10). Dead-zone nonlinearity: (i) nonlinear characteristic; (ii) sinusoidal input wave shape; (iii) output wave shape; (iv) describing-function coefficients; (v) normalized describing function.

plane is an exact representation of the (free) transient response for first and second-order systems. Of course, the phase-plane method theoretically can be extended for higher order systems, but the difficulty of visualizing the n th-order state space typically makes such a direct extension impractical. An approximate extension of the method has been used with some considerable success,⁸ however, in order to explore and validate the relationships among pairs of variables in complex simulation models. The approximation is based on the assumptions that the paired variables

define a second-order subsystem that, for the purposes of analysis, is weakly coupled to the remainder of the system.

8.5 Discrete and Hybrid Systems

A *discrete-time system* is one for which the dependent variables are defined only at distinct instants of time. Discrete-time models occur in the representation of systems that are inherently discrete, in the analysis and design of digital measurement and control systems, and in the numerical solution of differential equations

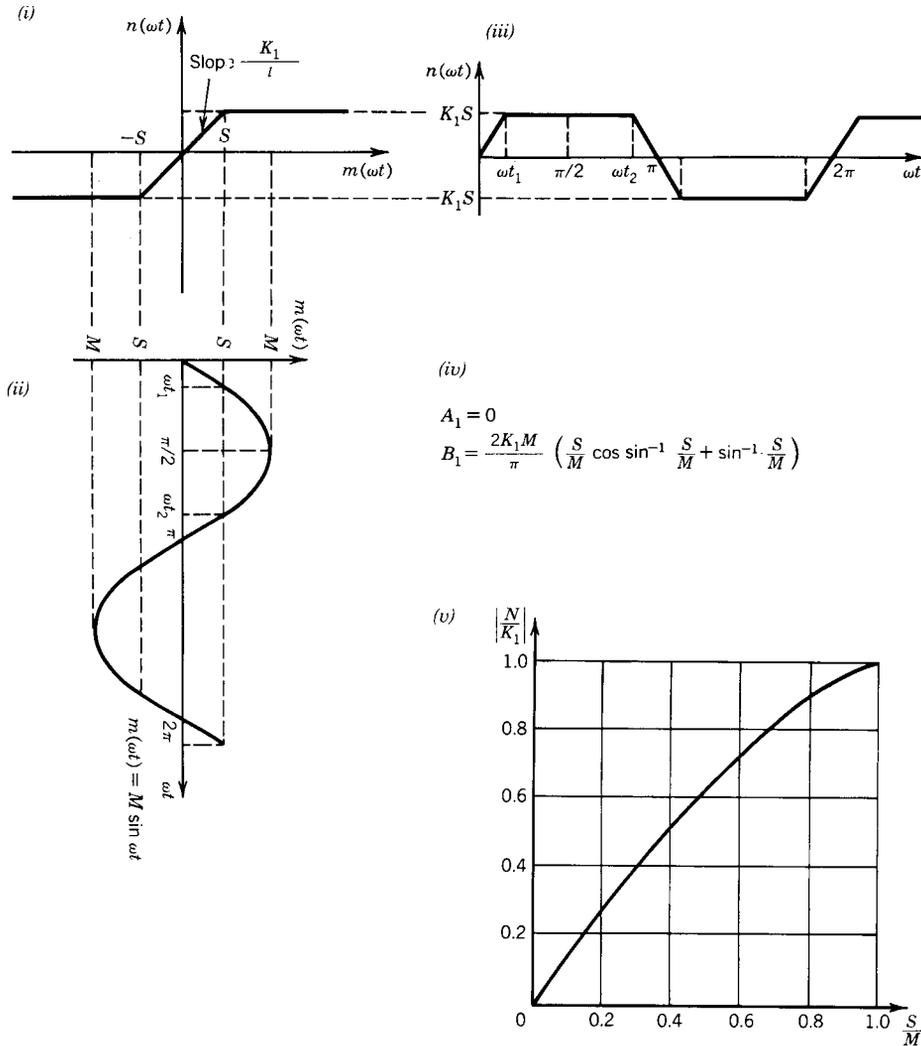

Fig. 30b Saturation nonlinearity: (i) nonlinear characteristic; (ii) sinusoidal input wave shape; (iii) output wave shape; (iv) describing-function coefficients; (v) normalized describing function.

(see Section 7). Because most control systems are now implemented using digital computers (especially microprocessors), discrete-time models are extremely important in dynamic systems analysis. The discrete-time nature of a computer's sampling of continuous physical signals also leads to the occurrence of *hybrid systems*, that is, systems that are in part discrete and in part continuous. Discrete-time models of hybrid systems are called *sampled-data systems*.

Difference Equations Dynamic models of discrete-time systems most naturally take the form of *difference equations*. The I/O form of an *n*th-order difference

equation model is

$$f[y(k+n), y(k+n-1), \dots, y(k), u(k+n-1), \dots, u(k)] = 0$$

which expresses the dependence of the $(k+n)$ th value of the output, $y(k+n)$, on the n preceding values of the output y and input u . For a linear system, the I/O form can be written as

$$y(k+n) + a_{n-1}(k)y(k+n-1) + \dots + a_1(k)y(k+1) + a_0(k)y(k) = b_{n-1}(k)u(k+n-1) + \dots + b_0(k)u(k)$$

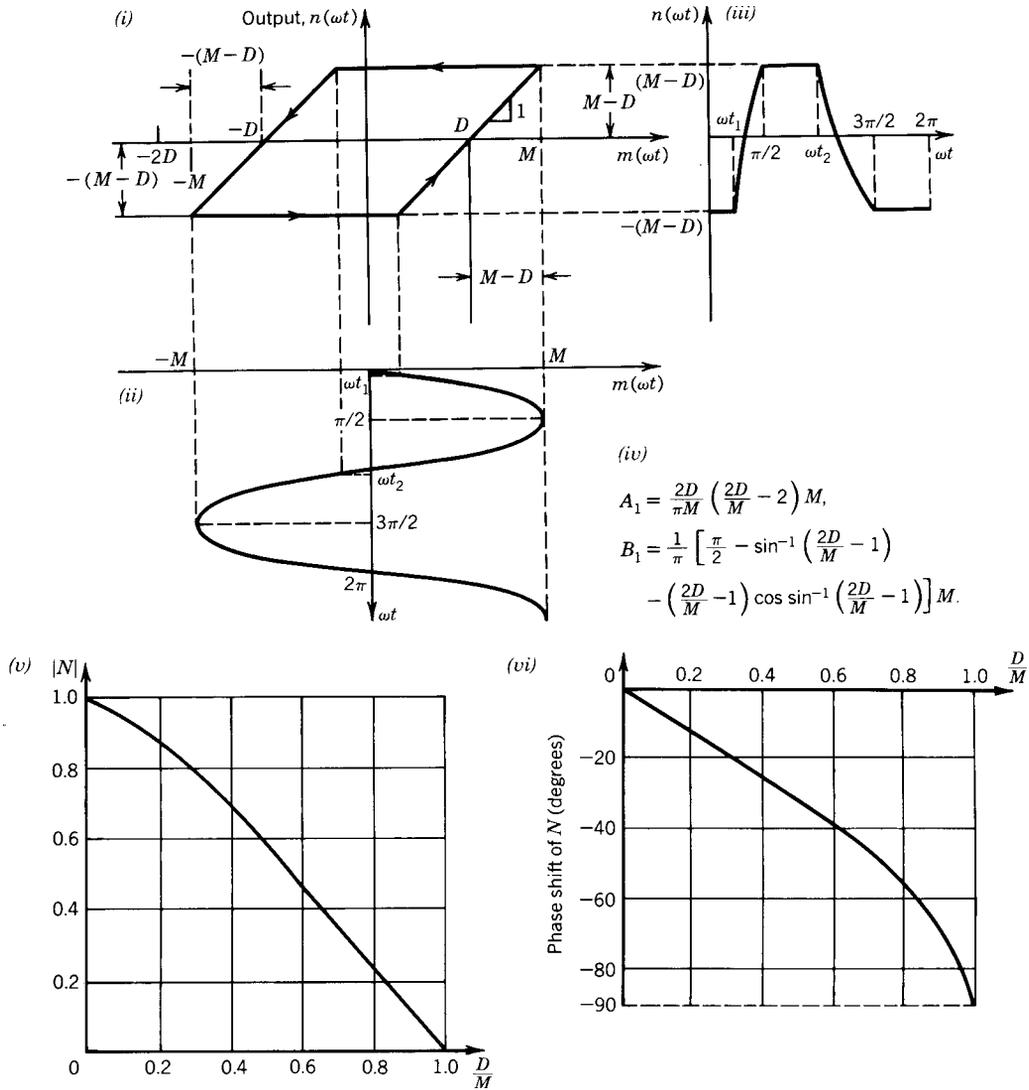

Fig. 30c Backlash nonlinearity: (i) nonlinear characteristic; (ii) sinusoidal input wave shape; (iii) output wave shape; (iv) describing-function coefficients; (v) normalized amplitude characteristics for the describing function; (vi) normalized phase characteristics for the describing function.

In state-variable form, the discrete-time model is the vector difference equation

$$x(k+1) = f[x(k), u(k)]$$

$$y(k) = g[x(k), u(k)]$$

where x is the state vector, u is the vector of inputs, and y is the vector of outputs. For a linear system, the discrete state-variable form can be written as

$$x(k+1) = A(k)x(k) + B(k)u(k)$$

$$y(k) = C(k)x(k) + D(k)u(k)$$

The mathematics of difference equations parallels that of differential equations in many important respects. In general, the concepts applied to differential equations have direct analogies for difference equations, although the mechanics of their implementation may vary (see Ref. 11 for a development of dynamic modeling based on difference equations).

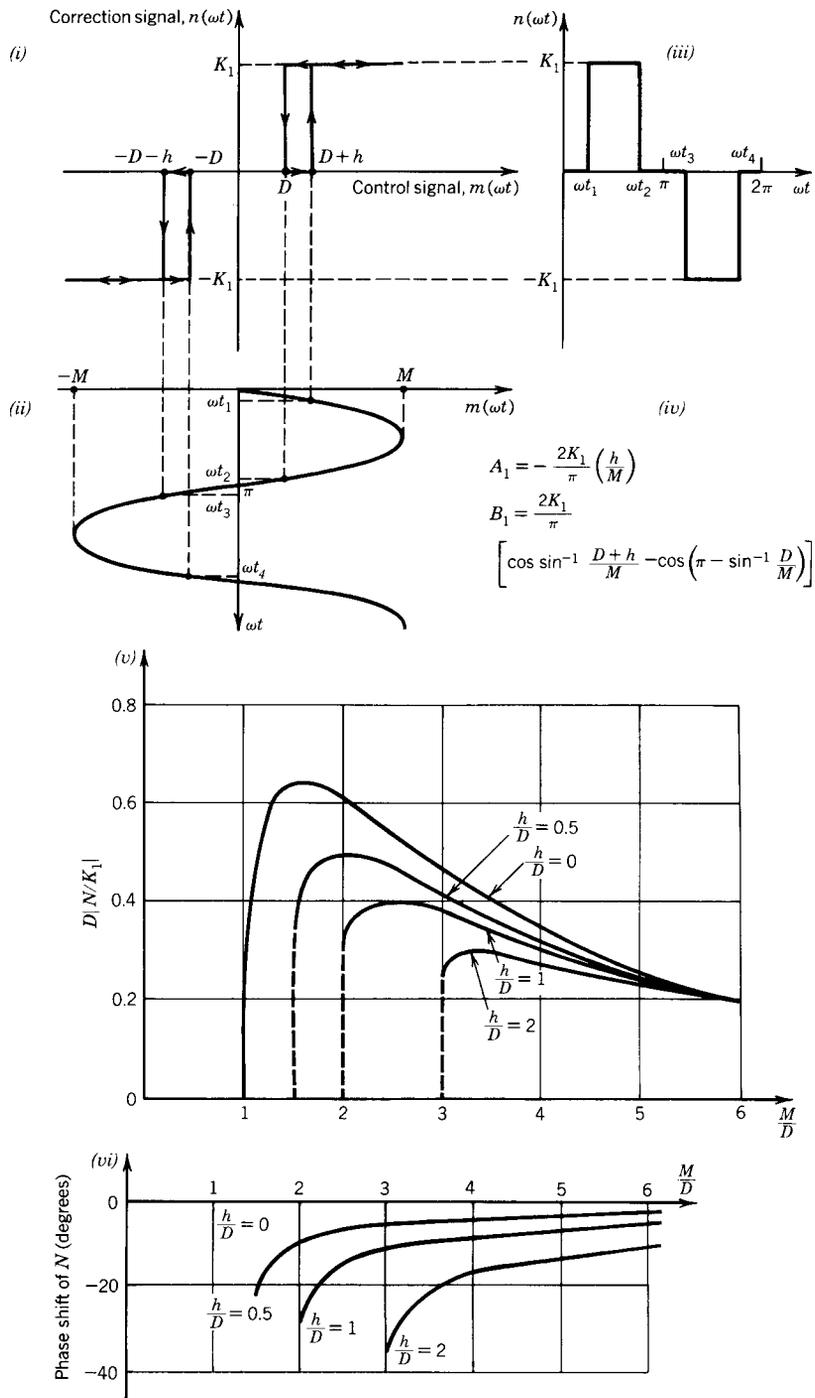

Fig. 30d Three-position on-off device with hysteresis: (i) nonlinear characteristic; (ii) sinusoidal input wave shape; (iii) output wave shape; (iv) describing-function coefficients; (v) normalized amplitude characteristics for the describing function; (vi) normalized phase characteristics for the describing function.

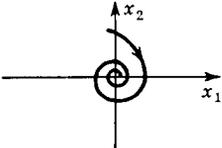

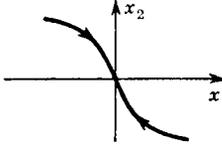

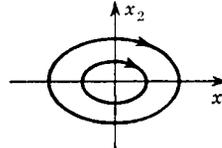

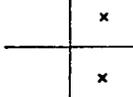

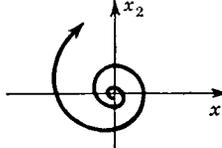

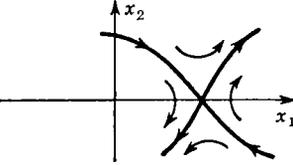

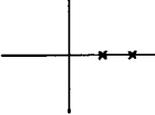

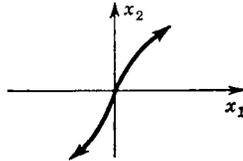

Name	Roots	Sketch
Stable focus or spiral	Damped complex conjugate 	 Trajectories spiral asymptotically to focus
Stable node	Stable real roots 	 Trajectories approach node monotonically
Vortex or center (structurally unstable)	Imaginary roots 	 Conservative system or oscillator
Unstable focus	Complex conjugate with positive real part 	
Saddle point	A point of unstable equilibrium 	
Unstable node	Unstable real roots 	 Trajectories diverge monotonically from node

Fig. 31b (Continued)

One important difference is that the general solution of nonlinear and time-varying difference equations can usually be obtained through *recursion*. For example, consider the discrete nonlinear model

$$y(k + 1) = \frac{y(k)}{1 + y(k)}$$

Recursive evaluation of the equation beginning with the initial condition $y(0)$ yields

$$\begin{aligned} y(1) &= \frac{y(0)}{1 + y(0)} \\ y(2) &= \frac{y(1)}{1 + y(1)} = \left[\frac{y(0)}{1 + y(0)} \right] / \left[1 + \frac{y(0)}{1 + y(0)} \right] \\ &= \frac{y(0)}{1 + 2y(0)} \\ y(3) &= \frac{y(2)}{1 + y(2)} = \frac{y(0)}{1 + 3y(0)} \\ &\vdots \end{aligned}$$

the pattern of which reveals, by induction,

$$y(k) = \frac{y(0)}{1 + ky(0)}$$

as the general solution.

Uniform Sampling *Uniform sampling* is the most common mathematical approach to *A/D conversion*, that is, to extracting the discrete-time approximation $y^*(k)$ of the form

$$y^*(k) = y(t = kT)$$

from the continuous-time signal $y(t)$, where T is a constant interval of time called the *sampling period*. If the sampling period is too large, however, it may not be possible to represent the continuous signal accurately. The *sampling theorem* guarantees that $y(t)$ can be reconstructed from the uniformly sampled values $y^*(k)$ if the sampling period satisfies the inequality

$$T \leq \frac{\pi}{\omega_u}$$

where ω_u is the highest frequency contained in the Fourier transform $Y(\omega)$ of $y(t)$, that is, if

$$Y(\omega) = 0 \quad \text{for all } \omega > \omega_u$$

The Fourier transform of a signal is defined to be

$$\mathcal{F}[y(t)] = Y(\omega) = \int_{-\infty}^{\infty} y(t)e^{-j\omega t} dt$$

Note that if $y(t) = 0$ for $t \geq 0$, and if the region of convergence for the Laplace transform includes the imaginary axis, then the Fourier transform can be obtained from the Laplace transform as

$$Y(\omega) = [Y(s)]_{s=j\omega}$$

For cases where it is impossible to determine the Fourier transform analytically, such as when the signal is described graphically or by a table, numerical solution based on the *fast Fourier transform (FFT) algorithm* is usually satisfactory.

In general, the condition $T \leq \pi/\omega_u$ cannot be satisfied exactly since most physical signals have no finite upper frequency ω_u . A useful approximation is to define the upper frequency as the frequency for which 99% of the signal “energy” lies in the frequency spectrum $0 \leq \omega \leq \omega_u$. This approximation is found from the relation

$$\int_0^{\omega_u} |Y(\omega)|^2 d\omega = 0.99 \int_0^{\infty} |Y(\omega)|^2 d\omega$$

where the square of the amplitude of the Fourier transform $|Y(\omega)|^2$ is said to be the *power spectrum*, and its integral over the entire frequency spectrum is referred to as the “energy” of the signal. Using a sampling frequency 2–10 times this approximate upper frequency (depending on the required factor of safety) and inserting a low-pass filter (called a *guard filter*) before the sampler to eliminate frequencies above the *Nyquist frequency* π/T usually lead to satisfactory results.⁴

The z Transform The z transform permits the development and application of transfer functions for discrete-time systems, in a manner analogous to continuous-time transfer functions based on the Laplace transform. A discrete signal may be represented as a series of impulses

$$\begin{aligned} y^*(t) &= y(0)\delta(t) + y(1)\delta(t - T) + y(2)\delta(t - 2T) + \dots \\ &= \sum_{k=0}^N y(k)\delta(t - kT) \end{aligned}$$

where $y(k) = y^*(t = kT)$ are the values of the discrete signal, $\delta(t)$ is the unit impulse function, and N is the

Table 12 z-Transform Pairs

	$X(s)$	$x(t)$ or $x(k)$	$X(z)$
1	1	$\delta(t)$	1
2	e^{-kTs}	$\delta(t - kT)$	z^{-k}
3	$\frac{1}{s}$	1(t)	$\frac{z}{z-1}$
4	$\frac{1}{s^2}$	t	$\frac{Tz}{(z-1)^2}$
5	$\frac{1}{s+a}$	e^{-at}	$\frac{z}{z-e^{-aT}}$
6	$\frac{a}{s(s+a)}$	$1 - e^{-at}$	$\frac{(1 - e^{-aT})z}{(z-1)(z - e^{-aT})}$
7	$\frac{\omega}{s^2 + \omega^2}$	$\sin \omega t$	$\frac{z \sin \omega T}{z^2 - 2z \cos \omega T + 1}$
8	$\frac{s}{s^2 + \omega^2}$	$\cos \omega t$	$\frac{z(z - \cos \omega T)}{z^2 - 2z \cos \omega T + 1}$
9	$\frac{1}{(s+a)^2}$	te^{-at}	$\frac{Tze^{-aT}}{(z - e^{-aT})^2}$
10	$\frac{\omega}{(s+a)^2 + \omega^2}$	$e^{-at} \sin \omega t$	$\frac{ze^{-aT} \sin \omega T}{z^2 - 2ze^{-aT} \cos \omega T + e^{-2aT}}$
11	$\frac{s+a}{(s+a)^2 + \omega^2}$	$e^{-at} \cos \omega t$	$\frac{z^2 - ze^{-aT} \cos \omega T}{z^2 - 2ze^{-aT} \cos \omega T + e^{-2aT}}$
12	$\frac{2}{s^3}$	t^2	$\frac{T^2 z(z+1)}{(z-1)^3}$
13		a	$\frac{z}{z-a}$
14		$a^k \cos k\pi$	$\frac{z}{z+a}$

number of samples of the discrete signal. The Laplace transform of the series is

$$Y^*(s) = \sum_{k=0}^N y(k)e^{-ksT}$$

where the shifting property of the Laplace transform has been applied to the pulses. Define the *shift* or *advance operator* as $z = e^{sT}$, $Y^*(s)$ may now be written as a function of z :

$$Y^*(z) = \sum_{k=0}^N \frac{y(k)}{z^k} = \mathcal{Z}[y(t)]$$

where the transformed variable $Y^*(z)$ is called the z transform of the function $y^*(t)$. The inverse of the shift operator $1/z$ is called the *delay operator* and corresponds to a time delay of T .

The z transforms for many sampled functions can be expressed in closed form. A listing of the transforms of several commonly encountered functions is given in Table 12. Properties of the z transform are listed in Table 13.

Pulse Transfer Functions The transfer function concept developed for continuous systems has a direct analog for sampled-data systems. For a continuous system with sampled output $u(t)$ and sampled input $y(t)$, the *pulse* or *discrete transfer function* $G(z)$ is defined as the ratio of the z -transformed output $Y(z)$ to the z -transformed input $U(z)$, assuming zero initial conditions. In general, the pulse transfer function has the form

$$G(z) = \frac{Y(z)}{U(z)} = \frac{b_0 + b_1 z^{-1} + b_2 z^{-2} + \dots + b_m z^{-m}}{1 + a_1 z^{-1} + a_2 z^{-2} + \dots + a_n z^{-n}}$$

Table 13 z-Transform Properties

	$x(t)$ or $x(k)$	$\mathcal{Z}[x(t)]$ or $\mathcal{Z}[x(k)]$
1	$ax(t)$	$aX(z)$
2	$x_1(t) + x_2(t)$	$X_1(z) + X_2(z)$
3	$x(t + T)$ or $x(k + 1)$	$zX(z) - zx(0)$
4	$x(t + 2T)$	$z^2X(z) - z^2x(0) - zx(T)$
5	$x(k + 2)$	$z^2X(z) - z^2x(0) - zx(1)$
6	$x(t + kT)$	$z^kX(z) - z^kx(0) - z^{k-1}x(T) - \dots - zx(kT - T)$
7	$x(k + m)$	$z^mX(z) - z^mx(0) - z^{m-1}x(1) - \dots - zx(m - 1)$
8	$tx(t)$	$-Tz \frac{d}{dz}[X(z)]$
9	$kx(k)$	$-z \frac{d}{dz}[X(z)]$
10	$e^{-at}x(t)$	$X(ze^{aT})$
11	$e^{-ak}x(k)$	$X(ze^a)$
12	$a^kx(k)$	$X\left(\frac{z}{a}\right)$
13	$ka^kx(k)$	$-z \frac{d}{dz}\left[X\left(\frac{z}{a}\right)\right]$
14	$x(0)$	$\lim_{z \rightarrow \infty} X(z)$ if the limit exists
15	$x(\infty)$	$\lim_{z \rightarrow 1} [(z - 1)X(z)]$ if $\frac{z - 1}{z}X(z)$ is analytic on and outside the unit circle
16	$\sum_{k=0}^{\infty} x(k)$	$X(1)$
17	$\sum_{k=0}^n x(kT)y(nT - kT)$	$X(z)Y(z)$

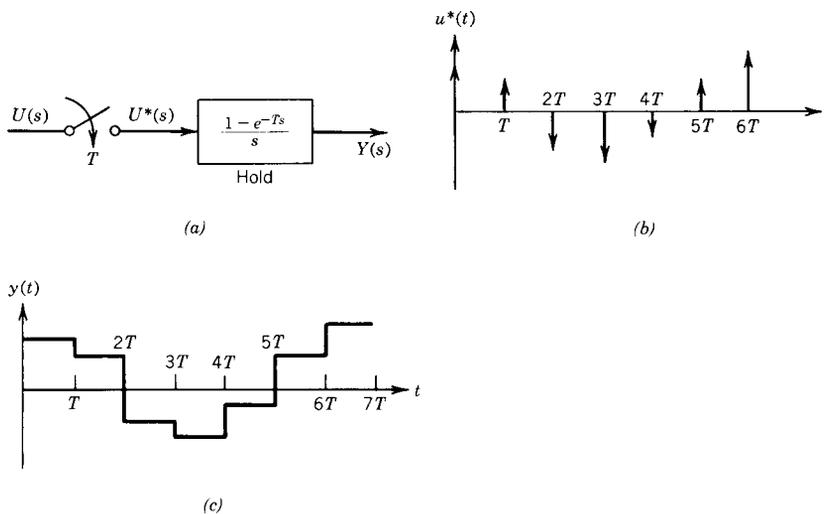

Fig. 32 Zero-order hold: (a) block diagram of hold with a sampler, (b) sampled input sequence, (c) analog output for the corresponding input sequence.⁴

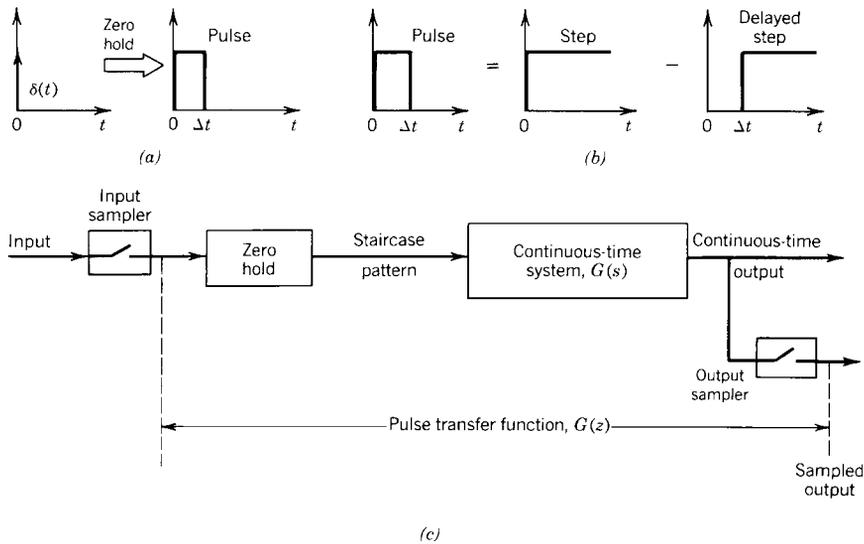

Fig. 33 Pulse transfer function of a continuous system with sampler and zero hold.¹²

Zero-Order Hold The *zero-order data hold* is the most common mathematical approach to *D/A conversion*, that is, to creating a piecewise continuous approximation $u(t)$ of the form

$$u(t) = u^*(k) \quad \text{for } kT \leq t < (k+1)T$$

from the discrete-time signal $u^*(k)$, where T is the period of the hold. The effect of the zero-order hold is to convert a sequence of discrete impulses into a staircase pattern, as shown in Fig. 32. The transfer function of the zero-order hold is

$$G(s) = \frac{1}{s}(1 - e^{-Ts}) = \frac{1 - z^{-1}}{s}$$

Using this relationship, the pulse transfer function of the sampled-data system shown in Fig. 33 can be derived as

$$G(z) = (1 - z^{-1}) \mathcal{Z} \left[\mathcal{L}^{-1} \frac{G(s)}{s} \right]$$

The continuous system with transfer function $G(s)$ has a sampler and a zero-order hold at its input and a sampler at its output. This is a common configuration in many computer control applications.

1 INTRODUCTION

The purpose of a *control system* is to produce a desired *output*. This output is usually specific by the command *input* and is often a function of time. For simple applications in well-structured situations, *sequencing* devices like timers can be used as the control system. But most systems are not that easy to control, and the controller must have the capability of reacting to disturbances, changes in its environment, and new input commands. The key element that allows a control system to do this is *feedback*, which is the process by which a system's output is used to influence its behavior. Feedback in the form of the room temperature measurement is used to control the furnace in a thermostatically controlled heating system. Figure 1 shows the *feedback loop* in the system's *block diagram*, which is a graphical representation of the system's control structure and logic. Another commonly found control system is the pressure regulator shown in Fig. 2.

Feedback has several useful properties. A system whose individual elements are nonlinear can often be modeled as a linear one over a wider range of its variables with the proper use of feedback. This is because feedback tends to keep the system near its reference operation condition. Systems that can maintain the output near its desired value despite changes in the environment are said to have good *disturbance rejection*. Often we do not have accurate values for some system parameter or these values might change with age. Feedback can be used to minimize the effects of parameter changes and uncertainties. A system that has both good disturbance rejection and low sensitivity to parameter variation is *robust*. The application that resulted in the general understanding of the properties

of feedback is shown in Fig. 3. The electronic amplifie gain A is large, but we are uncertain of its exact value. We use the resistors R_1 and R_2 to create a feedback loop around the amplifie and pick R_1 and R_2 to create a feedback loop around the amplifie and R_1 and R_2 so that $AR_2/R_1 \gg 1$. Then the input-output relation becomes $e_o \approx R_1 e_i / R_2$, which is independent of A as long as A remains large. If R_1 and R_2 are known accurately, then the system gain is now reliable.

Figure 4 shows the block diagram of a *closed-loop* system, which is a system with feedback. An *open-loop* system, such as a timer, has no feedback. Figure 4 serves as a focus for outlining the prerequisites for this chapter. The reader should be familiar with the *transfer function* concept based on the Laplace transform, the *pulse transfer function* based on the z transform, for digital control, and the differential equation modeling techniques needed to obtain them. It is also necessary to understand block diagram algebra, characteristic roots, the final-value theorem, and their use in evaluating system response for common inputs like the step function. Also required are stability analysis techniques such as the Routh criterion and transient performance specifications such as the damping ratio ζ , natural frequency ω_n , dominant time constant τ , maximum overshoot, settling time, and bandwidth. Treatment in depth is given in Refs. 1-4.

2 CONTROL SYSTEM STRUCTURE

The electromechanical position control system shown in Fig. 5 illustrates the structure of a typical control system. A load with an inertia I is to be positioned at some desired angle θ_r . A dc motor is provided for this purpose. The system contains viscous damping, and a disturbance torque T_d acts on the load, in addition to the motor torque T . Because of the disturbance, the

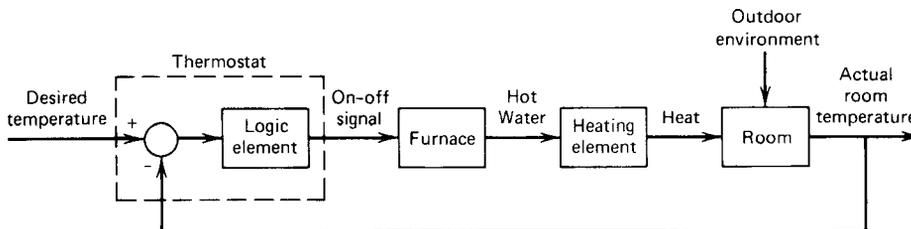

Fig. 1 Block diagram of thermostat system for temperature control.¹

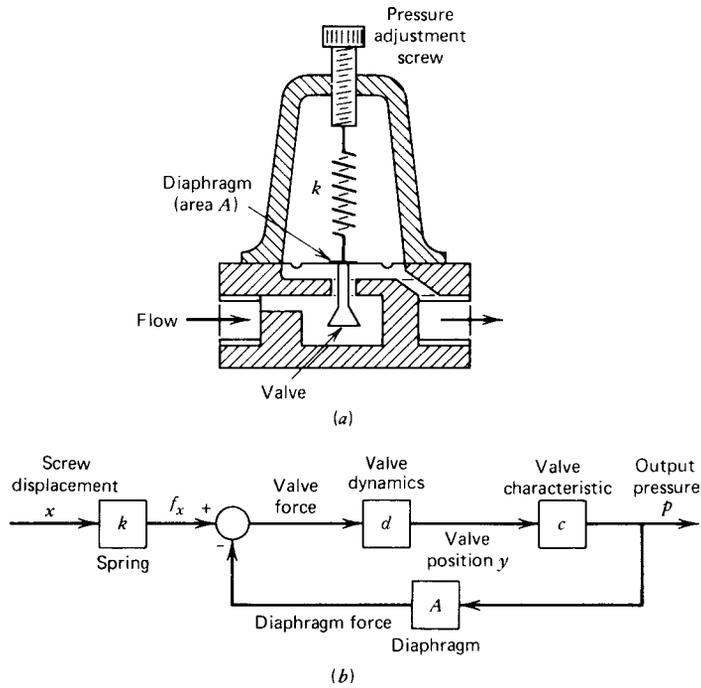

Fig. 2 Pressure regulator: (a) cutaway view; (b) block diagram.¹

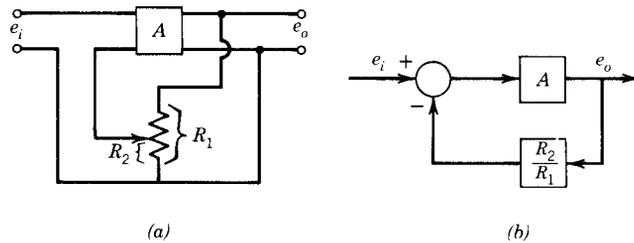

Fig. 3 Closed-loop system.

angular position θ of the load will not necessarily equal the desired value θ_r . For this reason, a potentiometer, or some other sensor such as an encoder, is used to measure the displacement θ . The potentiometer voltage representing the controlled position θ is compared to the voltage generated by the command potentiometer. This device enables the operator to dial in the desired angle θ_r . The amplifie sees the difference e between the two potentiometer voltages. The basic function of the amplifie is to increase the small error voltage e up to the voltage level required by the motor and to supply enough current required by the motor to drive the load. In addition, the amplifie may shape the voltage signal

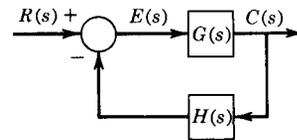

Fig. 4 Feedback compensation of amplifier.

in certain ways to improve the performance of the system.

The control system is seen to provide two basic functions: (a) to respond to a command input that specify a new desired value for the controlled variable and

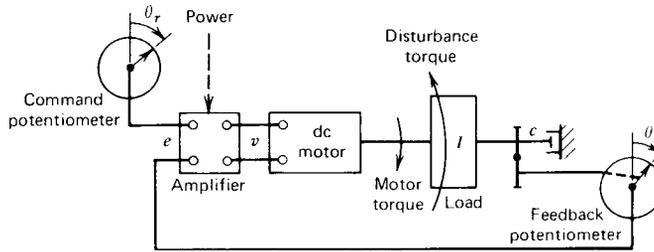

Fig. 5 Position control system using dc motor.¹

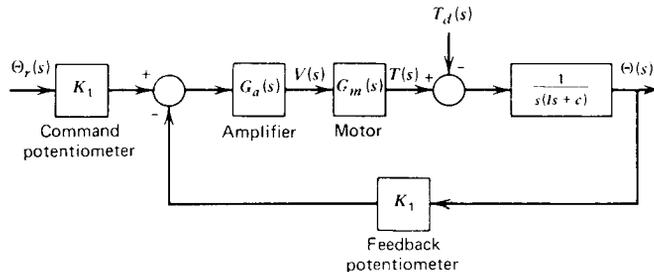

Fig. 6 Block diagram of position control system shown in Fig. 5.¹

(b) to keep the controlled variable near the desired value in spite of disturbances. The presence of the feedback loop is vital to both functions. A block diagram of this system is shown in Fig. 6. The power supplies required for the potentiometers and the amplifier are not shown in block diagrams of control system logic because they do not contribute to the control logic.

2.1 Standard Diagram

The electromechanical positioning system fits the general structure of a control system (Fig. 7). This figure also gives some standard terminology. Not all systems can be forced into this format, but it serves as a reference for discussion.

The controller is generally thought of as a logic element that compares the command with the measurement of the output and decides what should be done. The input and feedback elements are transducers for converting one type of signal into another type. This allows the error detector directly to compare two signals of the same type (e.g., two voltages). Not all functions show up as separate physical elements. The error detector in Fig. 5 is simply the input terminals of the amplifier

The control logic elements produce the control signal, which is sent to the *final control elements*. These are the devices that develop enough torque, pressure, heat, and so on to influence the elements under control. Thus, the final control elements are the “muscle” of the system, while the control logic elements are

the “brain.” Here we are primarily concerned with the design of the logic to be used by this brain.

The object to be controlled is the *plant*. The *manipulated* variable is generated by the final control elements for this purpose. The disturbance input also acts on the plant. This is an input over which the designer has no influence and perhaps for which little information is available as to the magnitude, functional form, or time of occurrence. The disturbance can be a random input, such as wind gust on a radar antenna, or deterministic, such as Coulomb friction effects. In the latter case, we can include the friction force in the system model by using a nominal value for the coefficient of friction. The disturbance input would then be the deviation of the friction force from this estimated value and would represent the uncertainty in our estimate.

Several control system classifications can be made with reference to Fig. 7. A *regulator* is a control system in which the controlled variable is to be kept constant in spite of disturbances. The command input for a regulator is its *set point*. A *follow-up system* is supposed to keep the control variable near a command value that is changing with time. An example of a follow-up system is a machine tool in which a cutting head must trace a specific path in order to shape the product properly. This is also an example of a *servomechanism*, which is a control system whose controlled variable is a mechanical position, velocity, or acceleration. A thermostat system is not a servomechanism, but a *process control system*, where the controlled variable describes a thermodynamic process.

system type, the better the system is able to follow a rapidly changing input. But higher type systems are more difficult to stabilize, so a compromise must be made in the design. The coefficients $c_0, c_1,$ and c_2 are called the *position, velocity,* and *acceleration error coefficients.*

3 TRANSDUCERS AND ERROR DETECTORS

The control system structure shown in Fig. 7 indicates a need for physical devices to perform several types of functions. Here we present a brief overview of some available transducers and error detectors. Actuators and devices used to implement the control logic are discussed in Sections 4 and 5.

3.1 Displacement and Velocity Transducers

A *transducer* is a device that converts one type of signal into another type. An example is the potentiometer, which converts displacement into voltage, as in Fig. 8. In addition to this conversion, the transducer can be used to make measurements. In such applications, the term *sensor* is more appropriate. Displacement can also be measured electrically with a *linear variable differential transformer (LVDT)* or a *synchro*. An LVDT measures the linear displacement of a movable magnetic core through a primary winding and two secondary windings (Fig. 9). An ac voltage is applied to the primary. The secondaries are connected together and also to a detector that measures the voltage and phase difference. A phase difference of 0° corresponds to a positive core displacement, while 180° indicates a negative displacement. The amount of displacement is indicated by the amplitude of the ac voltage in the secondary. The detector converts this

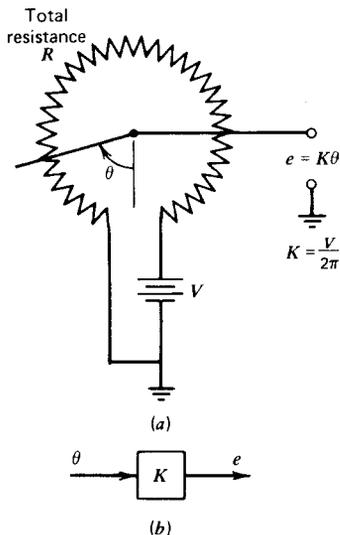

Fig. 8 Rotary potentiometer.¹

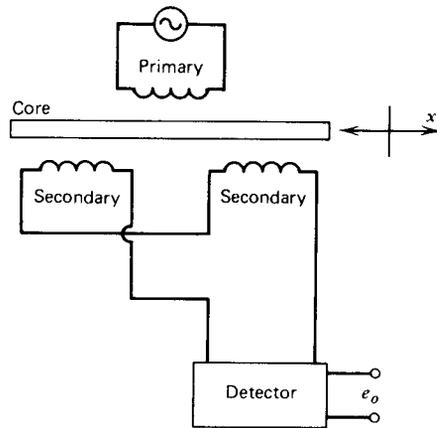

Fig. 9 Linear variable differential transformer.¹

information into a dc voltage e_o , such that $e_o = Kx$. The LVDT is sensitive to small displacements. Two of them can be wired together to form an error detector.

A synchro is a rotary differential transformer, with angular displacement as either the input or output. They are often used in pairs (a *transmitter* and a *receiver*) where a remote indication of angular displacement is needed. When a transmitter is used with a *synchro control transformer*, two angular displacements can be measured and compared (Fig. 10). The output voltage e_o is approximately linear with angular difference within $\pm 70^\circ$, so that $e_o = K(\theta_1 - \theta_2)$.

Displacement measurements can be used to obtain forces and accelerations. For example, the displacement of a calibrated spring indicates the applied force. The accelerometer is another example. Still another is the strain gage used for force measurement. It is based on the fact that the resistance of a fin wire changes as it is stretched. The change in resistance is detected by a circuit that can be calibrated to indicate the applied force. Sensors utilizing piezoelectric elements are also available.

Velocity measurements in control systems are most commonly obtained with a *tachometer*. This is essentially a dc generator (the reverse of a dc motor). The input is mechanical (a velocity). The output is a generated voltage proportional to the velocity. Translational velocity can be measured by converting it to angular velocity with gears, for example. Tachometers using ac signals are also available.

Other velocity transducers include a magnetic pickup that generates a pulse every time a gear tooth passes. If the number of gear teeth is known, a pulse counter and timer can be used to compute the angular velocity. This principle is also employed in turbine flowmeters

A similar principle is employed by *optical encoders*, which are especially suitable for digital control purposes. These devices use a rotating disk with

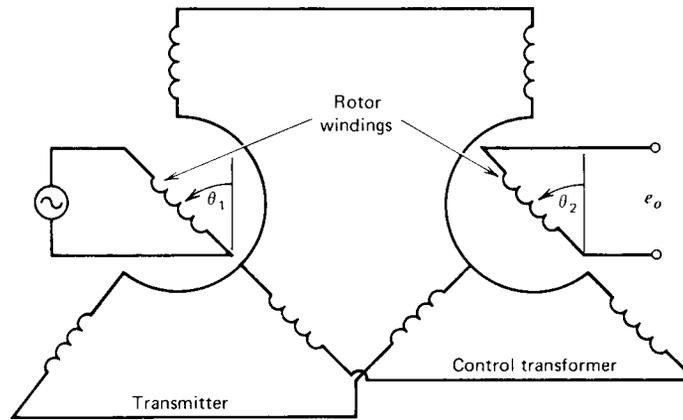

Fig. 10 Synchro transmitter control transformer.¹

alternating transparent and opaque elements whose passage is sensed by light beams and a photosensor array, which generates a binary (on-off) train of pulses. There are two basic types: the absolute encoder and the incremental encoder. By counting the number of pulses in a given time interval, the incremental encoder can measure the rotational speed of the disk. By using multiple tracks of elements, the absolute encoder can produce a binary digit that indicates the amount of rotation. Hence, it can be used as a position sensor.

Most encoders generate a train of transistor-transistor logic (TTL) voltage level pulses for each channel. The incremental encoder output contains two channels that each produce N pulses every revolution. The encoder is mechanically constructed so that pulses from one channel are shifted relative to the other channel by a quarter of a pulse width. Thus, each pulse pair can be divided into four segments called *quadratures*. The encoder output consists of $4N$ quadrature counts per revolution. The pulse shift also allows the direction of rotation to be determined by detecting which channel leads the other. The encoder might contain a third channel, known as the zero, index, or marker channel, that produces a pulse once per revolution. This is used for initialization.

The gain of such an incremental encoder is $4N/2\pi$. Thus, an encoder with 1000 pulses per channel per revolution has a gain of 636 counts per radian. If an absolute encoder produces a binary signal with n bits, the maximum number of positions it can represent is 2^n , and its gain is $2^n/2\pi$. Thus, a 16-bit absolute encoder has a gain of $2^{16}/2\pi = 10,435$ counts per radian.

3.2 Temperature Transducers

When two wires of dissimilar metals are joined together, a voltage is generated if the junctions are at different temperatures. If the reference junction is kept at a fixed known temperature, the thermocouple can be calibrated

to indicate the temperature at the other junction in terms of the voltage v . Electrical resistance changes with temperature. Platinum gives a linear relation between resistance and temperature, while nickel is less expensive and gives a large resistance change for a given temperature change. Semiconductors designed with this property are called *thermistors*. Different metals expand at different rates when the temperature is increased. This fact is used in the bimetallic strip transducer found in most home thermostats. Two dissimilar metals are bonded together to form the strip. As the temperature rises, the strip curls, breaking contact and shutting off the furnace. The temperature gap can be adjusted by changing the distance between the contacts. The motion also moves a pointer on the temperature scale of the thermostat. Finally, the pressure of a fluid inside a bulb will change as its temperature changes. If the bulb fluid is air, the device is suitable for use in pneumatic temperature controllers.

3.3 Flow Transducers

A flow rate q can be measured by introducing a flow restriction, such as an orific plate, and measuring the pressure drop Δp across the restriction. The relation is $\Delta p = Rq^2$, where R can be found from calibration of the device. The pressure drop can be sensed by converting it into the motion of a diaphragm. Figure 11 illustrates a related technique. The Venturi-type flowmeter measures the static pressures in the constricted and unconstricted flow regions. Bernoulli's principle relates the pressure difference to the flow rate. This pressure difference produces the diaphragm displacement. Other types of flowmeters are available, such as turbine meters.

3.4 Error Detectors

The error detector is simply a device for finding the difference between two signals. This function is sometimes an integral feature of sensors, such as with the synchro transmitter-transformer combination. This

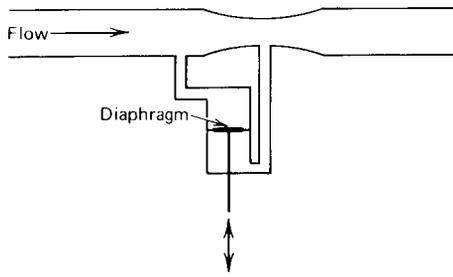

Fig. 11 Venturi-type flowmeter. The diaphragm displacement indicates the flow rate.¹

concept is used with the diaphragm element shown in Fig. 11. A detector for voltage difference can be obtained, as with the position control system shown in Fig. 5. An amplifier intended for this purpose is a *differential amplifier*. Its output is proportional to the difference between the two inputs. In order to detect differences in other types of signals, such as temperature, they are usually converted to a displacement or pressure. One of the detectors mentioned previously can then be used.

3.5 Dynamic Response of Sensors

The usual transducer and detector models are static models and as such imply that the components respond instantaneously to the variable being sensed. Of course,

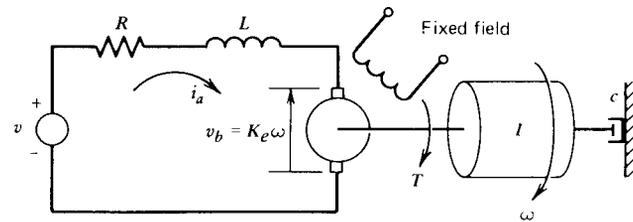

any real component has a dynamic response of some sort, and this response time must be considered in relation to the controlled process when a sensor is selected. If the controlled process has a time constant at least 10 times greater than that of the sensor, we often would be justified in using a static sensor model.

4 ACTUATORS

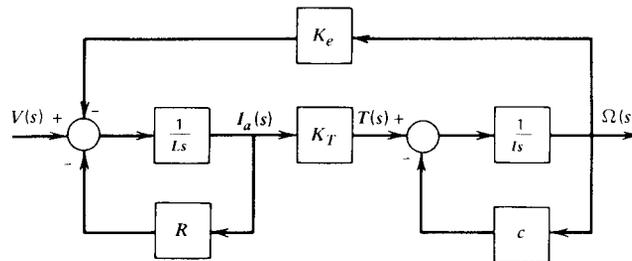

An *actuator* is the final control element that operates on the low-level control signal to produce a signal containing enough power to drive the plant for the intended purpose. The armature-controlled dc motor, the hydraulic servomotor, and the pneumatic diaphragm and piston are common examples of actuators.

4.1 Electromechanical Actuators

Figure 12 shows an electromechanical system consisting of an armature-controlled dc motor driving a load inertia. The rotating armature consists of a wire conductor wrapped around an iron core. This winding has an inductance L . The resistance R represents the lumped value of the armature resistance and any external resistance deliberately introduced to change the motor's behavior. The armature is surrounded by a magnetic field. The reaction of this field with the armature current produces a torque that causes the armature to rotate. If the armature voltage v is used to control the motor, the motor is said to be *armature controlled*. In this case, the field is produced by an electromagnet supplied with a constant voltage or by a permanent

(a)

(b)

Fig. 12 Armature-controlled dc motor with load and the system's block diagram.¹

magnet. This motor type produces a torque T that is proportional to the armature current i_a :

$$T = K_T i_a \quad (6)$$

The torque constant K_T depends on the strength of the field and other details of the motor's construction. The motion of a current-carrying conductor in a field produces a voltage in the conductor that opposes the current. This voltage is called the *back emf* (electromotive force). Its magnitude is proportional to the speed and is given by

$$e_b = K_e \omega \quad (7)$$

The transfer function for the armature-controlled dc motor is

$$\frac{\Omega(s)}{V(s)} = \frac{K_T}{LIs^2 + (RI + cL)s + cR + K_e K_T} \quad (8)$$

Another motor configuration is the *field-controlled* dc motor. In this case, the armature current is kept constant and the field voltage v is used to control the motor. The transfer function is

$$\frac{\Omega(s)}{V(s)} = \frac{K_T}{(Ls + R)(Is + c)} \quad (9)$$

where R and L are the resistance and inductance of the field circuit and K_T is the torque constant. No back emf exists in this motor to act as a self-braking mechanism.

Two-phase ac motors can be used to provide a low-power, variable-speed actuator. This motor type can accept the ac signals directly from LVDTs and

synchros without demodulation. However, it is difficult to design ac amplification circuitry to do other than proportional action. For this reason, the ac motor is not found in control systems as often as dc motors. The transfer function for this type is of the form of Eq. (9).

An actuator especially suitable for digital systems is the *stepper motor*, a special dc motor that takes a train of electrical input pulses and converts each pulse into an angular displacement of a fixed amount. Motors are available with resolutions ranging from about 4 steps per revolution to more than 800 steps per revolution. For 36 steps per revolution, the motor will rotate by 10° for each pulse received. When not being pulsed, the motors lock in place. Thus, they are excellent for precise positioning applications, such as required with printers and computer tape drives. A disadvantage is that they are low-torque devices. If the input pulse frequency is not near the resonant frequency of the motor, we can take the output rotation to be directly related to the number of input pulses and use that description as the motor model.

4.2 Hydraulic Actuators

Machine tools are one application of the hydraulic system shown in Fig. 13. The applied force f is supplied by the servomotor. The mass m represents that of a cutting tool and the power piston, while k represents the combined effects of the elasticity naturally present in the structure and that introduced by the designer to achieve proper performance. A similar statement applies to the damping c . The valve displacement z is generated by another control system in order to move the tool through its prescribed motion. The spool valve shown in Fig. 13 had two *lands*. If the width of the land is greater than the port width, the valve is said to be *overlapped*. In this case, a dead zone exists in which a slight change in the displacement z produces no power piston motion. Such dead zones

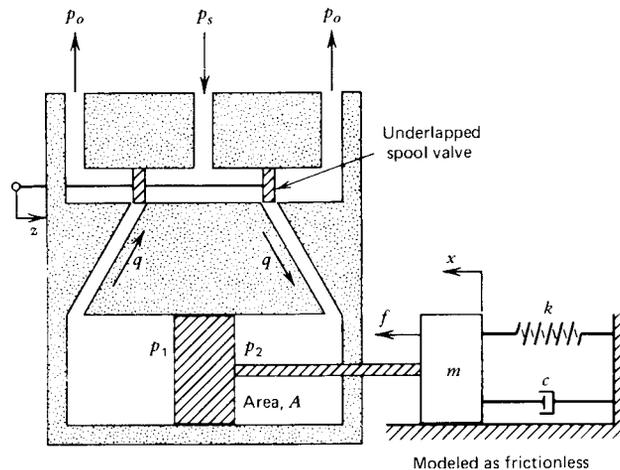

Fig. 13 Hydraulic servomotor with load.¹

create control difficulties and are avoided by designing the valve to be *underlapped* (the land width is less than the port width). For such valves there will be a small flow opening even when the valve is in the neutral position at $z = 0$. This gives it a higher sensitivity than an overlapped valve.

The variables z and $\Delta p = p_2 - p_1$ determine the volume flow rate, as

$$q = f(z, \Delta p)$$

For the reference equilibrium condition ($z = 0, \Delta p = 0, q = 0$), a linearization gives

$$q = C_1 z - C_2 \Delta p \tag{10}$$

The linearization constants are available from theoretical and experimental results.⁵ The transfer function for the system is^{1,2}

$$T(s) = \frac{X(s)}{Z(s)} = \frac{C_1}{(C_2 m/A)s^2 + (cC_2/A + A)s + C_2 k/A} \tag{11}$$

The development of the steam engine led to the requirement for a speed control device to maintain constant speed in the presence of changes in load torque or steam pressure. In 1788, James Watt of Glasgow developed his now-famous flyball governor for this purpose (Fig. 14). Watt took the principle of sensing speed with the centrifugal pendulum of Thomas Mead and used it in a feedback loop on a steam engine. As the motor speed increases, the flyball move outward and pull the slider upward. The upward motion of the slider closes the steam valve, thus causing the engine to slow down. If the engine speed is too slow, the spring force overcomes that due to the flyballs, and the slider moves down to open the steam valve. The desired speed can be set by moving the plate to change the compression in the spring. The principle of the flyball governor is still used for speed control applications. Typically, the pilot valve of a hydraulic servomotor is connected to the slider to provide the high forces required to move large supply valves.

Many hydraulic servomotors use multistage valves to obtain finer control and higher forces. A *two-stage valve* has a *slave valve*, similar to the pilot valve but situated between the pilot valve and the power piston.

Rotational motion can be obtained with a *hydraulic motor*, which is, in principle, a pump acting in reverse (fluid input and mechanical rotation output). Such motors can achieve higher torque levels than electric motors. A hydraulic pump driving a hydraulic motor constitutes a *hydraulic transmission*.

A popular actuator choice is the *electrohydraulic* system, which uses an electric actuator to control a hydraulic

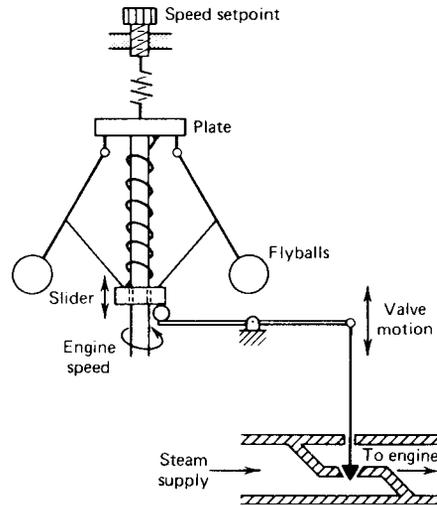

Fig. 14 James Watt's flyball governor for speed control of steam engine.¹

servomotor or transmission by moving the pilot valve or the swash-plate angle of the pump. Such systems combine the power of hydraulics with the advantages of electrical systems. Figure 15 shows a hydraulic motor whose pilot valve motion is caused by an armature-controlled dc motor. The transfer function between the motor voltage and the piston displacement is

$$\frac{X(s)}{V(s)} = \frac{K_1 K_2 C_1}{A s^2 (\tau s + 1)} \tag{12}$$

If the rotational inertia of the electric motor is small, then $\tau \approx 0$.

4.3 Pneumatic Actuators

Pneumatic actuators are commonly used because they are simple to maintain and use a readily available working medium. Compressed air supplies with the pressures required are commonly available in factories and laboratories. No flammable fluids or electrical sparks are present, so these devices are considered the safest to use with chemical processes. Their power output is less than that of hydraulic systems but greater than that of electric motors.

A device for converting pneumatic pressure into displacement is the bellows shown in Fig. 16. The transfer function for a linearized model of the bellows is of the form

$$\frac{X(s)}{P(s)} = \frac{K}{\tau s + 1} \tag{13}$$

where x and p are deviations of the bellows displacement and input pressure from nominal values.

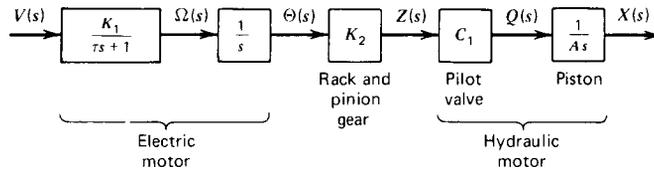

Fig. 15 Electrohydraulic system for translation.¹

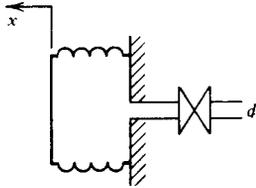

Fig. 16 Pneumatic bellows.¹

In many control applications, a device is needed to convert small displacements into relatively large pressure changes. The nozzle-flapper serves this purpose (Fig. 17a). The input displacement y moves the flapper, with little effort required. This changes the opening at the nozzle orifice. For a large enough opening, the nozzle back pressure is approximately the same as atmospheric pressure p_a . At the other extreme position with the flapper completely blocking the orifice the back pressure equals the supply pressure p_s . This variation is shown in Fig. 17b. Typical supply pressures are between 30 and 100 psia. The orifice diameter is approximately 0.01 in. Flapper displacement is usually less than one orifice diameter.

The nozzle-flapper is operated in the linear portion of the back-pressure curve. The linearized back-pressure relation is

$$p = -K_f x \quad (14)$$

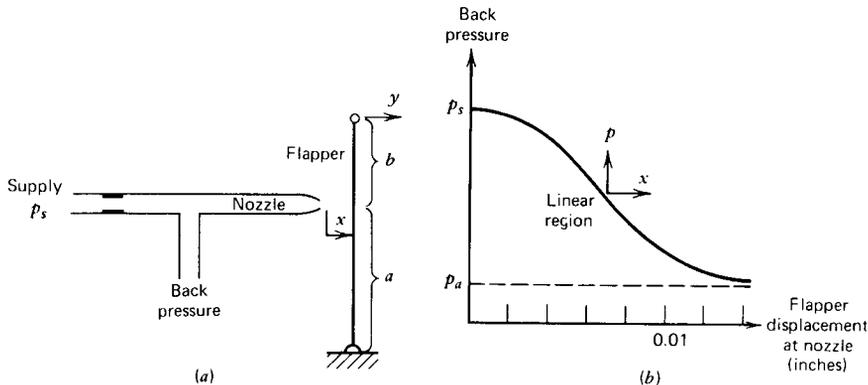

Fig. 17 Pneumatic nozzle-flapper amplifier and its characteristic curve.¹

where $-K_f$ is the slope of the curve and is a very large number. From the geometry of similar triangles, we have

$$p = \frac{aK_f}{a+b}y \quad (15)$$

In its operating region, the nozzle-flapper' back pressure is well below the supply pressure.

The output pressure from a pneumatic device can be used to drive a final control element like the pneumatic actuating valve shown in Fig. 18. The pneumatic pressure acts on the upper side of the diaphragm and is opposed by the return spring.

Formerly, many control systems utilized pneumatic devices to implement the control law in analog form. Although the overall, or higher level, control algorithm is now usually implemented in digital form, pneumatic devices are still frequently used for final control corrections at the actuator level, where the control action must eventually be supplied by a mechanical device. An example of this is the electropneumatic valve positioner used in Valtek valves and illustrated in Fig. 19. The heart of the unit is a pilot valve capsule that moves up and down according to the pressure difference across its two supporting diaphragms. The capsule has a plunger at its top and at its bottom. Each plunger has an exhaust seat at one end and a supply seat at the other. When the capsule is in its equilibrium position, no air is supplied to or

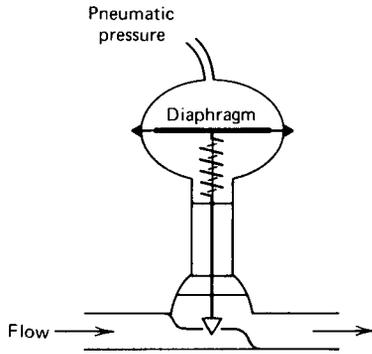

Fig. 18 Pneumatic flow control valve.¹

exhausted from the valve cylinder, so the valve does not move.

The process controller commands a change in the valve stem position by sending the 4–20-mA dc input signal to the positioner. Increasing this signal causes the electromagnetic actuator to rotate the lever counterclockwise about the pivot. This increases the air gap between the nozzle and flapper. This decreases the back pressure on top of the upper diaphragm and causes the capsule to move up. This motion lifts the upper plunger from its supply seat and allows the supply air to flow to the bottom of the valve cylinder. The lower plunger's exhaust seat is uncovered, thus

decreasing the air pressure on top of the valve piston, and the valve stem moves upward. This motion causes the lever arm to rotate, increasing the tension in the feedback spring and decreasing the nozzle–flapper gap. The valve continues to move upward until the tension in the feedback spring counteracts the force produced by the electromagnetic actuator, thus returning the capsule to its equilibrium position.

A decrease in the dc input signal causes the opposite actions to occur, and the valve moves downward.

5 CONTROL LAWS

The control logic elements are designed to act on the error signal to produce the control signal. The algorithm that is used for this purpose is called the *control law*, the *control action*, or the *control algorithm*. A nonzero error signal results from either a change in command or a disturbance. The general function of the controller is to keep the controlled variable near its desired value when these occur. More specifically the control objectives might be stated as follows:

1. Minimize the steady-state error.
2. Minimize the settling time.
3. Achieve other transient specifications such as minimizing the overshoot.

In practice, the design specification for a controller are more detailed. For example, the bandwidth might also be specific along with a safety margin for stability.

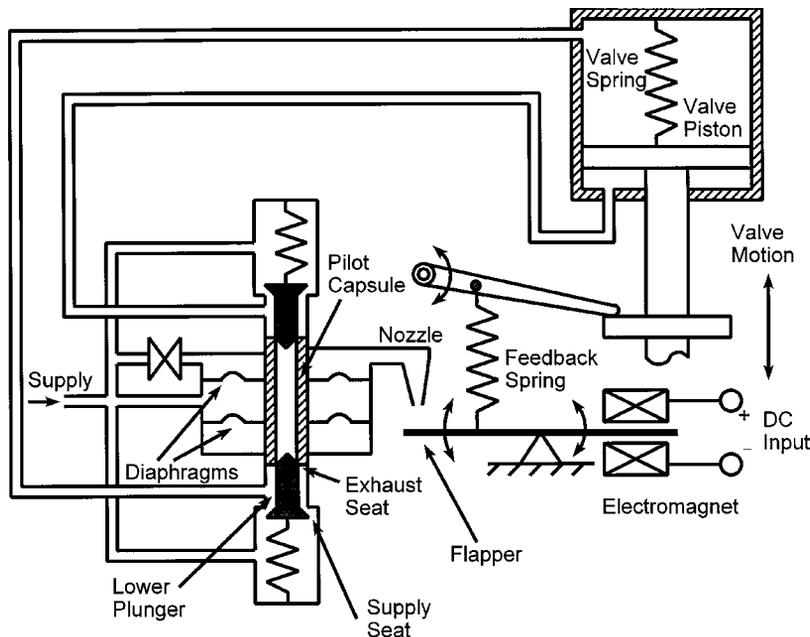

Fig. 19 Electro-pneumatic valve positioner.

We never know the numerical values of the system's parameters with true certainty, and some controller designs can be more sensitive to such parameter uncertainties than other designs. So a parameter sensitivity specification might also be included.

The following control laws form the basis of most control systems.

5.1 Proportional Control

Two-position control is the most familiar type, perhaps because of its use in home thermostats. The control output takes on one of two values. With the *on-off controller*, the controller output is either on or off (e.g., fully open or fully closed). Two-position control is acceptable for many applications in which the requirements are not too severe. However, many situations require fine control.

Consider a liquid level system in which the input flow rate is controlled by a valve. We might try setting the control valve manually to achieve a flow rate that balances the system at the desired level. We might then add a controller that adjusts this setting in proportion to the deviation of the level from the desired value. This is *proportional control*, the algorithm in which the change in the control signal is proportional to the error. Block diagrams for controllers are often drawn in terms of the deviations from a zero-error equilibrium condition. Applying this convention to the general terminology of Fig. 6, we see that proportional control is described by

$$F(s) = K_P E(s)$$

where $F(s)$ is the deviation in the control signal and K_P is the *proportional gain*. If the total valve displacement is $y(t)$ and the manually created displacement is x , then

$$y(t) = K_P e(t) + x$$

The percent change in error needed to move the valve full scale is the *proportional band*. It is related to the gain as

$$K_P = \frac{100}{\text{band \%}}$$

The zero-error valve displacement x is the *manual reset*.

Proportional Control of a First-Order System

To investigate the behavior of proportional control, consider the speed control system shown in Fig. 20; it is identical to the position controller shown in Fig. 6, except that a tachometer replaces the feedback potentiometer. We can combine the amplifier gains into one, denoted K_P . The system is thus seen to have proportional control. We assume the motor is field controlled and has a negligible electrical time constant. The disturbance is a torque T_d , for example, resulting from friction. Choose the reference equilibrium condition to be $T_d = T = 0$ and $\omega_r = \omega = 0$. The block diagram is shown in Fig. 21. For a meaningful error signal to be generated, K_1 and K_2 should be chosen to be equal. With this simplification the diagram becomes that

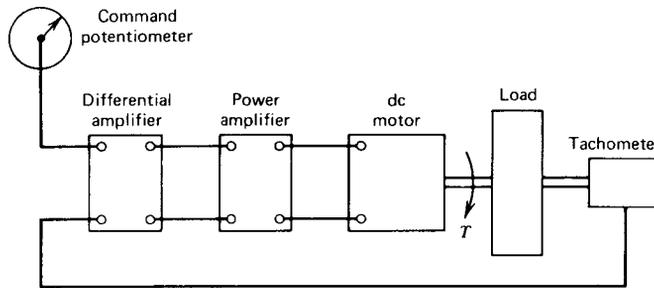

Fig. 20 Velocity control system using dc motor.¹

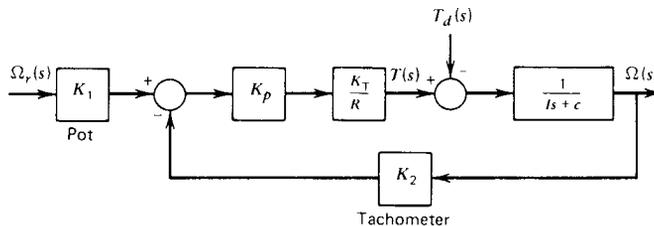

Fig. 21 Block diagram of velocity control system of Fig. 20.¹

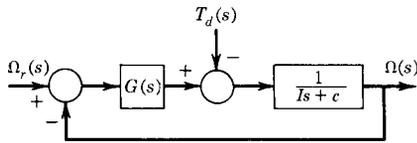

Fig. 22 Simplified form of Fig. 21 for case $K_1 = K_2$.

shown in Fig. 22, where $G(s) = K = K_1 K_P K_T / R$. A change in desired speed can be simulated by a unit step input for $\Omega_r(s) = 1/s$, the velocity approaches the steady-state value $\omega_{ss} = K / (c + K) < 1$. Thus, the final value is less than the desired value of 1, but it might be close enough if the damping c is small. The time required to reach this value is approximately four time constants, or $4\tau = 4I / (c + K)$. A sudden change in load torque can also be modeled by a unit step function $T_d(s) = 1/s$. The steady-state response due solely to the disturbance is $-1 / (c + K)$. If $c + K$ is large, this error will be small.

The performance of the proportional control law thus far can be summarized as follows. For a first-order plant with step function inputs:

1. The output never reaches its desired value if damping is present ($c \neq 0$), although it can be made arbitrarily close by choosing the gain K large enough. This is called *offset error*.
2. The output approaches its final value without oscillation. The time to reach this value is inversely proportional to K .
3. The output deviation due to the disturbance at steady state is inversely proportional to the gain K . This error is present even in the absence of damping ($c = 0$).

As the gain K is increased, the time constant becomes smaller and the response faster. Thus, the chief disadvantage of proportional control is that it results in steady-state errors and can only be used when the gain can be selected large enough to reduce the effect of the largest expected disturbance. Since proportional control gives zero error only for one load condition (the reference equilibrium), the operator must change the manual reset by hand (hence the name). An advantage to proportional control is that the control signal responds to the error instantaneously (in theory at least). It is used in applications requiring rapid action. Processes with time constants too small for the use of two-position control are likely candidates for proportional control. The results of this analysis can be applied to any type of first-order system (e.g., liquid level, thermal, etc.) having the form in Fig. 22.

Proportional Control of a Second-Order System

Proportional control of a neutrally stable second-order plant is represented by the position controller of Fig. 6 if the amplification transfer function is a constant $G_a(s) = K_a$.

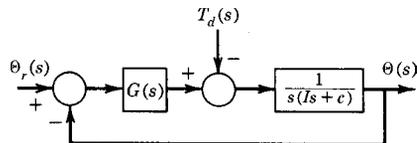

Fig. 23 Position servo.

Let the motor transfer function be $G_m(s) = K_T / R$, as before. The modified block diagram is given in Fig. 23 with $G(s) = K = K_1 K_a K_T / R$. The closed-loop system is stable if I , c , and K are positive. For no damping ($c = 0$), the closed-loop system is neutrally stable. With no disturbance and a unit step command, $\Theta_r(s) = 1/s$, the steady-state output is $\omega_{ss} = 1$. The offset error is thus zero if the system is stable ($c > 0$, $K > 0$). The steady-state output deviation due to a unit step disturbance is $-1/K$. This deviation can be reduced by choosing K large. The transient behavior is indicated by the damping ratio, $\zeta = c / 2\sqrt{TK}$.

For slight damping, the response to a step input will be very oscillatory and the overshoot large. The situation is aggravated if the gain K is made large to reduce the deviation due to the disturbance. We conclude, therefore, that proportional control of this type of second-order plant is not a good choice unless the damping constant c is large. We will see shortly how to improve the design.

5.2 Integral Control

The offset error that occurs with proportional control is a result of the system reaching an equilibrium in which the control signal no longer changes. This allows a constant error to exist. If the controller is modified to produce an increasing signal as long as the error is nonzero, the offset might be eliminated. This is the principle of *integral control*. In this mode the change in the control signal is proportional to the *integral* of the error. In the terminology of Fig. 7, this gives

$$F(s) = \frac{K_I}{s} E(s) \tag{16}$$

where $F(s)$ is the deviation in the control signal and K_I is the *integral gain*. In the time domain, the relation is

$$f(t) = K_I \int_0^t e(t) dt \tag{17}$$

if $f(0) = 0$. In this form, it can be seen that the integration cannot continue indefinitely because it would theoretically produce an infinite value of $f(t)$ if $e(t)$ does not change sign. This implies that special care must be taken to reinitialize a controller that uses integral action.

Integral Control of a First-Order System

Integral control of the velocity in the system of Fig. 20 has the block diagram shown in Fig. 22, where $G(s) =$

K/s , $K = K_1 K_I K_T / R$. The integrating action of the amplifier is physically obtained by the techniques to be presented in Section 6 or by the digital methods presented in Section 10. The control system is stable if I , c , and K are positive. For a unit step command input, $\omega_{ss} = 1$; so the offset error is zero. For a unit step disturbance, the steady-state deviation is zero if the system is stable. Thus, the steady-state performance using integral control is excellent for this plant with step inputs. The damping ratio is $\zeta = c/2\sqrt{TK}$. For slight damping, the response will be oscillatory rather than exponential as with proportional control. Improved steady-state performance has thus been obtained at the expense of degraded transient performance. The conflict between steady-state and transient specification is a common theme in control system design. As long as the system is underdamped, the time constant is $\tau = 2I/c$ and is not affected by the gain K , which only influence the oscillation frequency in this case. It might be physically possible to make K small enough so that $\zeta \gg 1$, and the nonoscillatory feature of proportional control recovered, but the response would tend to be sluggish. Transient specification for fast response generally require that $\zeta < 1$. The difficult with using $\zeta < 1$ is that τ is fixed by c and I . If c and I are such that $\zeta < 1$, then τ is large if $I \gg c$.

Integral Control of a Second-Order System

Proportional control of the position servomechanism in Fig. 23 gives a nonzero steady-state deviation due to the disturbance. Integral control [$G(s) = K/s$] applied to this system results in the command transfer function

$$\frac{\Theta(s)}{\Theta_r(s)} = \frac{K}{Is^3 + cs^2 + K} \quad (18)$$

With the Routh criterion, we immediately see that the system is not stable because of the missing s term. Integral control is useful in improving steady-state performance, but in general it does not improve and may even degrade transient performance. Improperly applied, it can produce an unstable control system. It is best used in conjunction with other control modes.

5.3 Proportional-Plus-Integral Control

Integral control raised the order of the system by 1 in the preceding examples but did not give a characteristic equation with enough flexibility to achieve acceptable transient behavior. The instantaneous response of proportional control action might introduce enough variability into the coefficients of the characteristic equation to allow both steady-state and transient specification to be satisfied. This is the basis for using *proportional-plus-integral control* (PI control). The algorithm for this two-mode control is

$$F(s) = K_P E(s) + \frac{K_I}{s} E(s) \quad (19)$$

The integral action provides an automatic, not manual, reset of the controller in the presence of a disturbance. For this reason, it is often called *reset action*.

The algorithm is sometimes expressed as

$$F(s) = K_P \left(1 + \frac{1}{T_I s} \right) E(s) \quad (20)$$

where T_I is the *reset time*. The reset time is the time required for the integral action signal to equal that of the proportional term if a constant error exists (a hypothetical situation). The reciprocal of reset time is expressed as repeats per minute and is the frequency with which the integral action repeats the proportional correction signal.

The proportional control gain must be reduced when used with integral action. The integral term does not react instantaneously to a zero-error signal but continues to correct, which tends to cause oscillations if the designer does not take this effect into account.

PI Control of a First-Order System

PI action applied to the speed controller of Fig. 20 gives the diagram shown in Fig. 21 with $G(s) = K_P + K_I/s$. The gains K_P and K_I are related to the component gains, as before. The system is stable for positive values of K_P and K_I . For $\Omega_r(s) = 1/s$, $\omega_{ss} = 1$, and the offset error is zero, as with integral action only. Similarly, the deviation due to a unit step disturbance is zero at steady state. The damping ratio is $\zeta = (c + K_P)/2\sqrt{TK_I}$. The presence of K_P allows the damping ratio to be selected without fixing the value of the dominant time constant. For example, if the system is underdamped ($\zeta < 1$), the time constant is $\tau = 2I/(c + K_P)$. The gain K_P can be picked to obtain the desired time constant, while K_I is used to set the damping ratio. A similar flexibility exists if $\zeta = 1$. Complete description of the transient response requires that the numerator dynamics present in the transfer functions be accounted for.^{1,2}

PI Control of a Second-Order System

Integral control for the position servomechanism of Fig. 23 resulted in a third-order system that is unstable. With proportional action, the diagram becomes that of Fig. 22, with $G(s) = K_P + K_I/s$. The steady-state performance is acceptable, as before, if the system is assumed to be stable. This is true if the Routh criterion is satisfied that is, if I , c , K_P , and K_I are positive and $cK_P - IK_I > 0$. The difficulty here occurs when the damping is slight. For small c , the gain K_P must be large in order to satisfy the last condition, and this can be difficult to implement physically. Such a condition can also result in an unsatisfactory time constant. The root-locus method of Section 9 provides the tools for analyzing this design further.

5.4 Derivative Control

Integral action tends to produce a control signal even after the error has vanished, which suggests that the controller be made aware that the error is approaching zero. One way to accomplish this is to design the controller to react to the derivative of the error with *derivative control* action, which is

$$F(s) = K_D s E(s) \tag{21}$$

where K_D is the *derivative gain*. This algorithm is also called *rate action*. It is used to damp out oscillations. Since it depends only on the error rate, derivative control should never be used alone. When used with proportional action, the following proportional-plus-derivative (PD) control algorithm results:

$$F(s) = (K_P + K_D s) E(s) = K_P (1 + T_D s) E(s) \tag{22}$$

where T_D is the *rate time* or *derivative time*. With integral action included, the *proportional-plus-integral-plus-derivative (PID) control law* is obtained:

$$F(s) = \left(K_P + \frac{K_I}{s} + K_D s \right) E(s) \tag{23}$$

This is called a *three-mode controller*.

PD Control of a Second-Order System The presence of integral action reduces steady-state error but tends to make the system less stable. There are applications of the position servomechanism in which a nonzero derivation resulting from the disturbance can be tolerated but an improvement in transient response over the proportional control result is desired. Integral action would not be required, but rate action can be added to improve the transient response. Application of PD control to this system gives the block diagram of Fig. 23 with $G(s) = K_P + K_D s$.

The system is stable for positive values of K_D and K_P . The presence of rate action does not affect the steady-state response, and the steady-state results are identical to those with proportional control; namely, zero offset error and a deviation of

$-1/K_P$, due to the disturbance. The damping ratio is $\zeta = (c + K_D)/2\sqrt{TK_P}$. For proportional control, $\zeta = c/2\sqrt{TK_P}$. Introduction of rate action allows the proportional gain K_P to be selected large to reduce the steady-state deviation, while K_D can be used to achieve an acceptable damping ratio. The rate action also helps to stabilize the system by adding damping (if $c = 0$, the system with proportional control is not stable).

The equivalent of derivative action can be obtained by using a tachometer to measure the angular velocity of the load. The block diagram is shown in Fig. 24. The gain of the amplifier–motor–potentiometer combination is K_1 , and K_2 is the tachometer gain. The advantage of this system is that it does not require signal differentiation, which is difficult to implement if signal noise is present. The gains K_1 and K_2 can be chosen to yield the desired damping ratio and steady-state deviation, as was done with K_P and K_I .

5.5 PID Control

The position servomechanism design with PI control is not completely satisfactory because of the difficulties encountered when the damping c is small. This problem can be solved by the use of the full PID control law, as shown in Fig. 23 with $G(s) = K_P + K_D s + K_I/s$.

A stable system results if all gains are positive and if $(c + K_D)K_P - IK_I > 0$. The presence of K_D relaxes somewhat the requirement that K_P be large to achieve stability. The steady-state errors are zero, and the transient response can be improved because three of the coefficients of the characteristic equation can be selected. To make further statements requires the root-locus technique presented in Section 9.

Proportional, integral, and derivative actions and their various combinations are not the only control laws possible, but they are the most common. PID controllers will remain for some time the standard against which any new designs must compete.

The conclusions reached concerning the performance of the various control laws are strictly true only for the plant model forms considered. These are the first-order model without numerator dynamics and the second-order model with a root at $s = 0$ and no numerator zeros. The analysis of a control law for any other

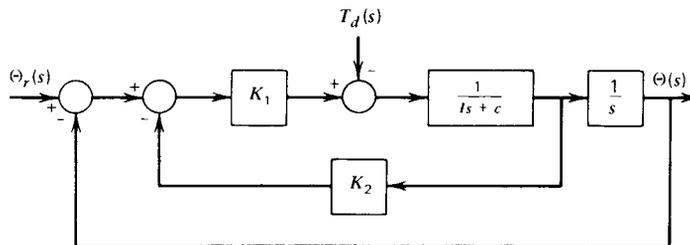

Fig. 24 Tachometer feedback arrangement to replace PD control for position servo.¹

linear system follows the preceding pattern. The overall system transfer functions are obtained, and all of the linear system analysis techniques can be applied to predict the system's performance. If the performance is unsatisfactory, a new control law is tried and the process repeated. When this process fails to achieve an acceptable design, more systematic methods of altering the system's structure are needed; they are discussed in later sections. We have used step functions as the test signals because they are the most common and perhaps represent the severest test of system performance. Impulse, ramp, and sinusoidal test signals are also employed. The type to use should be made clear in the design specifications.

6 CONTROLLER HARDWARE

The control law must be implemented by a physical device before the control engineer's task is complete. The earliest devices were purely kinematic and were mechanical elements such as gears, levers, and diaphragms that usually obtained their power from the controlled variable. Most controllers now are analog electronic, hydraulic, pneumatic, or digital electronic devices. We now consider the analog type. Digital controllers are covered starting in Section 10.

6.1 Feedback Compensation and Controller Design

Most controllers that implement versions of the PID algorithm are based on the following feedback principle. Consider the single-loop system shown in Fig. 1. If the open-loop transfer function is large enough that $|G(s)H(s)| \gg 1$, the closed-loop transfer function is approximately given by

$$T(s) = \frac{G(s)}{1 + G(s)H(s)} \approx \frac{G(s)}{G(s)H(s)} = \frac{1}{H(s)} \quad (24)$$

The principle states that a power unit $G(s)$ can be used with a feedback element $H(s)$ to create a desired transfer function $T(s)$. The power unit must have a gain high enough that $|G(s)H(s)| \gg 1$, and the feedback elements must be selected so that $H(s) = 1/T(s)$. This principle was used in Section 1 to explain the design of a feedback amplifier.

6.2 Electronic Controllers

The *operational amplifier* (*op amp*) is a high-gain amplifier with a high input impedance. A diagram of an op amp with feedback and input elements with impedances $T_f(s)$ and $T_i(s)$ is shown in Fig. 25. An approximate relation is

$$\frac{E_o(s)}{E_i(s)} = -\frac{T_f(s)}{T_i(s)}$$

The various control modes can be obtained by proper selection of the impedances. A proportional controller can be constructed with a *multiplier*, which uses two resistors, as shown in Fig. 26. An *inverter* is a multiplier circuit with $R_f = R_i$. It is sometimes needed because of the sign reversal property of the op amp. The multiplier circuit can be modified to act as an adder (Fig. 27).

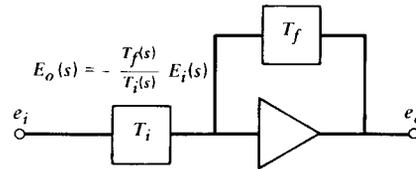

Fig. 25 Operational amplifier (op amp).¹

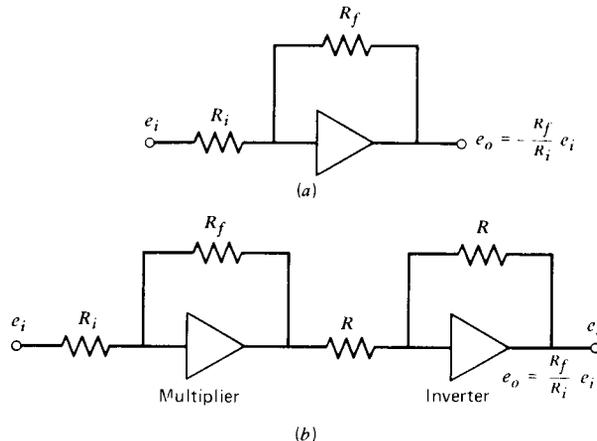

Fig. 26 Op-amp implementation of proportional control.¹

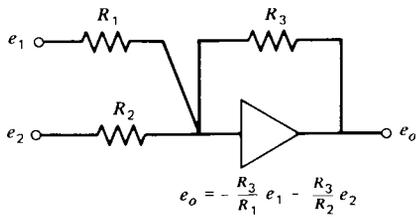

Fig. 27 Op-amp adder circuit.¹

$$e_o = -\frac{R_3}{R_1} e_1 - \frac{R_3}{R_2} e_2$$

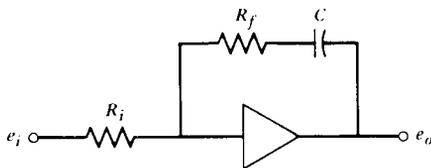

Fig. 28 Op-amp implementation of PI control.¹

PI control can be implemented with the circuit of Fig. 28. Figure 29 shows a complete system using op amps for PI control. The inverter is needed to

create an error detector. Many industrial controllers provide the operator with a choice of control modes, and the operator can switch from one mode to another when the process characteristics or control objectives change. When a switch occurs, it is necessary to provide any integrators with the proper initial voltages or else undesirable transients will occur when the integrator is switched into the system. Commercially available controllers usually have built-in circuits for this purpose.

In theory, a differentiator can be created by interchanging the resistance and capacitance in the integrating op amp. The difficulty with this design is that no electrical signal is "pure." Contamination always exists as a result of voltage spikes, ripple, and other transients generally categorized as "noise." These high-frequency signals have large slopes compared with the more slowly varying primary signal, and thus they will dominate the output of the differentiator. In practice, this problem is solved by filtering out high-frequency signals, either with a low-pass filter inserted in cascade with the differentiator or by using a redesigned differentiator such as the one shown in Fig. 30. For the ideal PD controller, $R_1 = 0$. The attenuation curve for the ideal controller breaks upward at $\omega = 1/R_2C$ with a slope of 20 dB/decade. The curve for the practical controller does the same but then becomes flat at

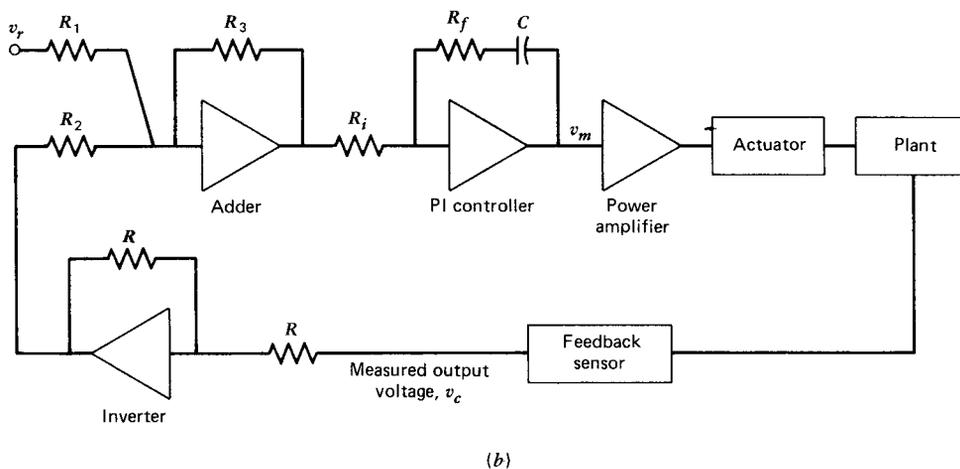

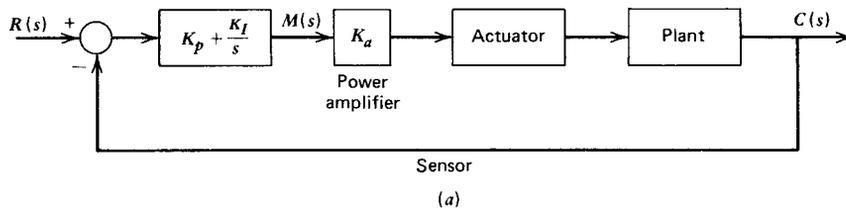

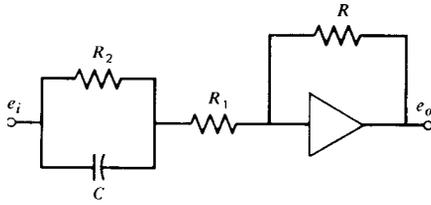

Fig. 29 Implementation of PI controller using op amps. (a) Diagram of system. (b) Diagram showing how op amps are connected.²

$$e_o = -K_p \left(e_i + T_D \frac{de_i}{dt} \right) - \alpha T_D \frac{de_o}{dt}$$

$$K_p = \frac{R}{R_1 + R_2} \quad T_D = R_2 C \quad \alpha = \frac{R_1}{R_1 + R_2}$$

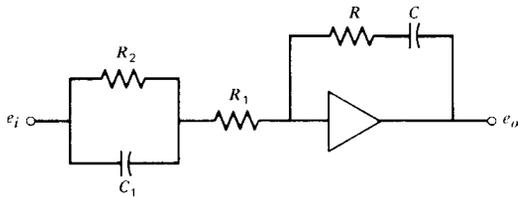

Fig. 30 Practical op-amp implementation of PD control.¹

for $\omega > (R_1 + R_2)/R_1 R_2 C$. This provides the required limiting effect at high frequencies.

PID control can be implemented by joining the PI and PD controllers in parallel, but this is expensive because of the number of op amps and power supplies required. Instead, the usual implementation is that shown in Fig. 31. The circuit limits the effect of frequencies above $\omega = 1/\beta R_1 C_1$. When $R_1 = 0$, ideal PID control results. This is sometimes called the *non-interactive* algorithm because the effect of each of the three modes is additive, and they do not interfere with one another. The form given for $R_1 \neq 0$ is the *real* or *interactive* algorithm. This name results from the fact that historically it was difficult to implement non-interactive PID control with mechanical or pneumatic devices.

6.3 Pneumatic Controllers

The nozzle-flappe introduced in Section 4 is a high-gain device that is difficult to use without modification

$$e_o = - \left(K_p e_i + K_I \int_0^t e_i dt + K_D \frac{de_i}{dt} \right) - \beta R_1 C_1 \frac{de_o}{dt}$$

$$\beta = \frac{R_2}{R_1 + R_2} \quad K_p = \beta \frac{RC + R_2 C_1}{R_2 C}$$

$$K_I = \frac{\beta}{R_2 C} \quad K_D = \beta R C_1$$

Fig. 31 Practical op-amp implementation of PID control.¹

The gain K_f is known only imprecisely and is sensitive to changes induced by temperature and other environmental factors. Also, the linear region over which Eq. (14) applies is very small. However, the device can be made useful by compensating it with feedback elements, as was illustrated with the electropneumatic valve positioner shown in Fig. 19.

6.4 Hydraulic Controllers

The basic unit for synthesis of hydraulic controllers is the hydraulic servomotor. The nozzle-flappe concept is also used in hydraulic controllers.⁵ A PI controller is shown in Fig. 32. It can be modified for proportional action. Derivative action has not seen much use in hydraulic controllers. This action supplies damping to the system, but hydraulic systems are usually highly damped intrinsically because of the viscous working fluid. PI control is the algorithm most commonly implemented with hydraulics.

7 FURTHER CRITERIA FOR GAIN SELECTION

Once the form of the control law has been selected, the gains must be computed in light of the performance specifications. In the examples of the PID family of control laws in Section 5, the damping ratio, dominant time constant, and steady-state error were taken to be the primary indicators of system performance in the interest of simplicity. In practice, the criteria are usually more detailed. For example, the rise time and maximum overshoot, as well as the other transient response specification of the previous chapter, may be encountered. Requirements can also be stated in terms of frequency response characteristics, such as bandwidth, resonant frequency, and peak amplitude. Whatever specifications they take, a complete set of specification for control system performance generally should include the following considerations for given forms of the command and disturbance inputs:

1. Equilibrium specification
 - (a) Stability
 - (b) Steady-state error
2. Transient specification
 - (a) Speed of response
 - (b) Form of response
3. Sensitivity specification
 - (a) Sensitivity to parameter variations
 - (b) Sensitivity to model inaccuracies
 - (c) Noise rejection (bandwidth, etc.)

In addition to these performance stipulations, the usual engineering considerations of initial cost, weight, maintainability, and so on must be taken into account. The considerations are highly specific to the chosen hardware, and it is difficult to deal with such issues in a general way.

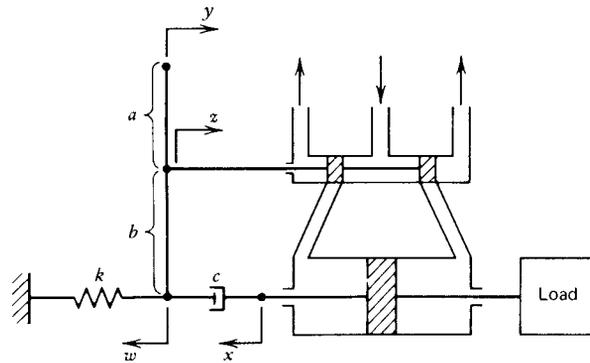

Fig. 32 Hydraulic implementation of PI control.¹

Two approaches exist for designing the controller. The proper one depends on the quality of the analytical description of the plant to be controlled. If an accurate model of the plant is easily developed, we can design a specialized controller for the particular application. The range of adjustment of controller gains in this case can usually be made small because the accurate plant model allows the gains to be precomputed with confidence. This technique reduces the cost of the controller and can often be applied to electromechanical systems.

The second approach is used when the plant is relatively difficult to model, which is often the case in process control. A standard controller with several control modes and wide ranges of gains is used, and the proper mode and gain settings are obtained by testing the controller on the process in the field. This approach should be considered when the cost of developing an accurate plant model might exceed the cost of controller tuning in the field. Of course, the plant must be available for testing for this approach to be feasible.

7.1 Performance Indices

The performance criteria encountered thus far require a set of conditions to be specific—for example, one for steady-state error, one for damping ratio, and one for the dominant time constant. If there are many such conditions, and if the system is of high order with several gains to be selected, the design process can get quite complicated because transient and steady-state criteria tend to drive the design in different directions. An alternative approach is to specify the system's desired performance by means of one analytical expression called a *performance index*. Powerful analytical and numerical methods are available that allow the gains to be systematically computed by minimizing (or maximizing) this index.

To be useful, a performance index must be selective. The index must have a sharply defined extremum in the vicinity of the gain values that give the desired performance. If the numerical value of the index does not change very much for large changes in the

gains from their optimal values, the index will not be selective.

Any practical choice of a performance index must be easily computed, either analytically, numerically, or experimentally. Four common choices for an index are the following:

$$J = \begin{cases} \int_0^{\infty} |e(t)| dt & \text{(IAE index) (25)} \\ \int_0^{\infty} t|e(t)| dt & \text{(ITAE index) (26)} \\ \int_0^{\infty} [e(t)]^2 dt & \text{(ISE index) (27)} \\ \int_0^{\infty} t[e(t)]^2 dt & \text{(ITSE index) (28)} \end{cases}$$

where $e(t)$ is the system error. This error usually is the difference between the desired and the actual values of the output. However, if $e(t)$ does not approach zero as $t \rightarrow \infty$, the preceding indices will not have finite values. In this case, $e(t)$ can be defined as $e(t) = c(\infty) - c(t)$, where $c(t)$ is the output variable. If the index is to be computed numerically or experimentally, the infinite upper limit can be replaced by a time t_f large enough that $e(t)$ is negligible for $t > t_f$.

The *integral absolute-error* (IAE) criterion (25) expresses mathematically that the designer is not concerned with the sign of the error, only its magnitude. In some applications, the IAE criterion describes the fuel consumption of the system. The index says nothing about the relative importance of an error occurring late in the response versus an error occurring early. Because of this, the index is not as selective as the *integral-of-time-multiplied absolute-error* (ITAE) criterion (26). Since the multiplier t is small in the early stages of the response, this index weights early errors less heavily than later errors. This makes sense physically. No system can respond instantaneously,

and the index is lenient accordingly, while penalizing any design that allows a nonzero error to remain for a long time. Neither criterion allows highly underdamped or highly overdamped systems to be optimum. The ITAE criterion usually results in a system whose step response has a slight overshoot and well-damped oscillations.

The *integral squared-error* (ISE) and *integral-of-time-multiplied squared-error* (ITSE) criteria are analogous to the IAE and ITAE criteria, except that the square of the error is employed for three reasons: (a) in some applications, the squared error represents the system's power consumption; (b) squaring the error weights large errors much more heavily than small errors; (c) the squared error is much easier to handle analytically. The derivative of a squared term is easier to compute than that of an absolute value and does not have a discontinuity at $e = 0$. These differences are important when the system is of high order with multiple error terms.

The closed-form solution for the response is not required to evaluate a performance index. For a given set of parameter values, the response and the resulting index value can be computed numerically. The optimum solution can be obtained using systematic computer search procedures; this makes this approach suitable for use with nonlinear systems.

7.2 Optimal-Control Methods

Optimal-control theory includes a number of algorithms for systematic design of a control law to minimize a performance index, such as the following generalization of the ISE index, called the *quadratic* index:

$$J = \int_0^{\infty} (\mathbf{x}^T \mathbf{Q} \mathbf{x} + \mathbf{u}^T \mathbf{R} \mathbf{u}) dt \quad (29)$$

where \mathbf{x} and \mathbf{u} are the deviations of the state and control vectors from the desired reference values. For example, in a servomechanism, the state vector might consist of the position and velocity, and the control vector might be a scalar—the force or torque produced by the actuator. The matrices \mathbf{Q} and \mathbf{R} are chosen by the designer to provide relative weighting for the elements of \mathbf{x} and \mathbf{u} . If the plant can be described by the linear state-variable model

$$\dot{\mathbf{x}} = \mathbf{A} \mathbf{x} + \mathbf{B} \mathbf{u} \quad (30)$$

$$\mathbf{y} = \mathbf{C} \mathbf{x} + \mathbf{D} \mathbf{u} \quad (31)$$

where \mathbf{y} is the vector of outputs—for example, position and velocity—then the solution of this *linear-quadratic* control problem is the linear control law:

$$\mathbf{u} = \mathbf{K} \mathbf{y} \quad (32)$$

where \mathbf{K} is a matrix of gains that can be found by several algorithms.^{1,6,7} A valid solution is guaranteed

to yield a stable closed-loop system, a major benefit of this method.

Even if it is possible to formulate the control problem in this way, several practical difficulties arise. Some of the terms in (29) might be beyond the influence of the control vector \mathbf{u} ; the system is then *uncontrollable*. Also, there might not be enough information in the output equation (31) to achieve control, and the system is then *unobservable*. Several tests are available to check controllability and observability. Not all of the necessary state variables might be available for feedback or the feedback measurements might be noisy or biased. Algorithms known as *observers*, *state reconstructors*, *estimators*, and *digital filters* are available to compensate for the missing information. Another source of error is the uncertainty in the values of the coefficient matrices \mathbf{A} , \mathbf{B} , \mathbf{C} , and \mathbf{D} . Identification schemes can be used to compare the predicted and the actual system performance and to adjust the coefficient values "online."

7.3 Ziegler–Nichols Rules

The difficulty of obtaining accurate transfer function models for some processes has led to the development of empirically based rules of thumb for computing the optimum gain values for a controller. Commonly used guidelines are the *Ziegler–Nichols rules*, which have proved so helpful that they are still in use 50 years after their development. The rules actually consist of two separate methods. The first method requires the open-loop step response of the plant, while the second uses the results of experiments performed with the controller already installed. While primarily intended for use with systems for which no analytical model is available, the rules are also helpful even when a model can be developed.

Ziegler and Nichols developed their rules from experiments and analysis of various industrial processes. Using the IAE criterion with a unit step response, they found that controllers adjusted according to the following rules usually had a step response that was oscillatory but with enough damping so that the second overshoot was less than 25% of the first (peak) overshoot. This is the *quarter-decay* criterion and is sometimes used as a specification.

The first method is the *process reaction* method and relies on the fact that many processes have an open-loop step response like that shown in Fig. 33. This is the *process signature* and is characterized by two parameters, R and L , where R is the slope of a line tangent to the steepest part of the response curve and L is the time at which this line intersects the time axis. First- and second-order linear systems do not yield positive values for L , and so the method cannot be applied to such systems. However, third- and higher order linear systems with sufficient damping do yield such a response. If so, the Ziegler–Nichols rules recommend the controller settings given in Table 2.

The *ultimate-cycle* method uses experiments with the controller in place. All control modes except

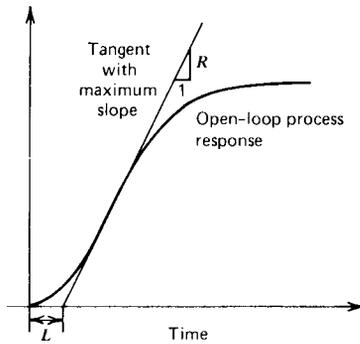

Fig. 33 Process signature for unit step input.¹

proportional are turned off, and the process is started with the proportional gain K_p set at a low value. The gain is slowly increased until the process begins to exhibit sustained oscillations. Denote the period of this oscillation by P_u and the corresponding ultimate gain by K_{pu} . The Ziegler–Nichols recommendations are given in Table 2 in terms of these parameters. The proportional gain is lower for PI control than for proportional control and is higher for PID control because integral action increases the order of the system and thus tends to destabilize it; thus, a lower gain is needed. On the other hand, derivative action tends to stabilize the system; hence, the proportional gain can be increased without degrading the stability characteristics. Because the rules were developed for a typical case out of many types of processes, final tuning of the gains in the field is usually necessary.

7.4 Nonlinearities and Controller Performance

All physical systems have nonlinear characteristics of some sort, although they can often be modeled as linear systems provided the deviations from the linearization reference condition are not too great. Under certain

conditions, however, the nonlinearities have significant effects on the system’s performance. One such situation can occur during the startup of a controller if the initial conditions are much different from the reference condition for linearization. The linearized model is then not accurate, and nonlinearities govern the behavior. If the nonlinearities are mild, there might not be much of a problem. Where the nonlinearities are severe, such as in process control, special consideration must be given to startup. Usually, in such cases, the control signal sent to the final control elements is manually adjusted until the system variables are within the linear range of the controller. Then the system is switched into automatic mode. Digital computers are often used to replace the manual adjustment process because they can be readily coded to produce complicated functions for the startup signals. Care must also be taken when switching from manual to automatic. For example, the integrators in electronic controllers must be provided with the proper initial conditions.

7.5 Reset Windup

In practice, all actuators and final control elements have a limited operating range. For example, a motor–amplifier combination can produce a torque proportional to the input voltage over only a limited range. No amplifier can supply an infinite current; there is a maximum current and thus a maximum torque that the system can produce. The final control elements are said to be *overdriven* when they are commanded by the controller to do something they cannot do. Since the limitations of the final control elements are ultimately due to the limited rate at which they can supply energy, it is important that all system performance specifications and controller designs be consistent with the energy delivery capabilities of the elements to be used.

Controllers using integral action can exhibit the phenomenon called *reset windup* or *integrator buildup* when overdriven, if they are not properly designed. For a step change in set point, the proportional term

Table 2 Ziegler–Nichols Rules

Controller transfer function $G(s) = K_p \left(1 + \frac{1}{T_I s} + T_D s \right)$		
Control Mode	Process Reaction Method	Ultimate-Cycle Method
P control	$K_p = \frac{1}{RL}$	$K_p = 0.5K_{pu}$
PI control	$K_p = \frac{0.9}{RL}$	$K_p = 0.45K_{pu}$
	$T_I = 3.3L$	$T_I = 0.83P_u$
PID control	$K_p = \frac{1.2}{RL}$	$K_p = 0.6K_{pu}$
	$T_I = 2L$	$T_I = 0.5P_u$
	$T_D = 0.5L$	$T_D = 0.125P_u$

responds instantly and saturates immediately if the set-point change is large enough. On the other hand, the integral term does not respond as fast. It integrates the error signal and saturates some time later if the error remains large for a long enough time. As the error decreases, the proportional term no longer causes saturation. However, the integral term continues to increase as long as the error has not changed sign, and thus the manipulated variable remains saturated. Even though the output is very near its desired value, the manipulated variable remains saturated until after the error has reversed sign. The result can be an undesirable overshoot in the response of the controlled variable.

Limits on the controller prevent the voltages from exceeding the value required to saturate the actuator and thus protect the actuator, but they do not prevent the integral buildup that causes the overshoot. One way to prevent integrator buildup is to select the gains so that saturation will never occur. This requires knowledge of the maximum input magnitude that the

system will encounter. General algorithms for doing this are not available; some methods for low-order systems are presented in Ref. 1, Chapter 7; Ref. 2, Chapter 7, and Ref. 4, Chapter 11. Integrator buildup is easier to prevent when using digital control; this is discussed in Section 10.

8 COMPENSATION AND ALTERNATIVE CONTROL STRUCTURES

A common design technique is to insert a *compensator* into the system when the PID control algorithm can be made to satisfy most but not all of the design specifications. A compensator is a device that alters the response of the controller so that the overall system will have satisfactory performance. The three categories of compensation techniques generally recognized are *series compensation*, *parallel* (or *feedback*) *compensation*, and *feedforward compensation*. The three structures are loosely illustrated in Fig. 34,

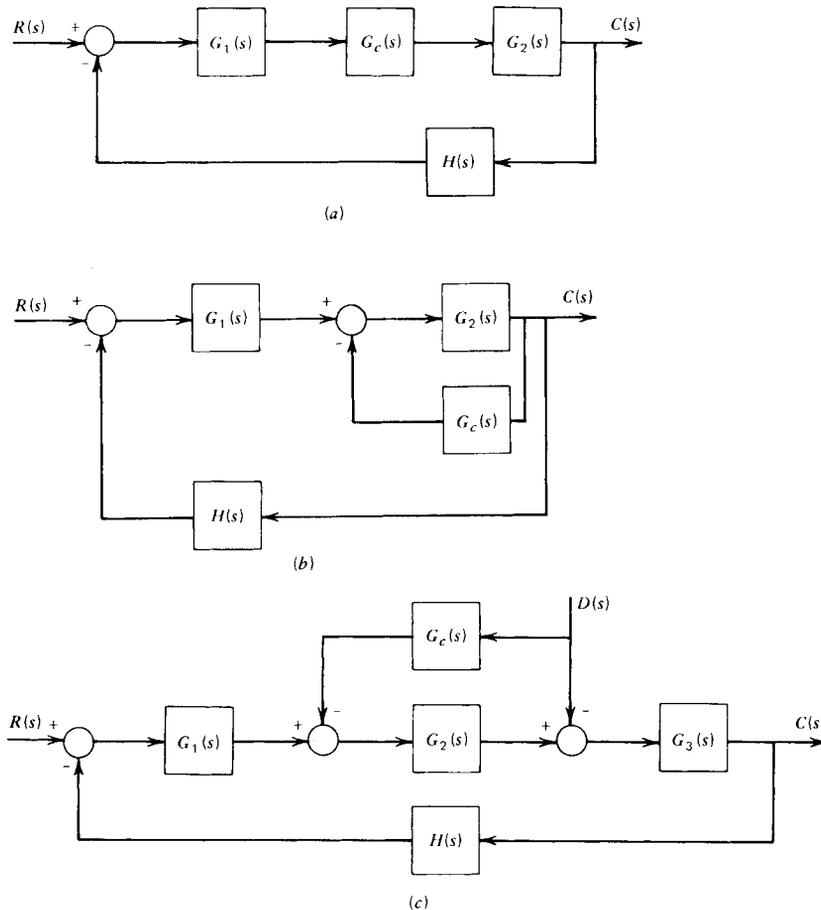

Fig. 34 General structures of three compensation types: (a) series; (b) parallel (or feedback); (c) feedforward. Compensator transfer function is $G_c(s)$.¹

where we assume the final control elements have a unity transfer function. The transfer function of the controller is $G_1(s)$. The feedback elements are represented by $H(s)$, and the compensator by $G_c(s)$. We assume that the plant is unalterable, as is usually the case in control system design. The choice of compensation structure depends on what type of specification must be satisfied. The physical devices used as compensators are similar to the pneumatic, hydraulic, and electrical devices treated previously. Compensators can be implemented in software for digital control applications.

8.1 Series Compensation

The most commonly used series compensators are the *lead*, the *lag*, and the *lead-lag* compensators. Electrical implementations of these are shown in Fig. 35. Other physical implementations are available. Generally, the lead compensator improves the speed of response; the lag compensator decreases the steady-state error; and the lead-lag affects both. Graphical aids, such as the root-locus and frequency response plots, are usually needed to design these compensators

(Ref. 1, Chapter 8; Ref. 2, Chapter 9; and Ref. 4, Chapter 11).

8.2 Feedback Compensation and Cascade Control

The use of a tachometer to obtain velocity feedback, as in Fig. 24, is a case of feedback compensation. The feedback compensation principle of Fig. 3 is another. Another form is *cascade control*, in which another controller is inserted within the loop of the original control system (Fig. 36). The new controller can be used to achieve better control of variables within the forward path of the system. Its set point is manipulated by the first controller.

Cascade control is frequently used when the plant cannot be satisfactorily approximated with a model of second order or lower. This is because the difficulty of analysis and control increases rapidly with system order. The characteristic roots of a second-order system can easily be expressed in analytical form. This is not so for third order or higher, and few general design rules are available. When faced with the problem of controlling a high-order system, the designer should first see if the performance requirements can be

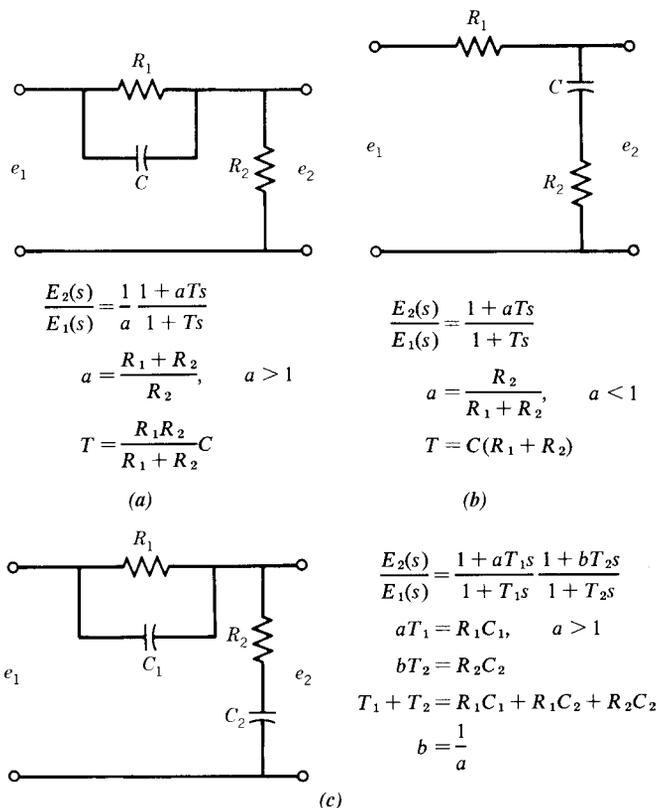

Fig. 35 Passive electrical compensators: (a) lead; (b) lag; (c) lead-lag.

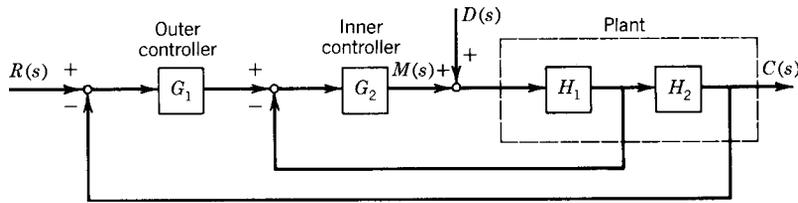

Fig. 36 Cascade control structure.

relaxed so that the system can be approximated with a low-order model. If this is not possible, the designer should attempt to divide the plant into subsystems, each of which is second order or lower. A controller is then designed for each subsystem. An application using cascade control is given in Section 11.

8.3 Feedforward Compensation

The control algorithms considered thus far have counteracted disturbances by using measurements of the output. One difficulty with this approach is that the effects of the disturbance must show up in the output of the plant before the controller can begin to take action. On the other hand, if we can measure the disturbance, the response of the controller can be improved by using the measurement to augment the control signal sent from the controller to the final control elements. This is the essence of feedforward compensation of the disturbance, as shown in Fig. 34c.

Feedforward compensation modifies the output of the main controller. Instead of doing this by measuring the disturbance, another form of feedforward compensation utilizes the command input. Figure 37 is an example of this approach. The closed-loop transfer function is

$$\frac{\Omega(s)}{\Omega_r(s)} = \frac{K_f + K}{Is + c + K} \quad (33)$$

For a unit step input, the steady-state output is $\omega_{ss} = (K_f + K)/(c + K)$. Thus, if we choose the feedforward gain K_f to be $K_f = c$, then $\omega_{ss} = 1$ as desired,

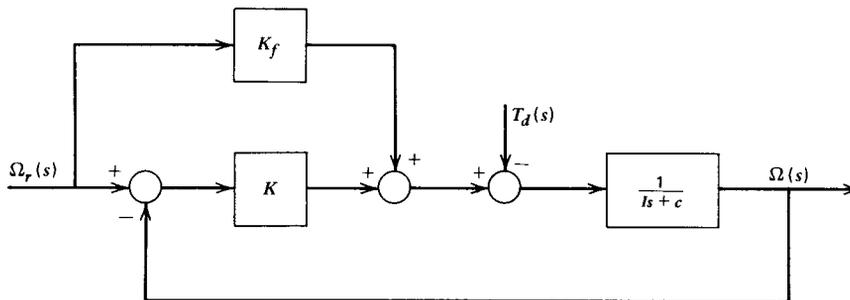

Fig. 37 Feedforward compensation of command input to augment proportional control.²

and the error is zero. Note that this form of feedforward compensation does not affect the disturbance response. Its effectiveness depends on how accurately we know the value of c . A digital application of feedforward compensation is presented in Section 11.

8.4 State-Variable Feedback

There are techniques for improving system performance that do not fall entirely into one of the three compensation categories considered previously. In some forms these techniques can be viewed as a type of feedback compensation, while in other forms they constitute a modification of the control law. *State-variable feedback* (SVFB) is a technique that uses information about all the system's state variables to modify either the control signal or the actuating signal. These two forms are illustrated in Fig. 38. Both forms require that the state vector \mathbf{x} be measurable or at least derivable from other information. Devices or algorithms used to obtain state-variable information other than directly from measurements are variously termed *state reconstructors*, *estimators*, *observers*, or *filters* in the literature.

8.5 Pseudoderivative Feedback

Pseudoderivative feedback (PDF) is an extension of the velocity feedback compensation concept of Fig. 24.^{1,2} It uses integral action in the forward path plus an internal feedback loop whose operator $H(s)$ depends on the plant (Fig. 39). For $G(s) = 1/(Is + c)$, $H(s) = K_1$. For $G(s) = 1/Is^2$, $H(s) = K_1 + K_2s$.

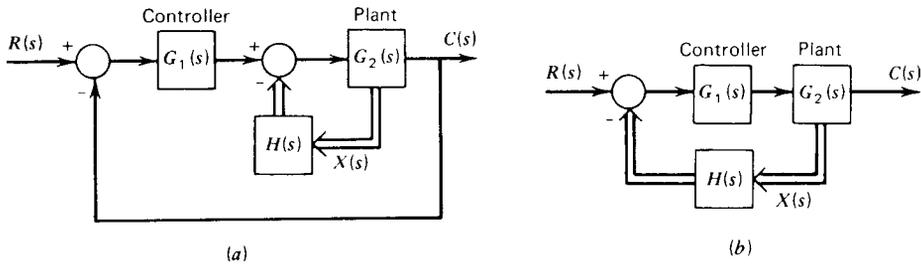

Fig. 38 Two forms of state-variable feedback: (a) internal compensation of the control signal; (b) modification of the actuating signal.¹

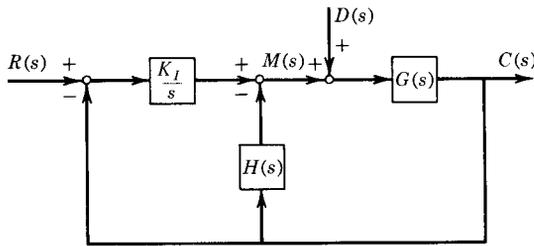

Fig. 39 Structure of pseudoderivative feedback.

The primary advantage of PDF is that it does not need derivative action in the forward path to achieve the desired stability and damping characteristics.

9 GRAPHICAL DESIGN METHODS

Higher order models commonly arise in control systems design. For example, integral action is often used with a second-order plant, and this produces a third-order system to be designed. Although algebraic solutions are available for third- and fourth-order polynomials, these solutions are cumbersome for design purposes. Fortunately, there exist graphical techniques to aid the designer. Frequency response plots of both the open- and closed-loop transfer functions are useful. The *Bode plot* and the *Nyquist plot* present the frequency response information in different forms. Each form has its own advantages. The root-locus plot shows the location of the characteristic roots for a range of values of some parameters, such as a controller gain. The design of two-position and other non-linear control systems is facilitated by the *describing function*, which is a linearized approximation based on the frequency response of the controller. Graphical design methods are discussed in more detail in Refs. 1–4.

9.1 Nyquist Stability Theorem

The Nyquist stability theorem is a powerful tool for linear system analysis. If the open-loop system has no poles with positive real parts, we can concentrate our

attention on the region around the point $-1 + i0$ on the polar plot of the open-loop transfer function. Figure 40 shows the polar plot of the open-loop transfer function of an arbitrary system that is assumed to be open-loop stable. The Nyquist stability theorem is stated as follows: A system is closed-loop stable if and only if the point $-1 + i0$ lies to the left of the open-loop Nyquist plot relative to an observer traveling along the plot in the direction of increasing frequency ω . Therefore, the system described by Fig. 39 is closed-loop stable.

The Nyquist theorem provides a convenient measure of the relative stability of a system. A measure of the proximity of the plot to the $-1 + i0$ point is given by the angle between the negative real axis and a line from the origin to the point where the plot crosses the unit circle (see Fig. 39). The frequency corresponding to this intersection is denoted ω_g . This angle is the *phase margin* (PM) and is positive when measured down from the negative real axis. The phase margin is the phase at the frequency ω_g where the magnitude ratio or “gain” of $G(i\omega)H(i\omega)$ is unity, or 0 decibels (dB). The frequency ω_p , the *phase crossover frequency*, is the frequency at which the phase angle is -180° . The *gain margin* (GM) is

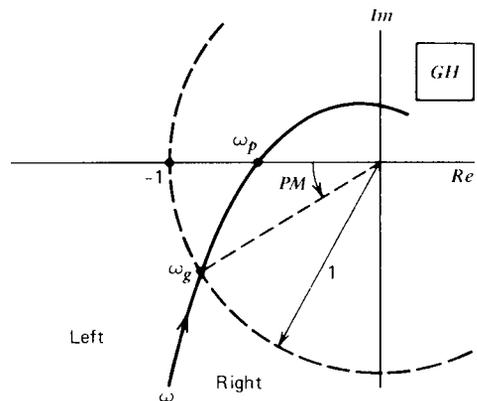

Fig. 40 Nyquist plot for a stable system.¹

the difference in decibels between the unity gain condition (0 dB) and the value of $|G(\omega_p)H(\omega_p)|$ decibels at the phase crossover frequency ω_p . Thus,

$$\text{Gain margin} = -|G(\omega_p)H(\omega_p)| \quad (\text{dB}) \quad (34)$$

A system is stable only if the phase and gain margins are both positive.

The phase and gain margins can be illustrated on the Bode plots shown in Fig. 41. The phase and gain margins can be stated as safety margins in the design specifications. A typical set of such specification is as follows:

$$\text{Gain margin} \geq 8 \text{ dB} \quad \text{Phase margin} \geq 30^\circ \quad (35)$$

In common design situations, only one of these equalities can be met, and the other margin is allowed to be greater than its minimum value. It is not desirable to make the margins too large because this results in a low gain, which might produce sluggish response and a large steady-state error. Another commonly used set of specification is

$$\text{Gain margin} \geq 6 \text{ dB} \quad \text{Phase margin} \geq 40^\circ \quad (36)$$

The 6-dB limit corresponds to the quarter amplitude decay response obtained with the gain settings given by the Ziegler–Nichols ultimate-cycle method (Table 2).

9.2 Systems with Dead-Time Elements

The Nyquist theorem is particularly useful for systems with dead-time elements, especially when the plant is of an order high enough to make the root-locus method cumbersome. A delay D in either the manipulated variable or the measurement will result in an open-loop transfer function of the form

$$G(s)H(s) = e^{-Ds} P(s) \quad (37)$$

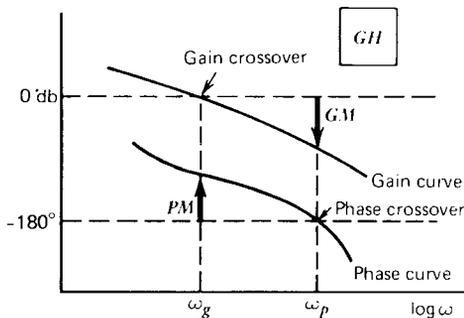

Fig. 41 Bode plot showing definitions of phase and gain margin.¹

Its magnitude and phase angle are

$$|G(i\omega)H(i\omega)| = |P(i\omega)||e^{-i\omega D}| = |P(i\omega)| \quad (38)$$

$$\begin{aligned} \angle G(i\omega)H(i\omega) &= \angle P(i\omega) + \angle e^{-i\omega D} \\ &= \angle P(i\omega) - \omega D \end{aligned} \quad (39)$$

Thus, the dead time decreases the phase angle proportionally to the frequency ω , but it does not change the gain curve. This makes the analysis of its effects easier to accomplish with the open-loop frequency response plot.

9.3 Open-Loop Design for PID Control

Some general comments can be made about the effects of proportional, integral, and derivative control actions on the phase and gain margins. Proportional action does not affect the phase curve at all and thus can be used to raise or lower the open-loop gain curve until the specification for the gain and phase margins are satisfied. If integral action or derivative action is included, the proportional gain is selected last. Therefore, when using this approach to the design, it is best to write the PID algorithm with the proportional gain factored out, as

$$F(s) = K_P \left(1 + \frac{1}{T_I s} + T_D s \right) E(s) \quad (40)$$

Derivative action affects both the phase and gain curves. Therefore, the selection of the derivative gain is more difficult than the proportional gain. The increase in phase margin due to the positive phase angle introduced by Derivative action is partly negated by the derivative gain, which reduces the gain margin. Increasing the derivative gain increases the speed of response, makes the system more stable, and allows a larger proportional gain to be used to improve the system's accuracy. However, if the phase curve is too steep near -180° , it is difficult to use Derivative action to improve the performance. Integral action also affects both the gain and phase curves. It can be used to increase the open-loop gain at low frequencies. However, it lowers the phase crossover frequency ω_p and thus reduces some of the benefit provided by derivative action. If required, the derivative action term is usually designed first, followed by integral action and proportional action, respectively.

The classical design methods based on the Bode plots obviously have a large component of trial and error because usually both the phase and gain curves must be manipulated to achieve an acceptable design. Given the same set of specifications two designers can use these methods and arrive at substantially different designs. Many rules of thumb and ad hoc procedures have been developed, but a general foolproof procedure does not exist. However, an experienced designer can often obtain a good design quickly with these

techniques. The use of a computer plotting routine greatly speeds up the design process.

9.4 Design with Root Locus

The effect of derivative action as a series compensator can be seen with the root locus. The term $1 + T_D s$ in Fig. 32 can be considered as a series compensator to the proportional controller. The derivative action adds an open-loop zero at $s = -1/T_D$. For example, a plant with the transfer function $1/s(s + 1)(s + 2)$, when subjected to proportional control, has the root locus shown in Fig. 42a. If the proportional gain is too high, the system will be unstable. The smallest achievable time constant corresponds to the root $s = -0.42$ and is $\tau = 1/0.42 = 2.4$. If derivative action is used to put an open-loop zero at $s = -1.5$, the resulting root locus is given by Fig. 42b. The derivative action prevents the system from becoming unstable and allows a smaller time constant to be achieved (τ can be made close to $1/0.75 = 1.3$ by using a high proportional gain).

The integral action in PI control can be considered to add an open-loop pole at $s = 0$ and a zero at $s = -1/T_I$. Proportional control of the plant $1/(s + 1)(s + 2)$ gives a root locus like that shown in Fig. 43, with $a = 1$ and $b = 2$. A steady-state error will exist for a step input. With the PI compensator applied to this plant, the root locus is given by Fig. 42b, with $T_I = \frac{2}{3}$. The steady-state error is eliminated, but the response of the system has been slowed because the dominant paths of the root locus of the compensated system lie closer to the imaginary axis than those of the uncompensated system.

As another example, let the plant transfer function be

$$G_P(s) = \frac{1}{s^2 + a_2s + a_1} \tag{41}$$

where $a_1 > 0$ and $a_2 > 0$. PI control applied to this plant gives the closed-loop command transfer function

$$T_1(s) = \frac{K_P s + K_I}{s^3 + a_2s^2 + (a_1 + K_P)s + K_I} \tag{42}$$

Note that the Ziegler–Nichols rules cannot be used to set the gains K_P and K_I . The second-order plant, Eq. (41), does not have the S-shaped signature of Fig. 33, so the process reaction method does not apply. The ultimate-cycle method requires K_I to be set to zero and the ultimate gain K_{Pu} determined. With $K_I = 0$ in Eq. (42) the resulting system is stable for all $K_P > 0$, and thus a positive ultimate gain does not exist.

Take the form of the PI control law given by Eq. (42) with $T_D = 0$, and assume that the characteristic roots of the plant (Fig. 44) are real values $-r_1$ and $-r_2$ such that $-r_2 < -r_1$. In this case the open-loop transfer function of the control system is

$$G(s)H(s) = \frac{K_P(s + 1/T_I)}{s(s + r_1)(s + r_2)} \tag{43}$$

One design approach is to select T_I and plot the locus with K_P as the parameter. If the zero at $s = -1/T_I$

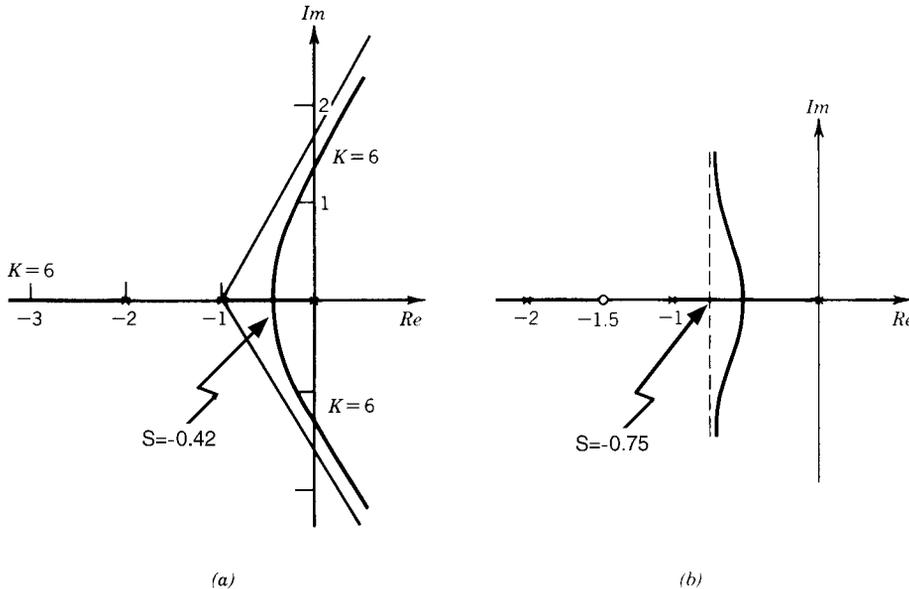

Fig. 42 (a) Root-locus plot for $s(s + 1)(s + 2) + K = 0$, for $K \geq 0$. (b) The effect of PD control with $T_D = \frac{2}{3}$.

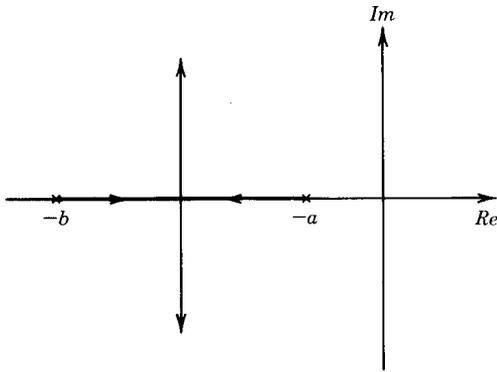

Fig. 43 Root-locus plot for $(s+a)(s+b) + K = 0$.

is located to the right of $s = -r_1$, the dominant time constant cannot be made as small as is possible with the zero located between the poles at $s = -r_1$ and $s = -r_2$ (Fig. 44). A large integral gain (small T_I and/or large K_P) is desirable for reducing the overshoot due to a disturbance, but the zero should not be placed to the left of $s = -r_2$ because the dominant time constant will be larger than that obtainable with the placement shown in Fig. 44 for large values of K_P . Sketch the root-locus plots to see this. A similar situation exists if the poles of the plant are complex.

The effects of the lead compensator in terms of time domain specification (characteristic roots) can be shown with the root-locus plot. Consider the second-order plant with the real distinct roots $s = -\alpha$,

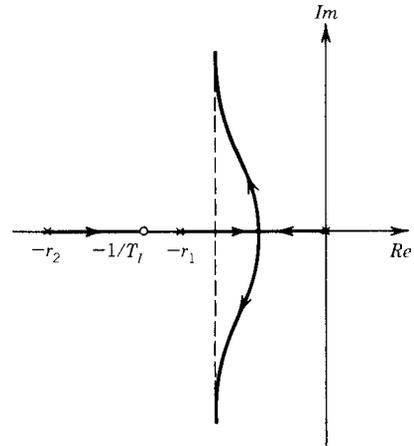

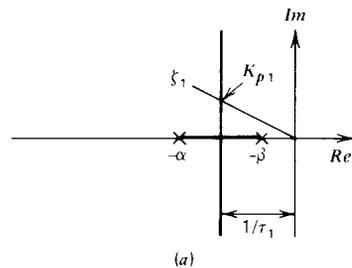

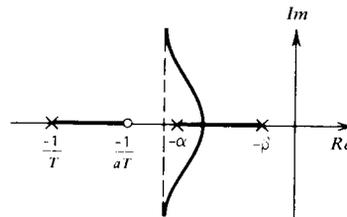

Fig. 44 Root-locus plot for PI control of a second-order plant.

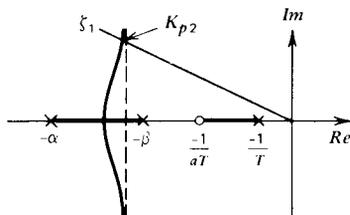

$s = -\beta$. The root locus for this system with proportional control is shown in Fig. 45a. The smallest dominant time constant obtainable is τ_1 , marked in the figure. A lead compensator introduces a pole at $s = -1/T$ and a zero at $s = -1/aT$, and the root locus becomes that shown in Fig. 45b. The pole and zero introduced by the compensator reshape the locus so that a smaller dominant time constant can be obtained. This is done by choosing the proportional gain high enough to place the roots close to the asymptotes.

(a)

(b)

(c)

Fig. 45 Effects of series lead and lag compensators: (a) uncompensated system's root locus; (b) root locus with lead compensation; (c) root locus with lag compensation.¹

With reference to the proportional control system whose root locus is shown in Fig. 45a, suppose that the desired damping ratio ζ_1 and desired time constant τ_1 are obtainable with a proportional gain of K_{P1} , but the resulting steady-state error $\alpha\beta/(\alpha\beta + K_{P1})$ due to a step input is too large. We need to increase the gain while preserving the desired damping ratio and time constant. With the lag compensator, the root locus is as shown in Fig. 45c. By considering specific numerical values, one can show that for the compensated system, roots with a damping ratio ζ_1 correspond to a high value of the proportional gain. Call this value K_{P2} . Thus $K_{P2} > K_{P1}$, and the steady-state error will be reduced. If the value of T is chosen large enough, the pole at $s = -1/T$ is approximately canceled by the zero at $s = -1/aT$, and the open-loop transfer function is given approximately by

$$G(s)H(s) = \frac{aK_P}{(s + \alpha)(s + \beta)} \quad (44)$$

Thus, the system's response is governed approximately by the complex roots corresponding to the gain value K_{P2} . By comparing Fig. 45a with 45c, we see that the compensation leaves the time constant relatively unchanged. From Eq. (44) it can be seen that since $a < 1$, K_P can be selected as the larger value K_{P2} . The ratio of K_{P1} to K_{P2} is approximately given by the parameter a .

Design by pole-zero cancellation can be difficult to accomplish because a response pattern of the system is essentially ignored. The pattern corresponds to the behavior generated by the canceled pole and zero, and this response can be shown to be beyond the influence of the controller. In this example, the canceled pole gives a stable response because it lies in the left-hand plane. However, another input not modeled here, such as a disturbance, might excite the response and cause unexpected behavior. The designer should therefore proceed with caution. None of the physical parameters of the system are known exactly, so exact pole-zero cancellation is not possible. A root-locus study of the effects of parameter uncertainty and a simulation study of the response are often advised before the design is accepted as final.

10 PRINCIPLES OF DIGITAL CONTROL

Digital control has several advantages over analog devices. A greater variety of control algorithms is possible, including nonlinear algorithms and ones with time-varying coefficients. Also, greater accuracy is possible with digital systems. However, their additional hardware complexity can result in lower reliability, and their application is limited to signals whose time variation is slow enough to be handled by the samplers and the logic circuitry. This is now less of a problem because of the large increase in the speed of digital systems.

10.1 Digital Controller Structure

The basic structure of a single-loop controller is shown in Fig. 46. The computer with its internal clock drives the *digital-to-analog* (D/A) and *analog-to-digital* (A/D) converters. It compares the command signals with the feedback signals and generates the control signals to be sent to the final control elements. These control signals are computed from the control algorithm stored in the memory. Slightly different structures exist, but Fig. 46 shows the important aspects. For example, the comparison between the command and feedback signals can be done with analog elements, and the A/D conversion made on the resulting error signal. The software must also provide for *interrupts*, which are conditions that call for the computer's attention to do something other than computing the control algorithm.

The time required for the control system to complete one loop of the algorithm is the time T , the *sampling time* of the control system. It depends on the time required for the computer to calculate the control algorithm and on the time required for the interfaces to convert data. Modern systems are capable of very high rates, with sample times under $1 \mu\text{s}$.

In most digital control applications, the plant is an analog system, but the controller is a discrete-time system. Thus, to design a digital control system, we must either model the controller as an analog system or model the plant as a discrete-time system. Each approach has its own merits, and we will examine both.

If we model the controller as an analog system, we use methods based on *differential* equations to

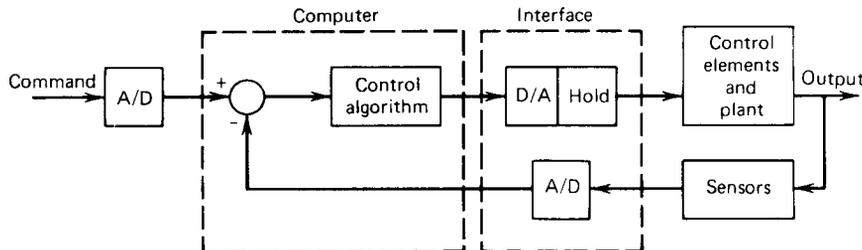

Fig. 46 Structure of digital control system.¹

compute the gains. However, a digital control system requires *difference* equations to describe its behavior. Thus, from a strictly mathematical point of view, the gain values we will compute will not give the predicted response exactly. However, if the sampling time is small compared to the smallest time constant in the system, then the digital system will act like an analog system, and our designs will work properly. Because most physical systems of interest have time constants greater than 1 ms and controllers can now achieve sampling times less than $1\mu\text{s}$, controllers designed with analog methods will often be adequate.

10.2 Digital Forms of PID Control

There are a number of ways that PID control can be implemented in software in a digital control system because the integral and derivative terms must be approximated with formulas chosen from a variety of available algorithms. The simplest integral approximation is to replace the integral with a sum of rectangular areas. With this rectangular approximation, the error integral is calculated as

$$\int_0^{(k+1)T} e(t) dt \approx Te(0) + Te(t_1) + Te(t_2) + \cdots + Te(t_k) = T \sum_{i=0}^k e(t_i) \quad (45)$$

where $t_k = kT$ and the width of each rectangle is the sampling time $T = t_{i+1} - t_i$. The times t_i are the times at which the computer updates its calculation of the control algorithm after receiving an updated command signal and an updated measurement from the sensor through the A/D interfaces. If the time T is small, then the value of the sum in (45) is close to the value of the integral. After the control algorithm calculation is made, the calculated value of the control signal $f(t_k)$ is sent to the actuator via the output interface. This interface includes a D/A converter and a *hold* circuit that “holds” or keeps the analog voltage corresponding to the control signal applied to the actuator until the next updated value is passed along from the computer. The simplest digital form of PI control uses (45) for the integral term. It is

$$f(t_k) = K_P e(t_k) + K_I T \sum_{i=0}^k e(t_i) \quad (46)$$

This can be written in a more efficient form by noting that

$$f(t_{k-1}) = K_P e(t_{k-1}) + K_I T \sum_{i=0}^{k-1} e(t_i)$$

and subtracting this from (46) to obtain

$$f(t_k) = f(t_{k-1}) + K_P [e(t_k) - e(t_{k-1})] + K_I T e(t_k) \quad (47)$$

This form—called the *incremental* or *velocity* algorithm—is well suited for incremental output devices such as stepper motors. Its use also avoids the problem of integrator buildup, the condition in which the actuator saturates but the control algorithm continues to integrate the error.

The simplest approximation to the derivative is the first-order difference approximation

$$\frac{de}{dt} \approx \frac{e(t_k) - e(t_{k-1})}{T} \quad (48)$$

The corresponding PID approximation using the rectangular integral approximation is

$$f(t_k) = K_P e(t_k) + K_I T \sum_{i=0}^k e(t_i) + \frac{K_D}{T} [e(t_k) - e(t_{k-1})] \quad (49)$$

The accuracy of the integral approximation can be improved by substituting a more sophisticated algorithm, such as the following trapezoidal rule:

$$\int_0^{(k+1)T} e(t) dt \approx T \sum_{i=0}^k \frac{1}{2} [e(t_{i+1}) + e(t_i)] \quad (50)$$

The accuracy of the derivative approximation can be improved by using values of the sampled error signal at more instants. Using the four-point central-difference method (Refs. 1 and 2), the derivative term is approximated by

$$\frac{de}{dt} \approx \frac{1}{6T} [e(t_k) + 3e(t_{k-1}) - 3e(t_{k-2}) - e(t_{k-3})]$$

The derivative action is sensitive to the resulting rapid change in the error samples that follows a step input. This effect can be eliminated by reformulating the control algorithm as follows (Refs. 1 and 2):

$$f(t_k) = f(t_{k-1}) + K_P [c(t_{k-1}) - c(t_k)] + K_I T [r(t_k) - c(t_k)] + \frac{K_D}{T} [-c(t_k) + 2c(t_{k-1}) - c(t_{k-2})] \quad (51)$$

where $r(t_k)$ is the command input and $c(t_k)$ is the variable being controlled. Because the command input $r(t_k)$ appears in this algorithm only in the integral term, we cannot apply this algorithm to PD control; that is, the integral gain K_I must be nonzero.

11 UNIQUELY DIGITAL ALGORITHMS

Development of analog control algorithms was constrained by the need to design physical devices that could implement the algorithm. However, digital control algorithms simply need to be programmable and are thus less constrained than analog algorithms.

11.1 Digital Feedforward Compensation

Classical control system design methods depend on linear models of the plant. With linearization we can obtain an approximately linear model, which is valid only over a limited operating range. Digital control now allows us to deal with nonlinear models more directly using the concepts of feedforward compensation discussed in Section 8.

Computed Torque Method Figure 47 illustrates a variation of feedforward compensation of the disturbance called the *computed torque method*. It is used to control the motion of robots. A simple model of a robot arm is the following nonlinear equation:

$$I\ddot{\theta} = T - mgL \sin \theta \tag{52}$$

where θ is the arm angle, I is its inertia, mg is its weight, and L is the distance from its mass center to the arm joint where the motor acts. The motor supplies the torque T . To position the arm at some desired angle θ_r , we can use PID control on the angle error $\theta_r - \theta$. This works well if the arm angle θ is never far from the desired angle θ_r so that we can linearize the plant model about θ_r . However, the controller will work for large-angle excursions if we compute the nonlinear gravity torque term $mgL \sin \theta$ and add it to the PID output. That is, part of the motor torque will be computed specifically to cancel the gravity torque, in effect producing a linear system for the PID

algorithm to handle. The nonlinear torque calculations required to control multi-degree-of-freedom robots are very complicated and can be done only with a digital controller.

Feedforward Command Compensation Computers can store lookup tables, which can be used to control systems that are difficult to model entirely with differential equations and analytical functions. Figure 48 shows a speed control system for an internal combustion engine. The fuel flow rate required to achieve a desired speed depends in a complicated way on many variables not shown in the figure such as temperature, humidity, and so on. This dependence can be summarized in tables stored in the control computer and can be used to estimate the required fuel flow rate. A PID algorithm can be used to adjust the estimate based on the speed error. This application is an example of feedforward compensation of the command input, and it requires a digital computer.

11.2 Control Design in z Plane

There are two common approaches to designing a digital controller:

1. The performance is specific in terms of the desired continuous-time response, and the controller design is done entirely in the s plane, as with an analog controller. The resulting control law is then converted to discrete-time form, using approximations for the integral and derivative terms. This method can be successfully applied if the sampling time is small. The technique is widely used for two reasons. When existing analog controllers are converted to digital control, the form of the control law and the values of its associated gains are known to have been satisfactory. Therefore, the digital version

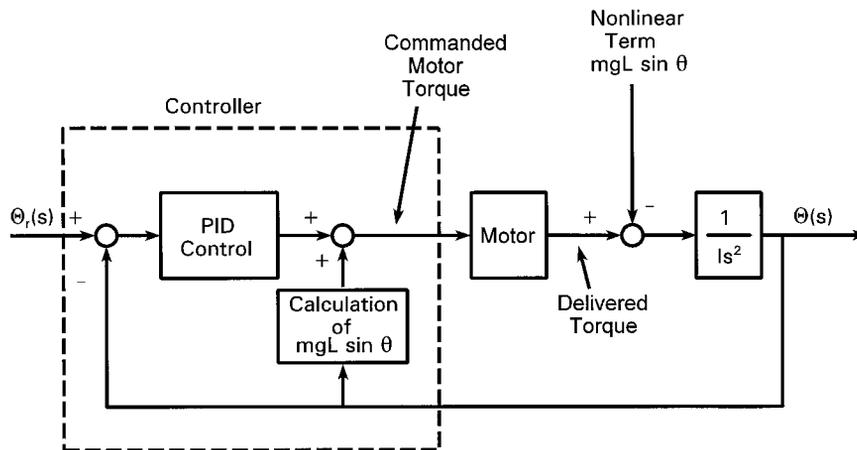

Fig. 47 Computed torque method applied to robot arm control.

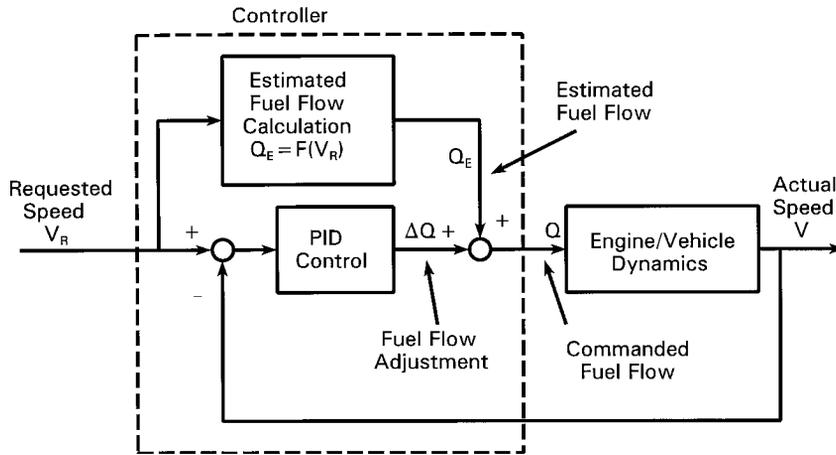

Fig. 48 Feedforward compensation applied to engine control.

can use the same control law and gain values. Second, because analog design methods are well established, many engineers prefer to take this route and then convert the design into a discrete-time equivalent.

- The performance specifications are given in terms of the desired continuous-time response and/or desired root locations in the s plane. From these the corresponding root locations in the z plane are found and a discrete control law is designed. This method avoids the derivative and integral approximation errors that are inherent in the first method and is the preferred method when the sampling time T is large. However, the algebraic manipulations are more cumbersome.

The second approach uses the z transform and pulse transfer functions. If we have an analog model of the plant, with its transfer function $G(s)$, we can obtain its pulse transfer function $G(z)$ by finding the z transform of the impulse response $g(t) = \mathcal{L}^{-1}[G(s)]$; that is, $G(z) = \mathcal{Z}[g(t)]$. A table of transforms facilitates this process; see Refs. 1 and 2. Figure 49a shows the basic elements of a digital control system. Figure 49b is an equivalent diagram with the analog transfer functions inserted. Figure 49c represents the same system in terms of pulse transfer functions. From the diagram we can find the closed-loop pulse transfer function. It is

$$\frac{C(z)}{R(z)} = \frac{G(z)P(z)}{1 + G(z)P(z)} \quad (53)$$

The variable z is related to the Laplace variable s by

$$z = e^{sT} \quad (54)$$

If we know the desired root locations and the sampling time T , we can compute the z roots from this equation.

Digital PI Control Design For example, the first order plant $1/(2s + 1)$ with a zero-order hold has the following pulse transfer function (Refs. 1 and 2):

$$P(z) = \frac{1 - e^{-0.5T}}{z - e^{-0.5T}} \quad (55)$$

Suppose we use a control algorithm described by the following pulse transfer function:

$$G(z) = \frac{F(z)}{E(z)} = \frac{K_1 z + K_2}{z - 1} = \frac{K_1 + K_2 z^{-1}}{1 - z^{-1}} \quad (56)$$

The corresponding difference equation that the control computer must implement is

$$f(t_k) = f(t_{k-1}) + K_1 e(t_k) + K_2 e(t_{k-1}) \quad (57)$$

where $e(t_k) = r(t_k) - c(t_k)$. By comparing (57) with (47), it can be seen that this is the digital equivalent of PI control, where $K_P = -K_2$ and $K_I = (K_1 + K_2)/T$. Using the form of $G(z)$ given by (56), the closed-loop transfer function is

$$\frac{C(z)}{R(z)} = \frac{(1 - b)(K_1 z + K_2)}{z^2 + (K_1 - 1 - b - bK_1)z + b + K_2 - bK_2} \quad (58)$$

where $b = e^{-0.5T}$.

If the design specification call for $\tau = 1$ and $\zeta = 1$, then the desired s roots are $s = -1, -1$, and the analog PI gains required to achieve these roots are $K_P = 3$ and $K_I = 2$. Using a sampling time of

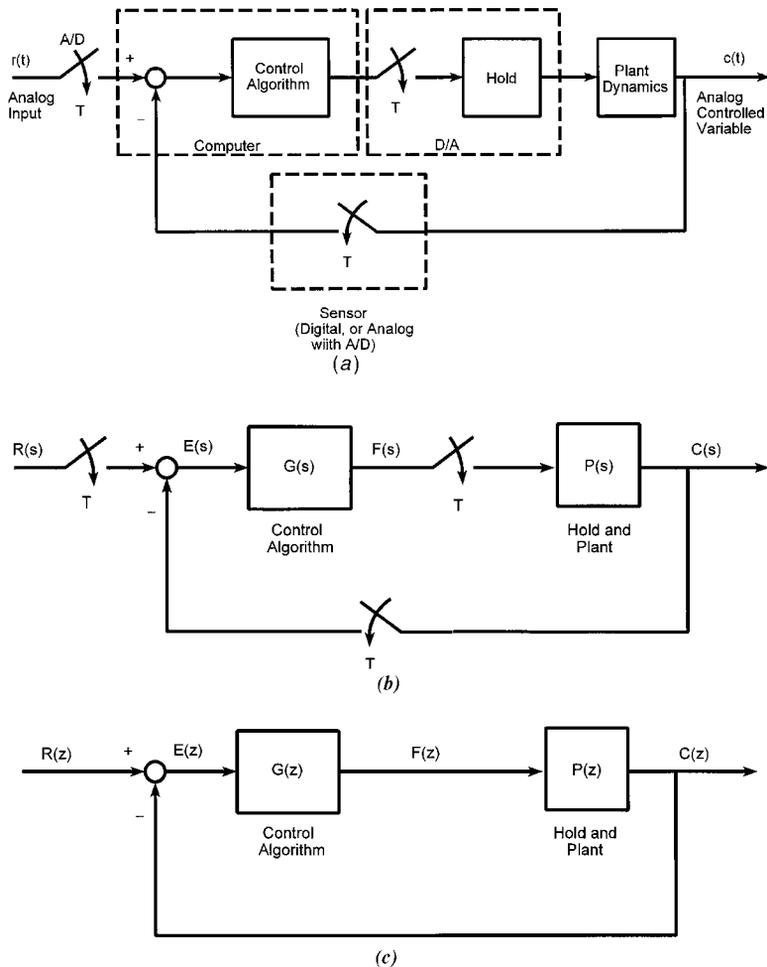

Fig. 49 Block diagrams of typical digital controller. (a) Diagram showing the components. (b) Diagram of the s-plane relations. (c) Diagram of the z-plane relations.

$T = 0.1$, the z roots must be $z = e^{-0.1}, e^{-0.1}$. To achieve these roots, the denominator of the transfer function (58) must be $z^2 - 2e^{-0.1}z + e^{-0.2}$. Thus the control gains must be $K_1 = 2.903$ and $K_2 = -2.717$. These values of K_1 and K_2 correspond to $K_P = 2.72$ and $K_I = 1.86$, which are close to the PI gains computed for an analog controller. If we had used a sampling time smaller than 0.1, say $T = 0.01$, the values of K_P and K_I computed from K_1 and K_2 would be $K_P = 2.97$ and $K_I = 1.98$, which are even closer to the analog gain values. This illustrates the earlier claim that analog design methods can be used when the sampling time is small enough.

Digital Series Compensation Series compensation can be implemented digitally by applying suitable discrete-time approximations for the derivative and

integral to the model represented by the compensator's transfer function $G_c(s)$. For example, the form of a lead or a lag compensator's transfer function is

$$G_c(s) = \frac{M(s)}{F(s)} = K \frac{s + c}{s + d} \quad (59)$$

where $m(t)$ is the actuator command and $f(t)$ is the control signal produced by the main (PID) controller. The differential equation corresponding to (59) is

$$\dot{m} + dm = K(\dot{f} + cf) \quad (60)$$

Using the simplest approximation for the derivative, Eq. (48), we obtain the following difference equation

that the digital compensator must implement:

$$\begin{aligned} & \frac{m(t_k) - m(t_{k-1})}{T} + dm(t_k) \\ &= K \left[\frac{f(t_k) - f(t_{k-1})}{T} + cf(t_k) \right] \end{aligned}$$

In the z plane, the equation becomes

$$\frac{1 - z^{-1}}{T} M(z) + dM(z) = K \left[\frac{1 - z^{-1}}{T} F(z) + cF(z) \right] \quad (61)$$

The compensator's pulse transfer function is thus seen to be

$$G_c(z) = \frac{M(z)}{F(z)} = \frac{K(1 - z^{-1}) + cT}{1 - z^{-1} + dT}$$

which has the form

$$G_c(z) = K_c \frac{z + a}{z + b} \quad (62)$$

where K_c , a , and b can be expressed in terms of K , c , d , and T if we wish to use analog design methods to design the compensator. When using commercial controllers, the user might be required to enter the values of the gain, the pole, and the zero of the compensator. The user must ascertain whether these values should be entered as s -plane values (i.e., K , c , and d) or as z -plane values (K_c , a , and b).

Note that the digital compensator has the same number of poles and zeros as the analog compensator. This is a result of the simple approximation used for the derivative. Note that Eq. (61) shows that when we use this approximation, we can simply replace s in the analog transfer function with $1 - z^{-1}$. Because the integration operation is the inverse of differentiation, we can replace $1/s$ with $1/(1 - z^{-1})$ when integration is used. [This is equivalent to using the rectangular approximation for the integral and can be verified by finding the pulse transfer function of the incremental algorithm (47) with $K_P = 0$.]

Some commercial controllers treat the PID algorithm as a series compensator, and the user is expected to enter the controller's values, not as PID gains, but as pole and zero locations in the z plane. The PID transfer function is

$$\frac{F(s)}{E(s)} = K_P + \frac{K_I}{s} + K_D s \quad (63)$$

Making the indicated replacements for the s terms, we obtain

$$\frac{F(z)}{E(z)} = K_P + \frac{K_I}{1 - z^{-1}} + K_D(1 - z^{-1})$$

which has the form

$$\frac{F(z)}{E(z)} = K_c \frac{z^2 - az + b}{z - 1} \quad (64)$$

where K_c , a , and b can be expressed in terms of K_P , K_I , K_D , and T . Note that the algorithm has two zeros and one pole, which is fixed at $z = 1$. Sometimes the algorithm is expressed in the more general form

$$\frac{F(z)}{F(z)} = K_c \frac{z^2 - az + b}{z - c} \quad (65)$$

to allow the user to select the pole as well.

Digital compensator design can be done with frequency response methods or with the root-locus plot applied to the z plane rather than the s plane. However, when better approximations are used for the derivative and integral, the digital series compensator will have more poles and zeros than its analog counterpart. This means that the root-locus plot will have more root paths, and the analysis will be more difficult. This topic is discussed in more detail in Refs. 1–3 and 8.

11.3 Direct Design of Digital Algorithms

Because almost any algorithm can be implemented digitally, we can specify the desired response and work backward to find the required control algorithm. This is the *direct-design* method. If we let $D(z)$ be the desired form of the closed-loop transfer function $C(z)/R(z)$ and solve for the controller transfer function $G(z)$, we obtain

$$G(z) = \frac{D(z)}{P(z)[1 - D(z)]} \quad (66)$$

We can pick $D(z)$ directly or obtain it from the specific input transform $R(z)$ and the desired output transform $C(z)$, because $D(z) = C(z)/R(z)$.

Finite-Settling-Time Algorithm This method can be used to design a controller to compensate for the effects of process dead time. A plant having such a response can often be approximately described by a first-order model with a dead-time element; that is,

$$G_P(s) = K \frac{e^{-Ds}}{\tau s + 1} \quad (67)$$

where D is the dead time. This model also approximately describes the S-shaped response curve used with the Ziegler–Nichols method (Fig. 33). When combined with a zero-order hold, this plant has the following pulse transfer function:

$$P(z) = K z^{-n} \frac{1 - a}{z - a} \quad (68)$$

where $a = \exp(-T/\tau)$ and $n = D/T$. If we choose $D(z) = z^{-(n+1)}$, then with a step command input, the output $c(k)$ will reach its desired value in $n + 1$ sample times, one more than is in the dead time D . This is the fastest response possible. From (66) the required controller transfer function is

$$G(z) = \frac{1}{K(1-a)} \frac{1-az^{-1}}{1-z^{-(n+1)}} \quad (69)$$

The corresponding difference equation that the control computer must implement is

$$f(t_k) = f(t_{k-n-1}) + \frac{1}{K(1-a)} [e(t_k) - ae(t_{k-1})] \quad (70)$$

This algorithm is called a *finite-settling-time* algorithm because the response reaches its desired value in a finite prescribed time. The maximum value of the manipulated variable required by this algorithm occurs at $t = 0$ and is $1/K(1-a)$. If this value saturates the actuator, this method will not work as predicted. Its success depends also on the accuracy of the plant model.

Dahlin's Algorithm This sensitivity to plant modeling errors can be reduced by relaxing the minimum response time requirement. For example, choosing $D(z)$ to have the same form as $P(z)$, namely,

$$D(z) = K_d z^{-n} \frac{1-a_d}{z-a_d} \quad (71)$$

we obtain from (66) the following controller transfer function:

$$G(z) = \frac{K_d(1-a_d)}{K(1-a)} \frac{1-az^{-1}}{1-az^{-1}-K_d(1-a_d)z^{-(n+1)}} \quad (72)$$

This is *Dahlin's algorithm*.³ The corresponding difference equation that the control computer must implement is

$$f(t_k) = a_d f(t_{k-1}) + K_d(1-a_d) f(t_{k-n-1}) + \frac{K_d(1-a_d)}{K(1-a)} [e(t_k) - ae(t_{k-1})] \quad (73)$$

Normally we would first try setting $K_d = K$ and $a_d = a$, but since we might not have good estimates of K and a , we can use K_d and a_d as tuning parameters to adjust the controller's performance. The constant a_d is related to the time constant τ_d of the desired response: $a_d = \exp(-T/\tau_d)$. Choosing τ_d smaller gives faster response.

Algorithms such as these are often used for system startup, after which the control mode is switched to PID, which is more capable of handling disturbances.

12 HARDWARE AND SOFTWARE FOR DIGITAL CONTROL

This section provides an overview of the general categories of digital controllers that are commercially available. This is followed by a summary of the software currently available for digital control and for control system design.

12.1 Digital Control Hardware

Commercially available controllers have different capabilities, such as different speeds and operator interfaces, depending on their targeted application.

Programmable Logic Controllers (PLCs) These are controllers that are programmed with relay ladder logic, which is based on Boolean algebra. Now designed around microprocessors, they are the successors to the large relay panels, mechanical counters, and drum programmers used up to the 1960s for sequencing control and control applications requiring only a finite set of output values (e.g., opening and closing of valves). Some models now have the ability to perform advanced mathematical calculations required for PID control, thus allowing them to be used for modulated control as well as finite-state control. There are numerous manufacturers of PLCs.

Digital Signal Processors (DSPs) A modern development is the *digital signal processor* (DSP), which has proved useful for feedback control as well as signal processing.⁹ This special type of processor chip has separate buses for moving data and instructions and is constructed to perform rapidly the kind of mathematical operations required for digital filtering and signal processing. The separate buses allow the data and the instructions to move in parallel rather than sequentially. Because the PID control algorithm can be written in the form of a digital filter, DSPs can also be used as controllers.

The DSP architecture was developed to handle the types of calculations required for digital filters and discrete Fourier transforms, which form the basis of most signal-processing operations. DSPs usually lack the extensive memory management capabilities of general-purpose computers because they need not store large programs or large amounts of data. Some DSPs contain A/D and D/A converters, serial ports, timers, and other features. They are programmed with specialized software that runs on popular personal computers. Low-cost DSPs are now widely used in consumer electronics and automotive applications, with Texas Instruments being a major supplier.

Motion Controllers *Motion controllers* are specialized control systems that provide feedback control for one or more motors. They also provide a convenient operator interface for generating the commanded trajectories. Motion controllers are particularly well suited for applications requiring coordinated motion of

two or more axes and for applications where the commanded trajectory is complicated. A higher level host computer might transmit required distance, speed, and acceleration rates to the motion controller, which then constructs and implements the continuous position profile required for each motor. For example, the host computer would supply the required total displacement, the acceleration and deceleration times, and the desired slew speed (the speed during the zero acceleration phase). The motion controller would generate the commanded position versus time for each motor. The motion controller also has the task of providing feedback control for each motor to ensure that the system follows the required position profile.

Figure 50 shows the functional elements of a typical motion controller, such as those built by Galil Motion Control, Inc. Provision for both analog and digital input signals allows these controllers to perform other control tasks besides motion control. Compared to DSPs, such controllers generally have greater capabilities for motion control and have operator interfaces that are better suited for such applications. Motion controllers are available as plug-in cards for most computer bus types. Some are available as stand-alone units.

Motion controllers use a PID control algorithm to provide feedback control for each motor (some manufacturers call this algorithm a "filter") The user enters the values of the PID gains (some manufacturers provide preset gain values, which can be changed; others provide tuning software that assists in selecting the proper gain values). Such controllers also have

their own language for programming a variety of motion profile and other applications. For example, they provide for linear and circular interpolation for two-dimensional coordinated motion, motion smoothing (to eliminate jerk), contouring, helical motion, and electronic gearing. The latter is a control mode that emulates mechanical gearing in software, in which one motor (the slave) is driven in proportion to the position of another motor (the master) or an encoder.

Process Controllers *Process controllers* are designed to handle inputs from sensors, such as thermocouples, and outputs to actuators, such as valve positioners, that are commonly found in process control applications. Figure 51 illustrates the input-output capabilities of a typical process controller such as those manufactured by Honeywell, which is a major supplier of such devices. This device is a stand-alone unit designed to be mounted in an instrumentation panel. The voltage and current ranges of the analog inputs are those normally found with thermocouple-based temperature sensors. The current outputs are designed for devices like valve positioners, which usually require 4–20-mA signals.

The controller contains a microcomputer with built-in math functions normally required for process control, such as thermocouple linearization, weighted averaging, square roots, ratio/bias calculations, and the PID control algorithm. These controllers do not have the same software and memory capabilities as desktop computers, but they are less expensive. Their operator interface consists of a small keypad with typically

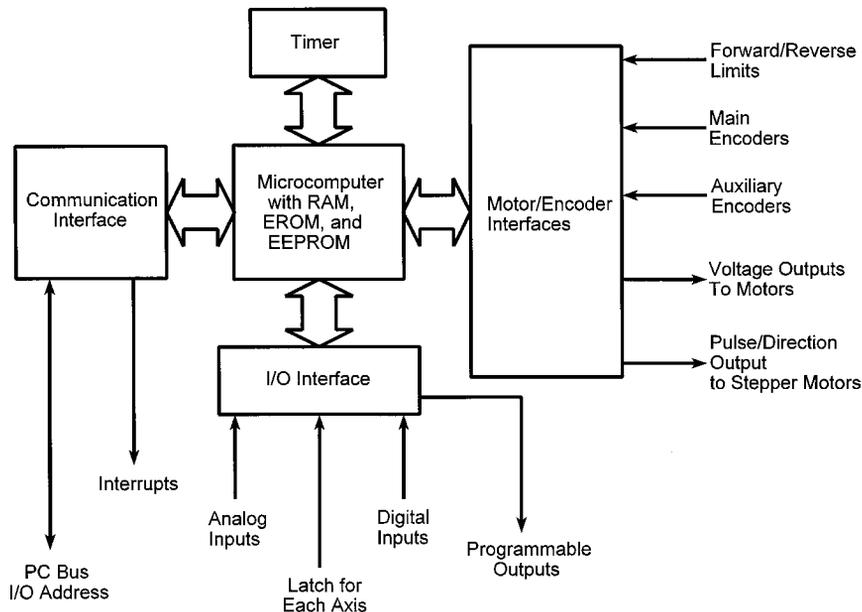

Fig. 50 Functional diagram of motion controller.

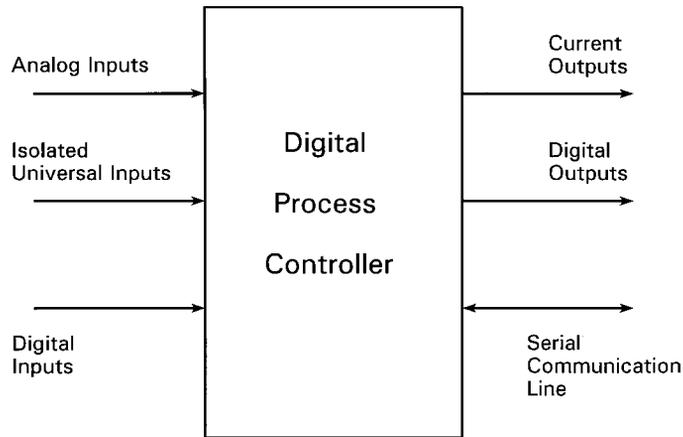

Fig. 51 Functional diagram of digital process controller.

fewer than 10 keys, a small graphical display for displaying bar graphs of the set points and the process variables, indicator lights, and an alphanumeric display for programming the controller.

The PID gains are entered by the user. Some units allow multiple sets of gains to be stored; the unit can be programmed to switch between gain settings when certain conditions occur. Some controllers have an adaptive tuning feature that is supposed to adjust

the gains to prevent overshoot in startup mode, to adapt to changing process dynamics, and to adapt to disturbances. However, at this time, adaptive tuning cannot claim a 100% success rate, and further research and development in adaptive control is needed.

Some process controllers have more than one PID control loop for controlling several variables. Figure 52 illustrates a boiler feedwater control application for a controller with two PID loops arranged

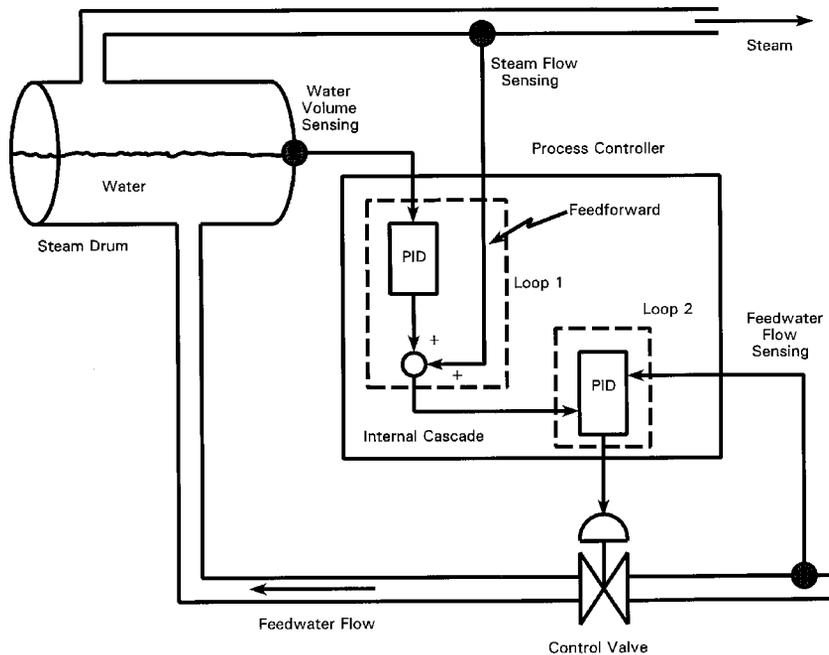

Fig. 52 Application of two-loop process controller for feedwater control.

in a cascade control structure. Loop 1 is the main or outer loop controller for maintaining the desired water volume in the boiler. It uses sensing of the steam flow rate to implement feedforward compensation. Loop 2 is the inner loop controller that directly controls the feedwater control valve.

12.2 Software for Digital Control

The software available to the modern control engineer is quite varied and powerful and can be categorized according to the following tasks:

1. Control algorithm design, gain selection, and simulation
2. Tuning
3. Motion programming
4. Instrumentation configuration
5. Real-time control functions

Many analysis and simulation packages now contain algorithms of specific interest to control system designers. *MATLAB* is one such package that is widely used. It contains built-in functions for generating root-locus and frequency response plots, system simulation, digital filtering, calculation of control gains, and data analysis. It can accept model descriptions in the form of transfer functions or as state-variable equations.^{1,4,10}

Some manufacturers provide software to assist the engineer in sizing and selecting components. An example is the *Motion Component Selector* (MCS) sold by Galil Motion Control, Inc. It assists the engineer in computing the load inertia, including the effects of the mechanical drive, and then selects the proper motor and amplifier based on the user's description of the desired motion profile.

Some hardware manufacturers supply software to assist the engineer in selecting control gains and modifying (*tuning*) them to achieve good response. This might require that the system to be controlled be available for experiments prior to installation. Some controllers, such as some Honeywell process controllers, have an autotuning feature that adjusts the gains in real time to improve performance.

Motion programming software supplied with motion controllers was mentioned previously. Some packages, such as Galil's, allow the user to simulate a multiaxis system having more than one motor and to display the resulting trajectory.

Instrumentation configuration software, such as *LabView*, provides specialized programming languages for interacting with instruments and for creating graphical real-time displays of instrument outputs.

Until recently, development of real-time digital control software involved tedious programming, often in assembly language. Even when implemented in a higher level language, such as Fortran or C, programming real-time control algorithms can be very

challenging, partly because of the need to provide adequately for interrupts. Software packages are now available that provide real-time control capability, usually a form of the PID algorithm, that can be programmed through user-friendly graphical interfaces. Examples include the Galil motion controllers and the add-on modules for Labview and MATLAB.

12.3 Embedded Control Systems and Hardware-in-the Loop Testing

An *embedded control system* is a microprocessor and sensor suite designed to be an integral part of a product. The aerospace and automotive industries have used embedded controllers for some time, but the decreased cost of components now makes embedded controllers feasible for more consumer and biomedical applications.

For example, embedded controllers can greatly increase the performance of orthopedic devices. One model of an artificial leg now uses sensors to measure in real time the walking speed, the knee joint angle, and the loading due to the foot and ankle. These measurements are used by the controller to adjust the hydraulic resistance of a piston to produce a stable, natural, and efficient gait. The controller algorithms are adaptive in that they can be tuned to an individual's characteristics and their settings changed to accommodate different physical activities.

Engines incorporate embedded controllers to improve efficiency. Embedded controllers in new active suspensions use actuators to improve on the performance of traditional passive systems consisting only of springs and dampers. One design phase of such systems is *hardware-in-the-loop testing*, in which the controlled object (the engine or vehicle suspension) is replaced with a real-time simulation of its behavior. This enables the embedded system hardware and software to be tested faster and less expensively than with the physical prototype and perhaps even before the prototype is available.

Simulink, which is built on top of MATLAB and requires MATLAB to run, is often used to create the simulation model for hardware-in-the-loop testing. Some of the *toolboxes* available for MATLAB, such as the control systems toolbox, the signal-processing toolbox, and the DSP and fixed-point blocksets, are also useful for such applications.

13 SOFTWARE SUPPORT FOR CONTROL SYSTEM DESIGN

Software packages are available for graphical control system design methods and control system simulation. These greatly reduce the tedious manual computation, plotting, and programming formerly required for control system design and simulation.

13.1 Software for Graphical Design Methods

Several software packages are available to support graphical control system design methods. The most

popular of these is MATLAB, which has extensive capabilities for generation and interactive analysis of root-locus plots and frequency response plots. Some of these capabilities are discussed in Refs. 1 and 4.

13.2 Software for Control Systems Simulation

It is difficult to obtain closed-form expressions for system response when the model contains *dead time* or nonlinear elements that represent realistic control system behavior. Dead time (also called *transport delay*), rate limiters, and actuator saturation are effects that often occur in real control systems, and simulation is often the only way to analyze their response. Several software packages are available to support system simulation. One of the most popular is Simulink.

Systems having dead-time elements are easily simulated in Simulink. Figure 53 shows a Simulink model for PID control of the plant $53/(3.44s^2 + 2.61s + 1)$, with a dead time between the output of the controller and the plant. The block implementing the dead-time transfer function e^{-Ds} is called the *transport delay* block. When you run this model, you will see the response in the scope block.

In addition to being limited by saturation, some actuators have limits on how fast they can react. This limitation is independent of the time constant of the actuator and might be due to deliberate restrictions placed on the unit by its manufacturer. An example is a flow control valve whose rate of opening and closing is controlled by a *rate limiter*. Simulink has such a block, and it can be used in series with the saturation block to

model the valve behavior. Consider the model of the height h of liquid in a tank whose input is a flow rate q_i . For specific parameter values, such a model has the form $H(s)/Q_i(s) = 2/(5s + 1)$. A Simulink model is shown in Figure 54 for a specific PI controller whose gains are $K_p = 4$ and $K_I = \frac{5}{4}$. The saturation block models the fact that the valve opening must be between 0 and 100%. The model enables us to experiment with the lower and upper limits of the rate limiter block to see its effect on the system performance.

An introduction to Simulink is given in Refs. 4 and 10. Applications of Simulink to control system simulation are given in Ref. 4.

14 FUTURE TRENDS IN CONTROL SYSTEMS

Microprocessors have rejuvenated the development of controllers for mechanical systems. Currently, there are several applications areas in which new control systems are indispensable to the product's success:

1. Active vibration control
2. Noise cancellation
3. Adaptive optics
4. Robotics
5. Micromachines
6. Precision engineering

Most of the design techniques presented here comprise "classical" control methods. These methods are

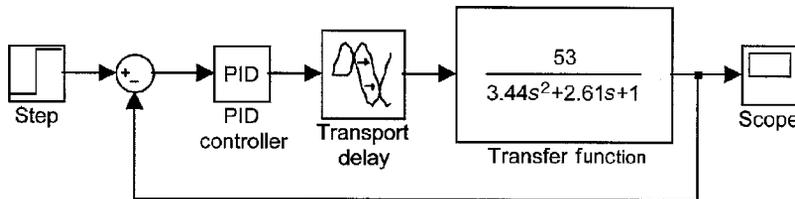

Fig. 53 Simulink model of system with transport delay.

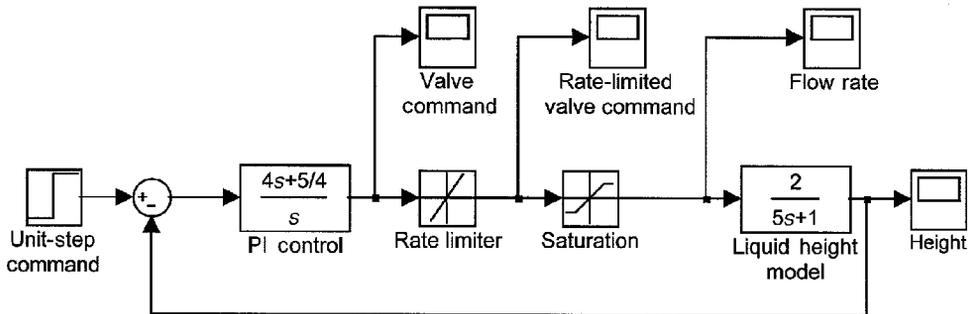

Fig. 54 Simulink model of system with actuator saturation and rate limiter.

widely used because when they are combined with some testing and computer simulation, an experienced engineer can rapidly achieve an acceptable design. Modern control algorithms, such as state-variable feedback and the linear-quadratic optimal controller, have had some significant mechanical engineering applications—for example, in the control of aerospace vehicles. The current approach to multivariable systems like the one shown in Fig. 55 is to use classical methods to design a controller for each subsystem because they can often be modeled with low-order linearized models. The coordination of the various low-level controllers is a nonlinear problem. High-order, nonlinear, multivariable systems that cannot be controlled with classical methods cannot yet be handled by modern control theory in a general way, and further research is needed.

In addition to the improvements, such as lower cost, brought on by digital hardware, microprocessors have allowed designers to incorporate algorithms of much greater complexity into control systems. The following is a summary of the areas currently receiving much attention in the control systems community.

14.1 Fuzzy Logic Control

In classical set theory, an object's membership in a set is clearly defined and unambiguous. *Fuzzy logic control* is based on a generalization of classical set theory to allow objects to belong to several sets with various degrees of membership. Fuzzy logic can be used to describe processes that defy precise definition or precise measurement, and thus it can be used to model

the inexact and subjective aspects of human reasoning. For example, room temperature can be described as cold, cool, just right, warm, or hot. Development of a fuzzy logic temperature controller would require the designer to specify the membership functions that describe "warm" as a function of temperature, and so on. The control logic would then be developed as a linguistic algorithm that models a human operator's decision process (e.g., if the room temperature is "cold," then "greatly" increase the heater output; if the temperature is "cool," then increase the heater output "slightly").

Fuzzy logic controllers have been implemented in a number of applications. Proponents of fuzzy logic control point to its ability to convert a human operator's reasoning process into computer code. Its critics argue that because all the controller's fuzzy calculations must eventually reduce to a specific output that must be given to the actuator (e.g., a specific voltage value or a specific valve position), why not be unambiguous from the start, and define a "cool" temperature to be the range between 65° and 68°, for example? Perhaps the proper role of fuzzy logic is at the human operator interface. Research is active in this area, and the issue is not yet settled.^{11,12}

14.2 Nonlinear Control

Most real systems are nonlinear, which means that they must be described by nonlinear differential equations. Control systems designed with the linear control theory described in this chapter depend on a linearized approximation to the original nonlinear model. This

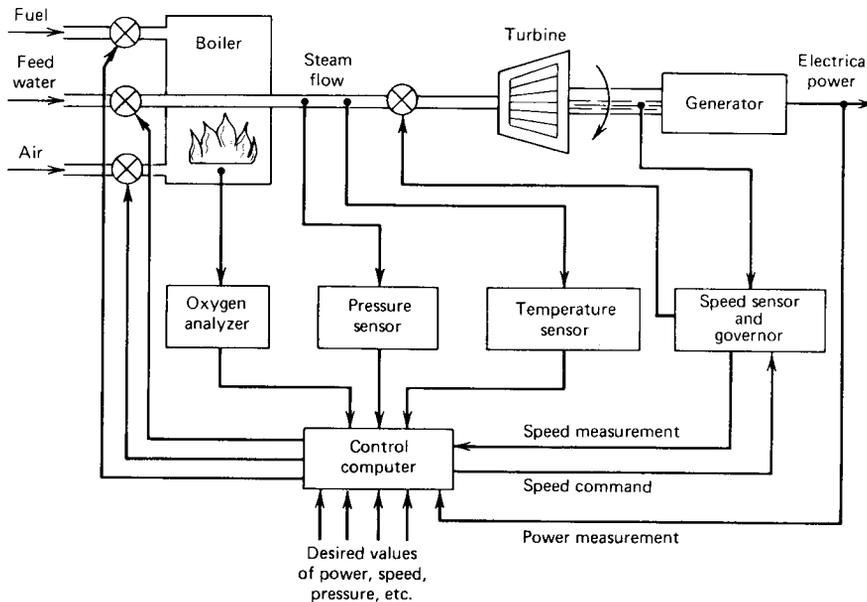

Fig. 55 Computer control system for a boiler-generator. Each important variable requires its own controller. Interaction between variables calls for coordinated control of all loops.¹

linearization can be explicitly performed, or implicitly made, as when we use the small-angle approximation: $\sin \theta \approx \theta$. This approach has been enormously successful because a well-designed controller will keep the system in the operating range where the linearization was done, thus preserving the accuracy of the linear model. However, it is difficult to control some systems accurately in this way because their operating range is too large. Robot arms are a good example.^{13,14} Their equations of motion are very nonlinear, due primarily to the fact that their inertia varies greatly as their configuration changes.

Nonlinear systems encompass everything that is “not linear,” and thus there is no general theory for nonlinear systems. There have been many nonlinear control methods proposed—too many to summarize here.¹⁵ *Lyapunov’s stability theory* and Popov’s method play a central role in many such schemes. Adaptive control is a subcase of nonlinear control (see below).

The high speeds of modern digital computers now allow us to implement nonlinear control algorithms not possible with earlier hardware. An example is the computed-torque method for controlling robot arms, which was discussed in Section 11 (see Fig. 47).

14.3 Adaptive Control

The term *adaptive control*, which unfortunately has been loosely used, describes control systems that can change the form of the control algorithm or the values of the control gains in real time, as the controller improves its internal model of the process dynamics or in response to unmodeled disturbances.¹⁶ Constant control gains do not provide adequate response for some systems that exhibit large changes in their dynamics over their entire operating range, and some adaptive controllers use several models of the process, each of which is accurate within a certain operating range. The adaptive controller switches between gain settings that are appropriate for each operating range. Adaptive controllers are difficult to design and are prone to instability. Most existing adaptive controllers change only the gain values, not the form of the control algorithm. Many problems remain to be solved before adaptive control theory becomes widely implemented.

14.4 Optimal Control

A rocket might be required to reach orbit using minimum fuel or it might need to reach a given intercept point in minimum time. These are examples of potential applications of *optimal control theory*. Optimal control problems often consist of two subproblems. For the rocket example, these subproblems

are (a) the determination of the minimum-fuel (or minimum-time) trajectory and the open-loop control outputs (e.g., rocket thrust as a function of time) required to achieve the trajectory and (b) the design of a feedback controller to keep the system near the optimal trajectory.

Many optimal control problems are nonlinear, and thus no general theory is available. Two classes of problems that have achieved some practical successes are the *bang-bang control* problem in which the control variable switches between two fixed values (e.g., on and off or open and closed),⁶ and the *linear-quadratic regulator* (LQG), discussed in Section 7, which has proven useful for high-order systems.^{1,6}

Closely related to optimal control theory are methods based on stochastic process theory, including *stochastic control theory*,¹⁷ *estimators*, *Kalman filters*, and *observers*.^{1,6,17}

1 INTRODUCTION

Thermodynamics describes the relationship between mechanical work and other forms of energy. There are two facets of contemporary thermodynamics that must be stressed in a review such as this. The first is the equivalence of *work* and *heat* as two possible forms of energy exchange. This facet is expressed by the first law of thermodynamics. The second aspect is the one-way character, or irreversibility, of all flow that occur in nature. As expressed by the second law of thermodynamics, irreversibility or entropy generation is what prevents us from extracting the most possible work from various sources; it is also what prevents us from doing the most with the work that is already at our disposal. The objective of this chapter is to review the first and second laws of thermodynamics and their implications in mechanical engineering, particularly with respect to such issues as energy conversion and conservation. The analytical aspects (the formulas) of engineering thermodynamics are reviewed primarily in terms of the behavior of a pure substance, as would be the case of the working fluid in a heat engine or in a refrigeration machine.

Symbols and Units

c specific heat of incompressible substance, J/(kg · K)

c_p specific heat at constant pressure, J/(kg · K)
 c_T constant temperature coefficient, m³/kg
 c_v specific heat at constant volume, J/(kg · K)
COP coefficient of performance
 E energy, J
 f specific Helmholtz free energy ($u - Ts$), J/kg
 \mathbf{F} force vector, N
 g gravitational acceleration, m/s²
 g specific Gibbs free energy ($h - Ts$), J/kg
 h specific enthalpy ($u + Pv$), J/kg
 K isothermal compressibility, m²/N
 m mass of closed system, kg
 \dot{m} mass flow rate, kg/s
 m_i mass of component in a mixture, kg
 M mass inventory of control volume, kg
 M molar mass, g/mol or kg/kmol
 n number of moles, mol
 N_0 Avogadro's constant
 P pressure
 δQ infinitesimal heat interaction, J
 \dot{Q} heat transfer rate, W
 \mathbf{r} position vector, m
 R ideal gas constant, J/(kg · K)
 s specific entropy, J/(kg · K)
 S entropy, J/K
 S_{gen} entropy generation, J/K
 \dot{S}_{gen} entropy generation rate, W/K
 T absolute temperature, K

u	specific internal energy, J/kg
U	internal energy, J
v	specific volume, m^3/kg
\bar{v}	specific volume of incompressible substance, m^3/kg
V	volume, m^3
V	velocity, m/s
δW	infinitesimal work interaction, J
\dot{W}_{lost}	rate of lost available work, W
\dot{W}_{sh}	rate of shaft (shear) work transfer, W
x	linear coordinate, m
x	quality of liquid and vapor mixture
Z	vertical coordinate, m
β	coefficient of thermal expansion, $1/\text{K}$
γ	ratio of specific heats, c_p/c_v
η	“efficiency ratio”
η_I	first-law efficiency
η_{II}	second-law efficiency
θ	relative temperature, $^{\circ}\text{C}$

Subscripts

$()_f$	saturated liquid state (f = “fluid”)
$()_g$	saturated vapor state (g = “gas”)
$()_s$	saturated solid state (s = “solid”)
$()_{\text{in}}$	inlet port
$()_{\text{out}}$	outlet port
$()_{\text{rev}}$	reversible path
$()_H$	high-temperature reservoir
$()_L$	low-temperature reservoir
$()_{\text{max}}$	maximum
$()_T$	turbine
$()_C$	compressor
$()_N$	nozzle
$()_D$	diffuser
$()_0$	reference state
$()_1$	initial state
$()_2$	final state
$()_-$	moderately compressed liquid state
$()_+$	slightly superheated vapor state

Definitions

Boundary: The real or imaginary surface delineating the thermodynamic system. The boundary separates the system from its environment. The boundary is an unambiguously defined surface. The boundary has zero thickness and zero volume.

Closed System: A thermodynamic system whose boundary is not crossed by mass flow.

Cycle: The special process in which the final state coincides with the initial state.

Environment: The thermodynamic system external to the thermodynamic system.

Extensive Properties: Properties whose values depend on the size of the system (e.g., mass, volume, energy, enthalpy, entropy).

Intensive Properties: Properties whose values do not depend on the system size (e.g., pressure, temperature). The collection of all intensive properties constitutes the *intensive state*.

Open System: A thermodynamic system whose boundary is permeable to mass flow. Open systems (flow systems) have their own nomenclature: The thermodynamic system is usually referred to as the *control volume*, the boundary of the open system is the *control surface*, and the particular regions of the boundary that are crossed by mass flows are the *inlet* and *outlet ports*.

Phase: The collection of all system elements that have the same intensive state (e.g., the liquid droplets dispersed in a liquid–vapor mixture have the same intensive state, that is, the same pressure, temperature, specific volume, specific entropy, etc.).

Process: The change of state from one initial state to a final state. In addition to the end states, knowledge of the process implies knowledge of the *interactions* experienced by the system while in communication with its environment (e.g., work transfer, heat transfer, mass transfer, and entropy transfer). To know the process also means to know the *path* (the history, or the succession of states) followed by the system from the initial to the final state.

State: The condition (the being) of a thermodynamic system at a particular point in time, as described by an ensemble of quantities called *thermodynamic properties* (e.g., pressure, volume, temperature, energy, enthalpy, entropy). Thermodynamic properties are only those quantities that do not depend on the “history” of the system between two different states. Quantities that depend on the system evolution (path) between states are not thermodynamic properties (examples of nonproperties are the work, heat, and mass transfer; the entropy transfer; the entropy generation; and the destroyed exergy—see also the definition of *process*).

Thermodynamic System: The region or the collection of matter in space selected for analysis.

2 FIRST LAW OF THERMODYNAMICS FOR CLOSED SYSTEMS

The first law of thermodynamics is a statement that brings together three concepts in thermodynamics: work transfer, heat transfer, and energy change. Of these concepts, only energy change, or simply energy, is a thermodynamic property. We begin with a review¹ of the concepts of work transfer, heat transfer, and energy change.

Consider the force F_x experienced by a system at a point on its boundary. The infinitesimal *work transfer* between system and environment is

$$\delta W = -F_x dx$$

where the boundary displacement dx is defined as positive in the direction of the force F_x . When the force \mathbf{F} and the displacement of its point of application $d\mathbf{r}$ are not collinear, the general definition of infinitesimal work transfer is

$$\delta W = -\mathbf{F} \cdot d\mathbf{r}$$

The work transfer interaction is considered positive when the system does work on its environment—in other words, when \mathbf{F} and $d\mathbf{r}$ are oriented in opposite directions. This sign convention has its origin in heat engine engineering, because the purpose of heat engines as thermodynamic systems is to deliver work while receiving heat.

For a system to experience work transfer, two things must occur: (1) a force must be present on the boundary and (2) the point of application of this force (hence, the boundary) must move. The mere presence of forces on the boundary, without the displacement or the deformation of the boundary, does not mean work transfer. Likewise, the mere presence of boundary displacement without a force opposing or driving this motion does not mean work transfer. For example, in the free expansion of a gas into an evacuated space, the gas system does not experience work transfer because throughout the expansion the pressure at the imaginary system–environment interface is zero.

If a closed system can interact with its environment only via work transfer (i.e., in the absence of heat transfer δQ discussed later), then measurements show that the work transfer during a change of state from state 1 to state 2 is the same for all processes linking states 1 and 2,

$$-\left(\int_1^2 \delta W\right)_{\delta Q=0} = E_2 - E_1$$

In this special case the work transfer interaction $(W_{1-2})_{\delta Q=0}$ is a property of the system because its value depends solely on the end states. This thermodynamic property is the *energy change* of the system, $E_2 - E_1$. The statement that preceded the last equation is the first law of thermodynamics for closed systems that do not experience heat transfer.

Heat transfer is, like work transfer, an energy interaction that can take place between a system and its environment. The distinction between δQ and δW is made by the second law of thermodynamics discussed in the next section: Heat transfer is the energy interaction accompanied by entropy transfer, whereas work transfer is the energy interaction taking place in the absence of entropy transfer. The transfer of heat is driven by the *temperature difference* established between the system and its environment.² The system temperature is measured by placing the system in thermal communication with a test system called *thermometer*. The result of this measurement is the *relative temperature* θ expressed in degrees Celsius, θ ($^{\circ}\text{C}$), or

Fahrenheit, θ ($^{\circ}\text{F}$); these alternative temperature readings are related through the conversion formulas

$$\theta$$
 ($^{\circ}\text{C}$) = $\frac{5}{9}[\theta$ ($^{\circ}\text{F}$) - 32]

$$\theta$$
 ($^{\circ}\text{F}$) = $\frac{5}{9}\theta$ ($^{\circ}\text{C}$) + 32

$$1^{\circ}\text{F} = \frac{5}{9}^{\circ}\text{C}$$

The boundary that prevents the transfer of heat, regardless of the magnitude of the system–environment temperature difference, is termed *adiabatic*. Conversely, the boundary that is crossed by heat even in the limit of a vanishingly small system–environment temperature difference is termed *diathermal*.

Measurements also show that a closed system undergoing a change of state 1 \rightarrow 2 in the absence of work transfer experiences a heat interaction whose magnitude depends solely on the end states:

$$\left(\int_1^2 \delta Q\right)_{\delta W=0} = E_2 - E_1$$

In the special case of zero work transfer, the heat transfer interaction is a thermodynamic property of the system, which is by definition equal to the energy change experienced by the system in going from state 1 to state 2. The last equation is the first law of thermodynamics for closed systems incapable of experiencing work transfer. Note that, unlike work transfer, the heat transfer is considered positive when it increases the energy of the system.

Most thermodynamic systems do not manifest purely mechanical ($\delta Q = 0$) or purely thermal ($\delta W = 0$) behavior. Most systems manifest a *coupled* mechanical and thermal behavior. The preceding first-law statements can be used to show that the first law of thermodynamics for a process executed by a closed system experiencing both work transfer and heat transfer is

$$\underbrace{\int_1^2 \delta Q}_{\text{heat transfer}} - \underbrace{\int_1^2 \delta W}_{\text{work transfer}} = E_2 - E_1$$

energy interaction (nonproperties) energy change (property)

The first law means that the net heat transfer into the system equals the work done by the system on the environment plus the increase in the energy of the system. The first law of thermodynamics for a cycle or for an integral number of cycles executed by a closed system is

$$\oint \delta Q = \oint \delta W = 0$$

Note that the net change in the thermodynamic property energy is zero during a cycle or an integral number of cycles.

The energy change term $E_2 - E_1$ appearing on the right-hand side of the first law can be replaced by a more general notation that distinguishes between macroscopically identifiable forms of energy storage (kinetic, gravitational) and energy stored internally,

$$E_2 - E_1 = \underbrace{U_2 - U_1}_{\text{internal energy change}} + \underbrace{\frac{mV_2^2}{2} - \frac{mV_1^2}{2}}_{\text{kinetic energy change}} + \underbrace{mgZ_2 - mgZ_1}_{\text{gravitational energy change}}$$

If the closed system expands or contracts *quasistatically* (i.e., slowly enough, in mechanical equilibrium internally and with the environment) so that at every point in time the pressure P is uniform throughout the system, then the work transfer term can be calculated as being equal to the work done by all the boundary pressure forces as they move with their respective points of application,

$$\int_1^2 \delta W = \int_1^2 P dV$$

The work transfer integral can be evaluated provided the path of the quasistatic process, $P(V)$, is known; this is another reminder that the work transfer is path dependent (i.e., not a thermodynamic property).

3 SECOND LAW OF THERMODYNAMICS FOR CLOSED SYSTEMS

A *temperature reservoir* is a thermodynamic system that experiences only heat transfer and whose temperature remains constant during such interactions. Consider first a closed system executing a cycle or an integral number of cycles *while in thermal communication with no more than one temperature reservoir*. To state the second law for this case is to observe that the net work transfer during each cycle cannot be positive,

$$\oint \delta W = 0$$

In other words, a closed system cannot deliver work during one cycle while in communication with one temperature reservoir or with no temperature reservoir at all. Examples of such cyclic operation are the vibration of a spring-mass system or a ball bouncing on the pavement: For these systems to return to their respective initial heights, that is, for them to execute cycles, the environment (e.g., humans) must perform work on them. The limiting case of frictionless cyclic operation is termed *reversible* because in this limit the system returns to its initial state without intervention (work transfer) from the environment. Therefore, the

distinction between reversible and irreversible cycles executed by closed systems in communication with no more than one temperature reservoir is

$$\begin{aligned} \oint \delta W &= 0 && \text{(reversible)} \\ \oint \delta W &< 0 && \text{(irreversible)} \end{aligned}$$

To summarize, the first and second laws for closed systems operating cyclically in contact with no more than one temperature reservoir are (Fig. 1)

$$\oint \delta W = \oint \delta Q \leq 0$$

This statement of the second law can be used to show¹ that in the case of a closed system executing one or an integral number of cycles *while in communication with two temperature reservoirs* the following inequality holds (Fig. 1):

$$\frac{Q_H}{T_H} + \frac{Q_L}{T_L} \leq 0$$

where H and L denote the high-temperature and the low-temperature reservoirs, respectively. Symbols Q_H and Q_L stand for the value of the cyclic integral $\oint \delta Q$, where δQ is in one case exchanged only with the H reservoir and in the other with the L reservoir. In the reversible limit, the second law reduces to $T_H/T_L = -Q_H/Q_L$, which serves as definition for the absolute *thermodynamic temperature* scale denoted by symbol T . Absolute temperatures are expressed either in kelvins, T (K), or in degrees Rankine, T ($^{\circ}$ R); the relationships between absolute and relative temperatures are

$$\begin{aligned} T(\text{K}) &= \theta(^{\circ}\text{C}) + 273.15\text{K} & T(^{\circ}\text{R}) &= \theta(^{\circ}\text{F}) + 459.67^{\circ}\text{R} \\ 1\text{K} &= 1^{\circ}\text{C} & 1^{\circ}\text{R} &= 1^{\circ}\text{F} \end{aligned}$$

A *heat engine* is a special case of a closed system operating cyclically while in thermal communication with two temperature reservoirs, a system that during each cycle receives heat and delivers work:

$$\oint \delta W = \oint \delta Q = Q_H + Q_L > 0$$

The goodness of the heat engine can be described in terms of the heat engine efficiency or the first-law efficiency

$$\eta = \frac{\oint \delta W}{Q_H} \leq 1 - \frac{T_L}{T_H}$$

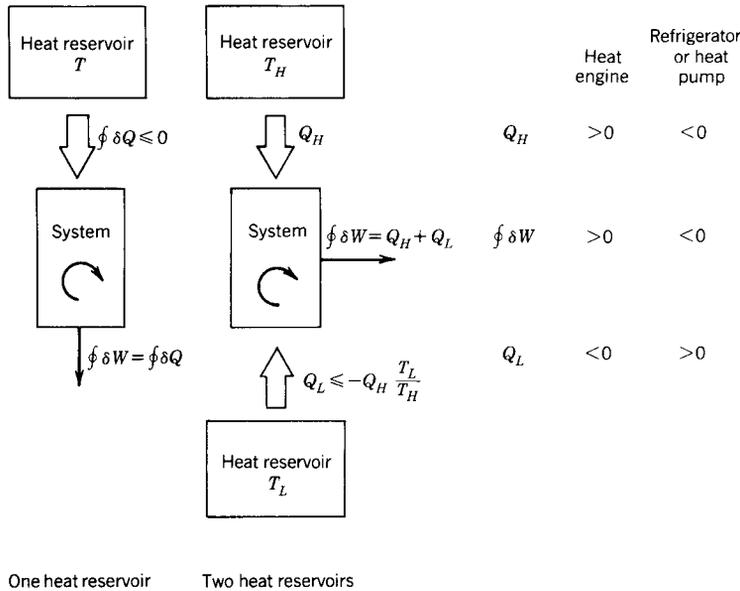

Fig. 1 First and second laws of thermodynamics for a closed system operating cyclically while in communication with one or two heat reservoirs.

Alternatively, the second-law efficiency of the heat engine is defined as^{1,3,4}

$$\eta_{II} = \frac{\oint \delta W}{(\oint \delta W)_{\text{maximum (reversible case)}}} = \frac{\eta_I}{1 - T_L/T_H}$$

A *refrigerating machine* or a *heat pump* operates cyclically between two temperature reservoirs in such a way that during each cycle it receives work and delivers net heat to the environment,

$$\oint \delta W = \oint \delta Q = Q_H + Q_L < 0$$

The goodness of such machines can be expressed in terms of a coefficient of performance (COP)

$$\text{COP}_{\text{refrigerator}} = \frac{Q_L}{-\oint \delta W} \leq \frac{1}{T_H/T_L - 1}$$

$$\text{COP}_{\text{heat pump}} = \frac{-Q_H}{-\oint \delta W} \leq \frac{1}{1 - T_L/T_H}$$

Generalizing the second law for closed systems operating cyclically, one can show that, if during each cycle the system experiences any number of heat interactions Q_i with any number of temperature reservoirs whose respective absolute temperatures are T_i , then

$$\sum_i \frac{Q_i}{T_i} \leq 0$$

Note that T_i is the absolute temperature of the boundary region crossed by Q_i . Another way to write the second law in this case is

$$\oint \frac{\delta Q}{T} \leq 0$$

where, again, T is the temperature of the boundary pierced by δQ . Of special interest is the reversible cycle limit, in which the second law states $(\oint \delta Q/T)_{\text{rev}} = 0$. According to the definition of thermodynamic property, the second law implies that during a reversible process the quantity $\delta Q/T$ is the infinitesimal change in a property of the system: By definition that property is the *entropy change*

$$dS = \left(\frac{\delta Q}{T}\right)_{\text{rev}} \quad \text{or} \quad S_2 - S_1 = \left(\int_1^2 \frac{\delta Q}{T}\right)_{\text{rev}}$$

Combining this definition with the second law for a cycle, $\oint \delta Q/T \leq 0$, yields the second law of thermodynamics for *any process* executed by a closed system,

$$\underbrace{S_2 - S_1}_{\substack{\text{entropy} \\ \text{change} \\ \text{(property)}}} - \underbrace{\int_1^2 \frac{\delta Q}{T}}_{\substack{\text{entropy} \\ \text{transfer} \\ \text{(nonproperty)}}} \geq 0$$

The entire left-hand side in this inequality is by definition the *entropy generated* by the process,

$$S_{\text{gen}} = S_2 - S_1 - \int_1^2 \frac{\delta Q}{T}$$

The entropy generation is a measure of the inequality sign in the second law and hence a measure of the irreversibility of the process. The entropy generation is proportional to the useful work destroyed during the process.^{1,3,4} Note again that any heat interaction (δQ) is accompanied by entropy transfer ($\delta Q/T$), whereas the work transfer δW is not.

4 ENERGY-MINIMUM PRINCIPLE

Consider now a closed system that executes an infinitesimally small change of state, which means that its state changes from (U, S, \dots) to $(U + dU, S + dS, \dots)$. The first and second-law statements are

$$\delta Q - \delta W = dU \quad dS - \frac{\delta Q}{T} \geq 0$$

If the system is *isolated* from its environment, then $\delta W = 0$ and $\delta Q = 0$, and the two laws dictate that during any such process the energy inventory stays constant ($dU = 0$) and the entropy inventory cannot decrease,

$$dS \geq 0$$

Isolated systems undergo processes when they experience internal changes that do not require intervention

from the outside, for example, the removal of one or more of the *internal constraints* plotted qualitatively in the vertical direction in Fig. 2. When all the constraints are removed, changes cease, and, according to $dS \geq 0$, the entropy inventory reaches its highest possible level. This *entropy-maximum principle* is a consequence of the first and second laws. When all the internal constraints have disappeared, the system has reached the *unconstrained equilibrium state*.

Alternatively, if changes occur in the absence of work transfer and at constant S , the first law and the second law require, respectively, $dU = \delta Q$ and $\delta Q \leq 0$, and hence

$$dU \leq 0$$

The energy inventory cannot increase, and when the unconstrained equilibrium state is reached, the system energy inventory is minimum. This *energy-minimum principle* is also a consequence of the first and second laws for closed systems.

The interest in this classical formulation of the laws (e.g., Fig. 2) has been renewed by the emergence of an analogous principle of performance increase (the *constructal law*) in the search for optimal configuration in the design of open (flow) systems.⁵ This analogy is based on the *constructal law* of maximization of flow access.^{1,6}

5 LAWS OF THERMODYNAMICS FOR OPEN SYSTEMS

If \dot{m} represents the mass flow rate through a port in the control surface, the principle of *mass conservation*

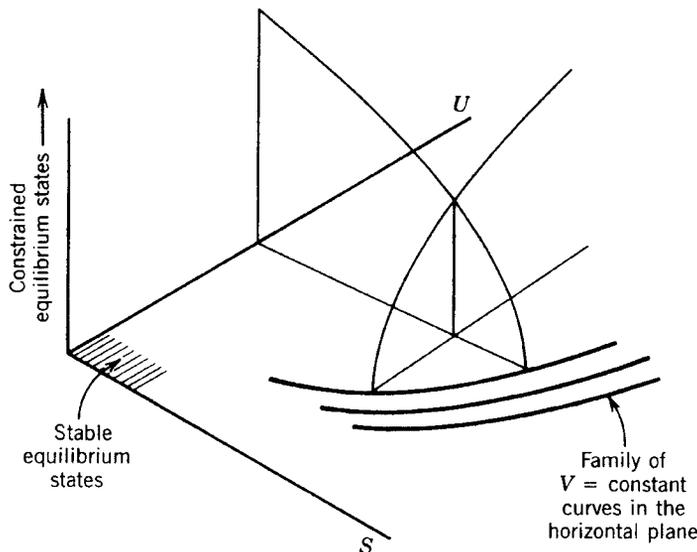

Fig. 2 Energy-minimum principle or entropy-maximum principle.

in the control volume is

$$\underbrace{\sum_{\text{in}} \dot{m} - \sum_{\text{out}} \dot{m}}_{\text{mass transfer}} = \underbrace{\frac{\partial M}{\partial t}}_{\text{mass change}}$$

Subscripts in and out refer to summation over all the inlet and outlet ports, respectively, while M stands for the instantaneous mass inventory of the control volume.

The *first law of thermodynamics* is more general than the statement encountered earlier for closed systems because this time we must account for the flow of energy associated with the \dot{m} streams:

$$\underbrace{\sum_{\text{in}} \dot{m} \left(h + \frac{V^2}{2} + gZ \right) - \sum_{\text{out}} \dot{m} \left(h + \frac{V^2}{2} + gZ \right) + \sum_i \dot{Q}_i - \dot{W}}_{\text{energy transfer}} = \frac{\partial E}{\partial t}$$

energy change

On the left-hand side we have the energy interactions: heat, work, and the energy transfer associated with mass flow across the control surface. The specific enthalpy h , fluid velocity V , and height Z are evaluated right at the boundary. On the right-hand side, E is the instantaneous system energy integrated over the control volume.

The *second law of thermodynamics* for an open system assumes the form

$$\underbrace{\sum_{\text{in}} \dot{m}s - \sum_{\text{out}} \dot{m}s + \sum_i \frac{\dot{Q}_i}{T_i}}_{\text{entropy transfer}} \leq \underbrace{\frac{\partial S}{\partial t}}_{\text{entropy change}}$$

The specific entropy s is representative of the thermodynamic state of each stream right at the system boundary. The *entropy generation rate* is defined by

$$\dot{S}_{\text{gen}} = \frac{\partial S}{\partial t} + \sum_{\text{out}} \dot{m}s - \sum_{\text{in}} \dot{m}s - \sum_i \frac{\dot{Q}_i}{T_i}$$

and is a measure of the irreversibility of open-system operation. The engineering importance of \dot{S}_{gen} stems from its proportionality to the rate of destruction of available work. If the following parameters are fixed—all the mass flows (\dot{m}), the peripheral conditions (h, s, V, Z), and the heat interactions (\dot{Q}_i, T_i) except (\dot{Q}_0, T_0)—then one can use the first law and the second law to show that the work transfer rate cannot exceed a theoretical maximum^{1,3,4}:

$$\dot{W} \leq \sum_{\text{in}} \dot{m} \left(h + \frac{V^2}{2} + gZ - T_0s \right) - \sum_{\text{out}} \dot{m} \left(h + \frac{V^2}{2} + gZ - T_0s \right) - \frac{\partial}{\partial t} (E - T_0s)$$

The right-hand side in this inequality is the maximum work transfer rate $\dot{W}_{\text{sh,max}}$, which would exist only in the ideal limit of reversible operation. The rate of *lost work*, or the rate of exergy (availability) destruction, is defined as

$$\dot{W}_{\text{lost}} = \dot{W}_{\text{max}} - \dot{W}$$

Again, using both laws, one can show that lost work is directly proportional to entropy generation,

$$\dot{W}_{\text{lost}} = T_0 \dot{S}_{\text{gen}}$$

This result is known as the Gouy–Stodola theorem.^{1,3,4} Conservation of useful work (exergy) in thermodynamic systems can only be achieved based on the systematic minimization of entropy generation in all the components of the system. Engineering applications of entropy generation minimization as a design optimization philosophy may be found in Refs. 1, 3, and 4.

6 RELATIONS AMONG THERMODYNAMIC PROPERTIES

The analytical forms of the first and second laws of thermodynamics contain properties such as internal energy, enthalpy, and entropy, which cannot be measured directly. The values of these properties are derived from measurements that can be carried out in the laboratory (e.g., pressure, volume, temperature, specific heat); the formulas connecting the derived properties to the measurable properties are reviewed in this section. Consider an infinitesimal change of state experienced by a closed system. If kinetic and gravitational energy changes can be neglected, the first law reads

$$\delta Q_{\text{any path}} - \delta W_{\text{any path}} = dU$$

which emphasizes that dU is path independent. In particular, for a reversible path (rev), the same dU is given by

$$\delta Q_{\text{rev}} - \delta W_{\text{rev}} = dU$$

Note that from the second law for closed systems we have $\delta Q_{\text{rev}} = T dS$. Reversibility (or zero-entropy generation) also requires internal mechanical equilibrium at every stage during the process; hence,

$\delta W_{\text{rev}} = P dV$, as for a quasistatic change in volume. The infinitesimal change experienced by U is therefore

$$T dS - P dV = dU$$

Note that this formula holds for an infinitesimal change of state along any path (because dU is path independent); however, $T dS$ matches δQ and $P dV$ matches δW only if the path is reversible. In general, $\delta Q < T dS$ and $\delta W < P dV$. The formula derived above for dU can be written for a unit mass: $T ds - P dv = du$. Additional identities implied by this relation are

$$T = \left(\frac{\partial u}{\partial s}\right)_v \quad -P = \left(\frac{\partial u}{\partial v}\right)_s$$

$$\frac{\partial^2 u}{\partial s \partial v} = \left(\frac{\partial T}{\partial v}\right)_s = -\left(\frac{\partial P}{\partial s}\right)_v$$

where the subscript indicates which variable is held constant during partial differentiation. Similar relations and partial derivative identities exist in conjunction with other derived functions such as enthalpy, Gibbs free energy, and Helmholtz free energy:

- Enthalpy (define as $h = u + Pv$):

$$dh = T ds + v dP$$

$$T = \left(\frac{\partial h}{\partial s}\right)_P \quad v = \left(\frac{\partial h}{\partial P}\right)_s$$

$$\frac{\partial^2 h}{\partial s \partial P} = \left(\frac{\partial T}{\partial P}\right)_s = \left(\frac{\partial v}{\partial s}\right)_P$$

- Gibbs free energy (define as $g = h - Ts$):

$$dg = -s dT + v dP$$

$$-s = \left(\frac{\partial g}{\partial T}\right)_P \quad v = \left(\frac{\partial g}{\partial P}\right)_T$$

$$\frac{\partial^2 g}{\partial T \partial P} = -\left(\frac{\partial s}{\partial P}\right)_T = \left(\frac{\partial v}{\partial T}\right)_P$$

- Helmholtz free energy (define as $f = u - Ts$):

$$df = -s dT - P dv$$

$$-s = \left(\frac{\partial f}{\partial T}\right)_v \quad -P = \left(\frac{\partial f}{\partial v}\right)_T$$

$$\frac{\partial^2 f}{\partial T \partial v} = -\left(\frac{\partial s}{\partial v}\right)_T = -\left(\frac{\partial P}{\partial T}\right)_v$$

In addition to the (P, v, T) surface, which can be determined based on measurements (Fig. 3), the following partial derivatives are furnished by special experiments¹:

- The specific heat at constant volume, $c_v = (\partial u / \partial T)_v$, follows directly from the constant-volume ($\delta W = 0$) heating of a unit mass of pure substance.
- The specific heat at constant pressure, $c_P = (\partial h / \partial T)_P$, is determined during the constant-pressure heating of a unit mass of pure substance.
- The Joule–Thompson coefficient $\mu = (\partial T / \partial P)_h$, is measured during a throttling process, that is, during the flow of a stream through an adiabatic duct with friction (see the first law for an open system in the steady state).
- The coefficient of thermal expansion $\beta = (1/v)(\partial v / \partial T)_P$.
- The isothermal compressibility $K = (-1/v)(\partial v / \partial P)_T$.
- The constant-temperature coefficient $c_T = (\partial h / \partial P)_T$.

Two noteworthy relationships between some of the partial-derivative measurements are

$$c_P - c_v = \frac{T v \beta^2}{K} \quad \mu = \frac{1}{c_P} \left[T \left(\frac{\partial v}{\partial T}\right)_P - v \right]$$

The general equations relating the derived properties (u, h, s) to measurable quantities are

$$du = c_v dT + \left[T \left(\frac{\partial P}{\partial T}\right)_v - P \right] dv$$

$$dh = c_P dT + \left[-T \left(\frac{\partial v}{\partial T}\right)_P + v \right] dP$$

$$ds = \frac{c_v}{T} dT + \left(\frac{\partial v}{\partial T}\right)_v dv \quad \text{or}$$

$$ds = \frac{c_P}{T} dT - \left(\frac{\partial v}{\partial T}\right)_P dP$$

These relations also suggest the following identities:

$$\left(\frac{\partial u}{\partial T}\right)_v = T \left(\frac{\partial s}{\partial T}\right)_v = c_v$$

$$\left(\frac{\partial h}{\partial T}\right)_P = T \left(\frac{\partial s}{\partial T}\right)_P = c_P$$

The relationships between thermodynamic properties and the analyses associated with applying the laws of thermodynamics are simplified considerably in cases

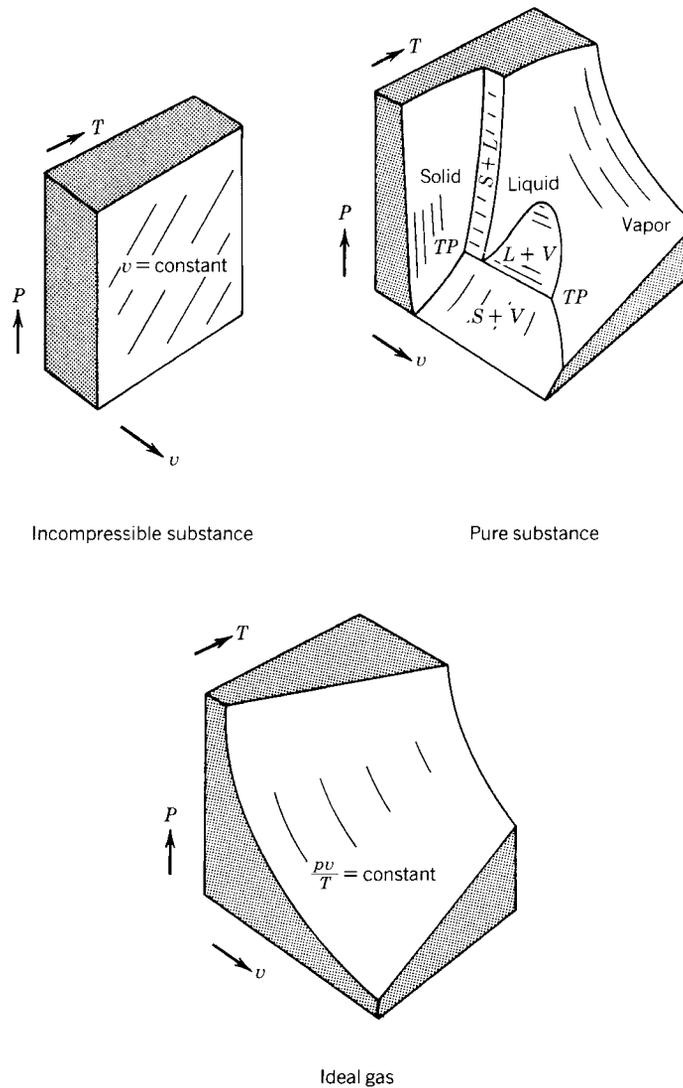

Fig. 3 The (P, v, T) surface for a pure substance that contracts upon freezing, showing regions of ideal-gas and incompressible fluid behavior: S = solid, V = vapor, L = liquid, TP = triple point.

where the pure substance exhibits *ideal-gas* behavior. As shown in Fig. 3, this behavior sets in at sufficient high temperatures and low pressures; in this limit, the (P, v, T) surface is fitted closely by the simple expression

$$\frac{Pv}{T} = R \quad (\text{constant})$$

where R is the ideal-gas constant of the substance of interest (Table 1). The formulas for internal energy,

enthalpy, and entropy, which concluded the preceding section, assume the following form in the ideal-gas limit:

$$\begin{aligned} du &= c_v dT & c_v &= c_v(T) \\ dh &= c_p dT & c_p &= c_p(T) = c_v + R \\ ds &= \frac{c_v}{T} dT + \frac{R}{v} dv & \text{or } ds &= \frac{c_p}{T} dT - \frac{R}{P} dP & \text{or} \\ ds &= \frac{c_v}{P} dP + \frac{c_p}{v} dv \end{aligned}$$

Table 1 Ideal-Gas Constants and Specific Heats at Constant Volume for Gases Encountered in Mechanical Engineering

Ideal Gas	R [J/(kg · K)]	c_p [J/(kg · K)]
Air	286.8	715.9
Argon, Ar	208.1	316.5
Butane, C ₄ H ₁₀	143.2	1595.2
Carbon dioxide, CO ₂	188.8	661.5
Carbon monoxide, CO	296.8	745.3
Ethane, C ₂ H ₆	276.3	1511.4

Helium, He ₂	2076.7	3152.7
Hydrogen, H	4123.6	10216.0
Methane, CH ₄	518.3	1687.3
Neon, Ne	412.0	618.4
Nitrogen, N ₂	296.8	741.1
Octane, C ₈ H ₁₈	72.85	1641.2
Oxygen, O ₂	259.6	657.3
Propane, C ₃ H ₈	188.4	1515.6
Steam, H ₂ O	461.4	1402.6

Source: From Ref. 1.

If the coefficients c_v and c_p are constant in the temperature domain of interest, then the changes in specific internal energy, enthalpy, and entropy relative to a reference state (\cdot)₀ are given by the formulas

$$u - u_0 = c_v(T - T_0)$$

$$h - h_0 = c_p(T - T_0) \quad (\text{where } h_0 = u_0 + RT_0)$$

$$s - s_0 = \begin{cases} c_v \ln \frac{T}{T_0} + R \ln \frac{v}{v_0} \\ c_p \ln \frac{T}{T_0} - R \ln \frac{P}{P_0} \\ c_v \ln \frac{P}{P_0} + c_p \ln \frac{v}{v_0} \end{cases}$$

The ideal-gas model rests on two empirical constants, c_v and c_p , or c_v and R , or c_p and R . The ideal-gas limit is also characterized by

$$\mu = 0 \quad \beta = \frac{1}{P} \quad K = \frac{1}{P} \quad c_T = 0$$

The extent to which a thermodynamic system destroys available work is intimately tied to the system's entropy generation, that is, to the system's departure from the theoretical limit of reversible operation. Idealized processes that can be modeled as reversible occupy a central role in engineering thermodynamics because they can serve as standard in assessing the goodness of real processes. Two benchmark reversible processes executed by closed ideal-gas systems are particularly simple and useful. A *quasistatic adiabatic process* 1 → 2 executed by a closed ideal-gas system has the following characteristics:

$$\int_1^2 \delta Q = 0$$

$$\int_1^2 \delta W = \frac{P_2 V_2}{\gamma - 1} \left[\left(\frac{V_2}{V_1} \right)^{\gamma - 1} - 1 \right]$$

where $\gamma = c_p/c_v$.

- Path:

$$P V^\gamma = P_1 V_1^\gamma = P_2 V_2^\gamma \quad (\text{constant})$$

- Entropy change:

$$S_2 - S_1 = 0$$

Hence the name *isoentropic* or *isentropic* for this process.

- Entropy generation:

$$S_{\text{gen}1 \rightarrow 2} = S_2 - S_1 - \int_1^2 \frac{\delta Q}{T} = 0 \quad (\text{reversible})$$

A *quasistatic isothermal process* 1 → 2 executed by a closed ideal-gas system in communication with a single temperature reservoir T is characterized by:

- Energy interactions:

$$\int_1^2 \delta Q = \int_1^2 \delta W = mRT \ln \frac{V_2}{V_1}$$

- Path:

$$T = T_1 = T_2 \quad (\text{constant}) \quad \text{or}$$

$$P V = P_1 V_1 = P_2 V_2 \quad (\text{constant})$$

- Entropy change:

$$S_2 - S_1 = mR \ln \frac{V_2}{V_1}$$

- Entropy generation:

$$S_{\text{gen}1 \rightarrow 2} = S_2 - S_1 - \int_1^2 \frac{\delta Q}{T} = 0 \quad (\text{reversible})$$

Mixtures of ideal gases also behave as ideal gases in the high-temperature, low-pressure limit. If a certain mixture of mass m contains ideal gases mixed in mass proportions m_i , and if the ideal-gas constants of each

component are (c_{vi}, c_{Pi}, R_i) , then the equivalent ideal-gas constants of the mixture are

$$c_v = \frac{1}{m} \sum_i m_i c_{vi} \quad c_p = \frac{1}{m} \sum_i m_i c_{Pi}$$

$$R = \frac{1}{m} \sum_i m_i R_i$$

where $m = \sum_i m_i$.

One mole is the amount of substance of a system that contains as many elementary entities (e.g., molecules) as there are in 12 g of carbon 12; the number of such entities is Avogadro's constant, $N_0 \cong 6.022 \times 10^{23}$. The mole is not a mass unit because the mass of 1 mol is not the same for all substances. The *molar mass* M of a given molecular species is the mass of 1 mol of that species, so that the total mass m is equal to M times the number of moles n ,

$$m = nM$$

Thus, the ideal-gas equation of state can be written as

$$PV = nMRT$$

where the product MR is the *universal gas constant*

$$\bar{R} = MR = 8.314 \text{ J}/(\text{mol} \cdot \text{K})$$

The equivalent molar mass of a mixture of ideal gases with individual molar masses M_i is

$$M = \frac{1}{n} \sum_i n_i M_i$$

where $n = \sum_i n_i$. The molar mass of air, as a mixture of nitrogen, oxygen, and traces of other gases, is 28.966 g/mol (or 28.966 kg/kmol). A more useful model of the air gas mixture relies on only nitrogen and oxygen as constituents, in the proportion 3.76 mol of nitrogen to every mole of oxygen; this simple model is used frequently in the field of combustion.¹

At the opposite end of the spectrum is the *incompressible substance* model. At sufficiently high pressures and low temperatures in Fig. 3, solids and liquids behave so that their density or specific volume is practically constant. In this limit the (P, v, T) surface is adequately represented by the equation

$$v = \bar{v} \quad (\text{constant})$$

The formulas for calculating changes in internal energy, enthalpy, and entropy become (see the end of the section on relations among thermodynamic properties)

$$du = c \, dT \quad dh = c \, dT + \bar{v} \, dP \quad ds = \frac{c}{T} \, dT$$

where c is the specific heat of the incompressible substance,

$$c = c_v = c_p$$

The specific heat c is a function of temperature only. In a sufficiently narrow temperature range where c can be regarded as constant, the finite changes in internal energy, enthalpy, and entropy relative to a reference state denoted by $()_0$ are

$$u - u_0 = c (T - T_0)$$

$$h - h_0 = c (T - T_0) + \bar{v} (P - P_0)$$

$$(\text{where } h_0 = u_0 + P_0 \bar{v})$$

$$s - s_0 = c \ln \frac{T}{T_0}$$

The incompressible substance model rests on two empirical constants, c and \bar{v} .

As shown in Fig. 3, the domains in which the pure substance behaves either as an ideal gas or as an incompressible substance intersect over regions where the substance exists as a mixture of two phases, liquid and vapor, solid and liquid, or solid and vapor. The two-phase regions themselves intersect along the *triple-point* line labeled TP-TP on the middle sketch of Fig. 3. In engineering cycle calculations, the projections of the (P, v, T) surface on the P - v plane or, through the relations reviewed earlier, on the T - s plane are useful. The terminology associated with two-phase equilibrium states is defined on the P - v diagram of Fig. 4a, where we imagine the isothermal compression of a unit mass of substance (a closed system). As the specific volume v decreases, the substance ceases to be a pure vapor at state g , where the first droplets of liquid are formed. State g is a *saturated vapor state*. It is observed that isothermal compression beyond g proceeds at constant pressure up to state f , where the last bubble (immersed in liquid) is suppressed. State f is a *saturated liquid state*. Isothermal compression beyond f is accompanied by a steep rise in pressure, depending on the compressibility of the liquid phase. The *critical state* is the intersection of the locus of saturated vapor states with the locus of saturated liquid states (Fig. 4a). The temperature and pressure corresponding to the critical state are the *critical temperature* and *critical pressure*. Table 2 contains a compilation of critical-state properties of some of the more common substances.

Figure 4b shows the projection of the liquid and vapor domain on the T - s plane. On the same drawing is shown the relative positioning (the relative slopes) of the traces of various constant-property cuts through the three-dimensional surface on which all the equilibrium states are positioned. In the two-phase region, the temperature is a unique function of pressure. This

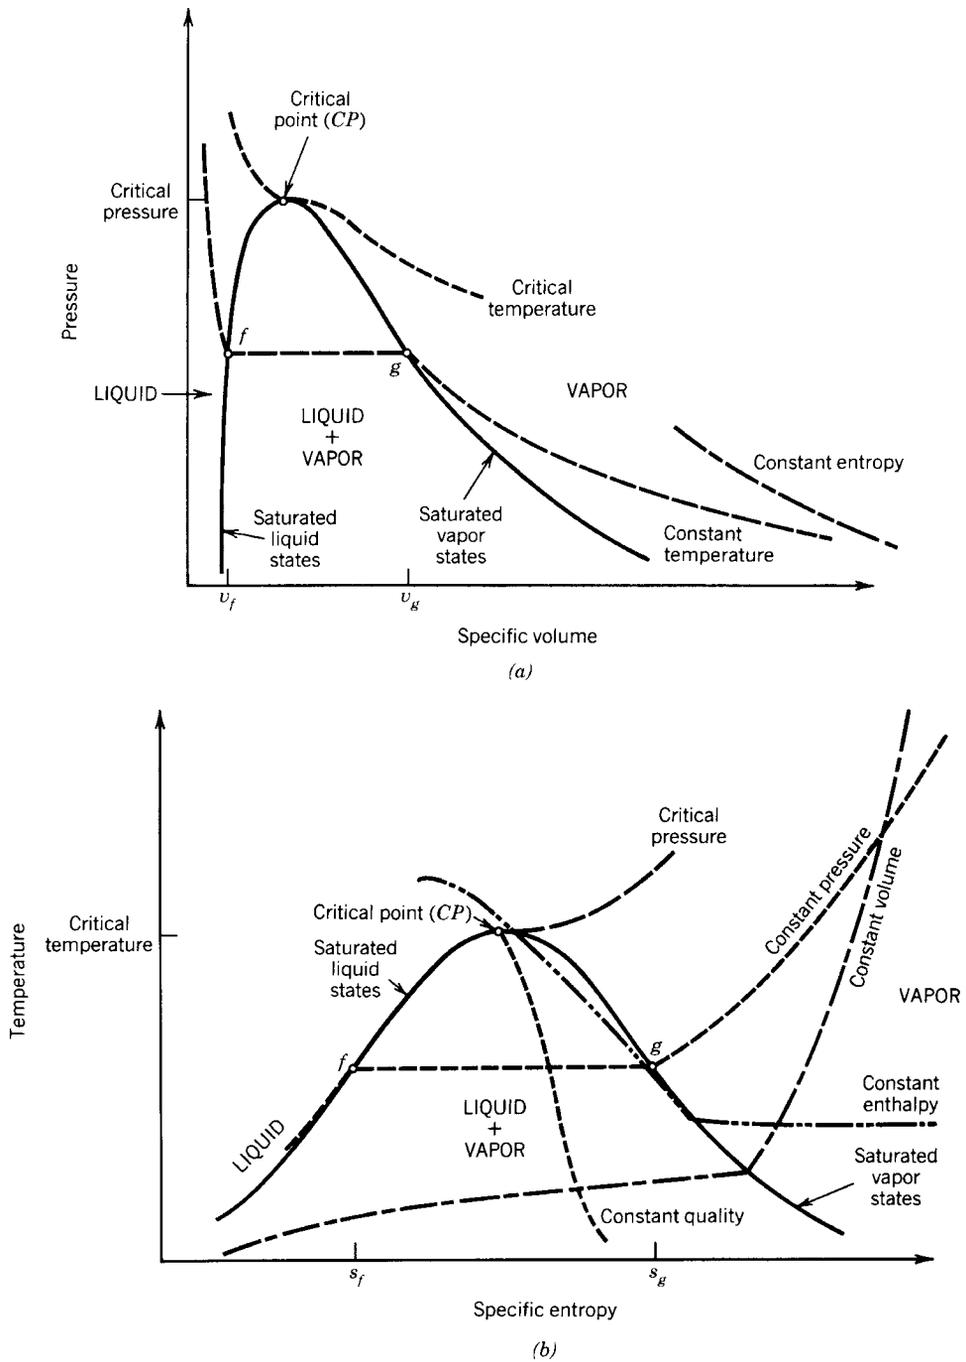

Fig. 4 Locus of two-phase (liquid and vapor) states, projected on (a) $P-v$ plane and (b) $T-s$ plane.

Table 2 Critical-State Properties

Fluid	Critical Temperature [K (°C)]	Critical Pressure [MPa (atm)]	Critical Specific Volume (cm ³ /g)
Air	133.2(-140)	3.77(37.2)	2.9
Alcohol (methyl)	513.2(240)	7.98(78.7)	3.7

Source: From Ref. 1.

one-to-one relationship is indicated also by the *Clapeyron* relation

$$\left(\frac{dP}{dT}\right)_{\text{sat}} = \frac{h_g - h_f}{T(v_g - v_f)} = \frac{s_g - s_f}{v_g - v_f}$$

where the subscript sat is a reminder that the relation holds for saturated states (such as g and f) and for mixtures of two saturated phases. Subscripts g and f indicate properties corresponding to the saturated vapor and liquid states found at temperature T_{sat} (and pressure P_{sat}). Built into the last equation is the identity

$$h_g - h_f = T(s_g - s_f)$$

which is equivalent to the statement that the Gibbs free energy is the same for the saturated states and their mixtures found at the same temperature, $g_g = g_f$.

The properties of a two-phase mixture depend on the proportion in which saturated vapor, m_g , and saturated liquid, m_f , enter the mixture. The composition of the mixture is described by the property called *quality*,

$$x = \frac{m_g}{m_f + m_g}$$

The quality varies between 0 at state f and 1 at state g . Other properties of the mixture can be calculated in

terms of the properties of the saturated states found at the same temperature,

$$\begin{aligned} u &= u_f + xu_{fg} & s &= s_f + xs_{fg} \\ h &= h_f + xh_{fg} & v &= v_f + xv_{fg} \end{aligned}$$

with the notation $(\)_{fg} = (\)_g - (\)_f$. Similar relations can be used to calculate the properties of two-phase states other than liquid and vapor, namely, solid and vapor or solid and liquid. For example, the enthalpy of a solid and liquid mixture is given by $h = h_s + xh_{sf}$, where subscript s stands for the *saturated solid state* found at the same temperature as for the two-phase state and h_{sf} is the latent heat of melting or solidification

In general, the states situated immediately outside the two-phase dome sketched in Figs. 3 and 4 do not follow very well the limiting models discussed earlier in this section (ideal gas, incompressible substance). Because the properties of closely neighboring states are usually not available in tabular form, the following approximate calculation proves useful. For a *moderately compressed liquid state*, which is indicated by the subscript $(\)_*$, that is, for a state situated close to the left of the dome in Fig. 4, the properties may be calculated as slight deviations from those of the saturated liquid state found at the same temperature as the

compressed liquid state of interest,

$$h_* \cong (h_f)_{T^*} + (v_f)_{T^*}[P_* - (P_f)_{T^*}] \quad s \cong (s_f)_{T^*}$$

For a *slightly superheated vapor state*, that is, a state situated close to the right of the dome in Fig. 4, the properties may be estimated in terms of those of the saturated vapor state found at the same temperature:

$$h_+ \cong (h_g)_{T_+} \quad s_+ \cong (s_g)_{T_+} + \left(\frac{P_g v_g}{T_g} \right)_{T_+} \ln \frac{(P_g)_{T_+}}{P_+}$$

In these expressions, subscript $()_+$ indicates the properties of the slightly superheated vapor state.

7 ANALYSIS OF ENGINEERING SYSTEM COMPONENTS

This section contains a summary¹ of the equations obtained by applying the first and second laws of thermodynamics to the components encountered in most engineering systems, such as power plants and refrigeration plants. It is assumed that each component operates in *steady flow*:

- Valve (throttle) or adiabatic duct with friction (Fig. 5a):

First law: $h_1 = h_2$

Second law: $\dot{S}_{\text{gen}} = \dot{m}(s_2 - s_1) > 0$

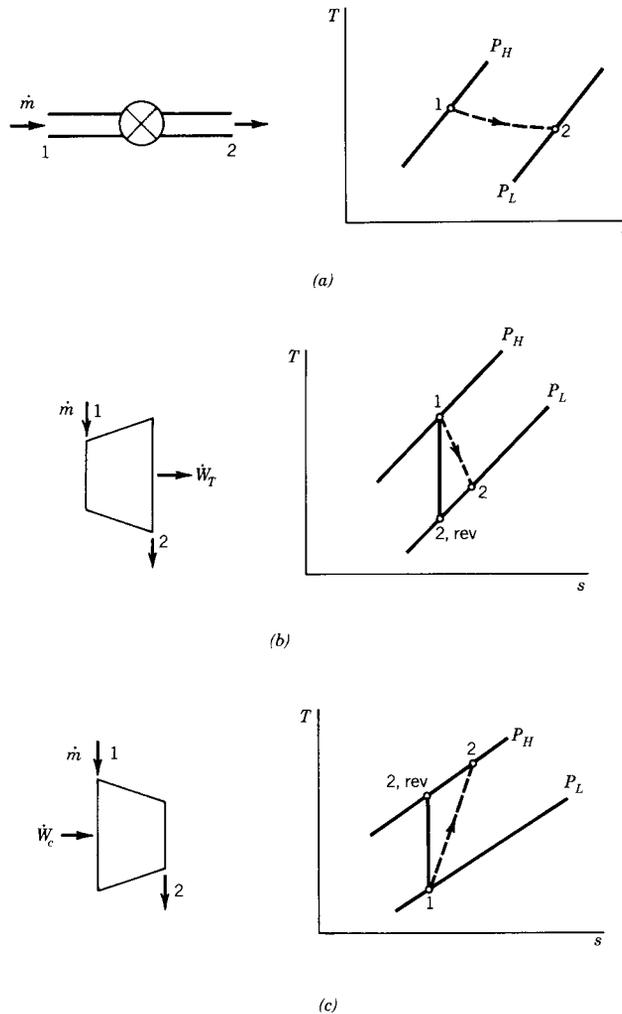

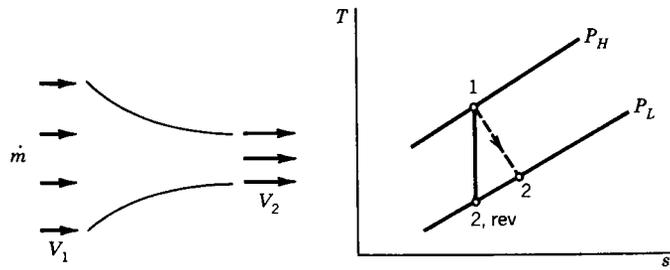

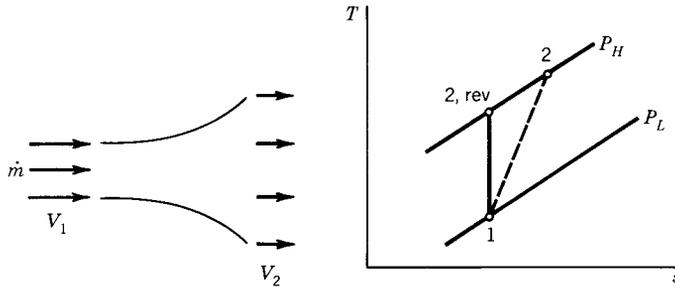

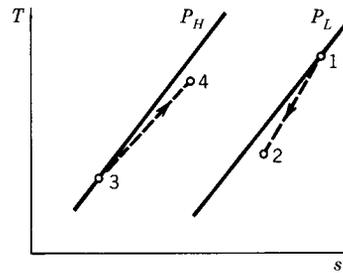

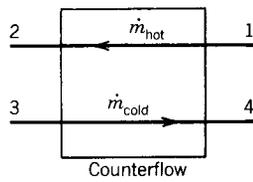

Fig. 5 Engineering system components and their inlet and outlet states on the T - s plane: P_H = high pressure; P_L = low pressure.

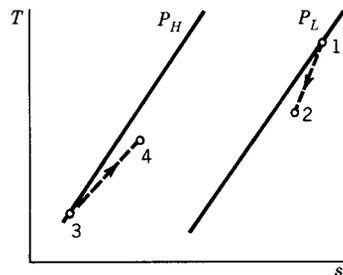

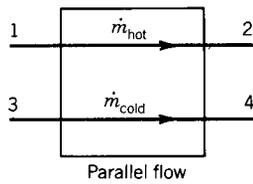

(d)

(e)

(f)

(g)

Fig. 5 (Continued)

- *Expander or turbine* with negligible heat transfer to the ambient (Fig. 5b):

$$\text{First law: } \dot{W}_T = \dot{m}(h_1 - h_2)$$

$$\text{Second law: } \dot{S}_{\text{gen}} = \dot{m}(s_2 - s_1) \geq 0$$

$$\text{Efficiency } \eta_T = \frac{h_1 - h_2}{h_1 - h_{2,\text{rev}}} \leq 1$$

- *Compressor or pump* with negligible heat transfer to the ambient (Fig. 5c):

$$\text{First law: } \dot{W}_c = \dot{m}(h_2 - h_1)$$

$$\text{Second law: } \dot{S}_{\text{gen}} = \dot{m}(s_2 - s_1) \geq 0$$

$$\text{Efficiency } \eta_c = \frac{h_{2,\text{rev}} - h_1}{h_2 - h_1} \leq 1$$

- *Nozzle* with negligible heat transfer to the ambient (Fig. 5d):

$$\text{First law: } \frac{1}{2}(V_2^2 - V_1^2) = h_1 - h_2$$

$$\text{Second law: } \dot{S}_{\text{gen}} = \dot{m}(s_2 - s_1) \geq 0$$

$$\text{Efficiency } \eta_N = \frac{V_2^2 - V_1^2}{V_{2,\text{rev}}^2 - V_1^2} \leq 1$$

- *Diffuser* with negligible heat transfer to the ambient (Fig. 5e):

$$\text{First law: } h_2 - h_1 = \frac{1}{2}(V_1^2 - V_2^2)$$

$$\text{Second law: } \dot{S}_{\text{gen}} = \dot{m}(s_2 - s_1) \geq 0$$

$$\text{Efficiency } \eta_D = \frac{h_{2,\text{rev}} - h_1}{h_2 - h_1} \leq 1$$

- *Heat exchangers* with negligible heat transfer to the ambient (Figs. 5f and g):

$$\text{First law: } \dot{m}_{\text{hot}}(h_1 - h_2) = \dot{m}_{\text{cold}}(h_4 - h_3)$$

$$\text{Second law: } \dot{S}_{\text{gen}} - \dot{m}_{\text{hot}}(s_2 - s_1) + \dot{m}_{\text{cold}}(s_4 - s_3) \geq 0$$

Figures 5f and g show that a pressure drop always occurs in the direction of flow in any heat exchanger flow passage.

SYMBOLS AND UNITS

A	Area of heat transfer
Bi	Biot number, hL/k , dimensionless
C	Circumference, m, constant define in text
C_p	Specific heat under constant pressure, $J/kg \cdot K$
D	Diameter, m
e	Emissive power, W/m^2
f	Drag coefficient dimensionless
F	Cross-flow correction factor, dimensionless
F_{i-j}	Configuration factor from surface i to surface j , dimensionless
Fo	Fourier number, $\alpha t A^2/V^2$, dimensionless
$F_{o-\lambda T}$	Radiation function, dimensionless
G	Irradiation, W/m^2 ; mass velocity, $kg/m^2 \cdot s$
g	Local gravitational acceleration, $9.8 m/s^2$
g_c	Proportionality constant, $1 kg \cdot m/N \cdot s^2$
Gr	Grashof number, $gL^3\beta \Delta T/v^2$ dimensionless
h	Convection heat transfer coefficient equals $q/A \Delta T$, $W/m^2 \cdot K$

h_{fg}	Heat of vaporization, J/kg
J	Radiosity, W/m^2
k	Thermal conductivity, $W/m \cdot K$
K	Wick permeability, m^2
L	Length, m
Ma	Mach number, dimensionless
N	Screen mesh number, m^{-1}
Nu	Nusselt number, $Nu_L = hL/k$, $Nu_D = hD/k$, dimensionless
\overline{Nu}	Nusselt number averaged over length, dimensionless
P	Pressure, N/m^2 , perimeter, m
Pe	Peclet number, $RePr$, dimensionless
Pr	Prandtl number, $C_p\mu/k$, dimensionless
q	Rate of heat transfer, W
q''	Rate of heat transfer per unit area, W/m^2
R	Distance, m; thermal resistance, K/W
r	Radial coordinate, m; recovery factor, dimensionless
Ra	Rayleigh number, $GrPr$; $Ra_L = Gr_LPr$, dimensionless

Reprinted from *Mechanical Engineers' Handbook*, Vol. 4, Wiley, New York, 2006, with permission of the publisher.

Re	Reynolds Number, $Re_L = \rho V L / \mu$, $Re_D = \rho V D / \mu$, dimensionless
S	Conduction shape factor, m
T	Temperature, K or °C
t	Time, s
$T_{\alpha s}$	Adiabatic surface temperature, K
T_{sat}	Saturation temperature, K
T_b	Fluid bulk temperature or base temperature of fins K
T_e	Excessive temperature, $T_s - T_{sat}$, K or °C
T_f	Film temperature, $(T_{\infty} + T_s)/2$, K
T_i	Initial temperature; at $t = 0$, K
T_0	Stagnation temperature, K
T_s	Surface temperature, K
T_{∞}	Free-stream fluid temperature, K
U	Overall heat transfer coefficient $W/m^2 \cdot K$
V	Fluid velocity, m/s; volume, m^3
w	Groove width, m; or wire spacing, m
We	Weber number, dimensionless
x	One of the axes of Cartesian reference frame, m

m	Mean, maximum
n	Nucleation
o	Outer
O	Stagnation condition
p	Pipe
r	Radiation
s	Surface, sonic or sphere
w	Wire spacing, wick
v	Vapor
λ	Spectral
∞	Free stream
—	Axial hydrostatic pressure
+	Normal hydrostatic pressure

GREEK SYMBOLS

α	Thermal diffusivity, $k/\rho C_p$, m^2/s ; absorp- tivity, dimensionless
β	Coefficient of volume expansion, $1/K$
Γ	Mass flow rate of condensate per unit width, $kg/m \cdot s$
γ	Specific heat ratio, dimensionless
ΔT	Temperature difference, K
δ	Thickness of cavity space, groove depth, m
ϵ	Emissivity, dimensionless
ε	Wick porosity, dimensionless
λ	Wavelength, μm
η_f	Fin efficiency, dimensionless
μ	Viscosity, $kg/m \cdot s$
ν	Kinematic viscosity, m^2/s
ρ	Reflectivity dimensionless; density, kg/m^3
σ	Surface tension, N/m; Stefan–Boltzmann constant, $5.729 \times 10^{-8} W/m^2 \cdot K^4$
τ	Transmissivity, dimensionless, shear stress, N/m^2
Ψ	Angle of inclination, degrees or radians

Transport phenomena represents the overall field of study and encompasses a number of subfields. One of these is heat transfer, which focuses primarily on the energy transfer occurring as a result of an energy gradient that manifests itself as a temperature difference. This form of energy transfer can occur as a result of a number of different mechanisms, including *conduction*, which focuses on the transfer of energy through the direct impact of molecules; *convection*, which results from the energy transferred through the motion of a fluid and *radiation*, which focuses on the transmission of energy through electromagnetic waves. In the following review, as is the case with most texts on heat transfer, *phase change heat transfer*, that is, *boiling* and *condensation*, will be treated as a subset of convection heat transfer.

1 CONDUCTION HEAT TRANSFER

The exchange of energy or heat resulting from the kinetic energy transferred through the direct impact of molecules is referred to as *conduction*, and takes place from a region of high energy (or temperature) to a region of lower energy (or temperature). The fundamental relationship that governs this form of heat transfer is *Fourier's law of heat conduction*, which states that in a one-dimensional system with no fluid motion, the rate of heat flow in a given direction is proportional to the product of the temperature gradient in that direction and the area normal to the direction of heat flow. For conduction heat transfer in the x direction this expression takes the form

$$q_x = -kA \frac{\partial T}{\partial x}$$

where q_x is the heat transfer in the x direction, A is the area normal to the heat flow $\partial T/\partial x$ is the temperature gradient, and k is the thermal conductivity of the substance.

Writing an energy balance for a three-dimensional body and utilizing Fourier's law of heat conduction yields an expression for the transient diffusion occurring within a body or substance:

$$\frac{\partial}{\partial x} \left(k \frac{\partial T}{\partial x} \right) + \frac{\partial}{\partial y} \left(k \frac{\partial T}{\partial y} \right) + \frac{\partial}{\partial z} \left(k \frac{\partial T}{\partial z} \right) + \dot{q} = \rho c_p \frac{\partial T}{\partial x} \frac{\partial T}{\partial t}$$

This expression, usually referred to as the *heat diffusion equation* or heat equation, provides a basis for most types of heat conduction analyses. Specialized cases of this equation can be used to solve many steady-state or transient problems. Some of these specialized cases are as follows:

Thermal conductivity is a constant:

$$\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} + \frac{\partial^2 T}{\partial z^2} + \frac{\dot{q}}{k} = \frac{\rho c_p}{k} \frac{\partial T}{\partial t}$$

Steady state with heat generation:

$$\frac{\partial}{\partial x} \left(k \frac{\partial T}{\partial x} \right) + \frac{\partial}{\partial y} \left(k \frac{\partial T}{\partial y} \right) + \frac{\partial}{\partial z} \left(k \frac{\partial T}{\partial z} \right) + \dot{q} = 0$$

Steady-state, one-dimensional heat transfer with no heat sink (i.e., a fn):

$$\frac{\partial}{\partial x} \left(\frac{\partial T}{\partial x} \right) + \frac{\dot{q}}{k} = 0$$

One-dimensional heat transfer with no internal heat generation:

$$\frac{\partial}{\partial x} \left(\frac{\partial T}{\partial x} \right) = \frac{\rho c_p}{k} \frac{\partial T}{\partial t}$$

In the following sections, the heat diffusion equation will be utilized for several specific cases. However, in general, for a three-dimensional body of constant thermal properties without heat generation under steady-state heat conduction the temperature field satisfies the expression

$$\nabla^2 T = 0$$

1.1 Thermal Conductivity

The ability of a substance to transfer heat through conduction can be represented by the constant of proportionality, k , referred to as the thermal conductivity. Figure 1 illustrates the characteristics of the thermal conductivity as a function of temperature for several solids, liquids, and gases. As shown, the thermal conductivity of solids is higher than liquids, and liquids higher than gases. Metals typically have higher thermal conductivities than nonmetals, with pure metals having thermal conductivities that decrease with increasing temperature, while the thermal conductivity of non-metallic solids generally increases with increasing temperature and density. The addition of other metals to create alloys, or the presence of impurities, usually decreases the thermal conductivity of a pure metal.

In general, the thermal conductivity of liquids decreases with increasing temperature. Alternatively, the thermal conductivity of gases and vapors, while

lower, increases with increasing temperature and decreases with increasing molecular weight. The thermal conductivities of a number of commonly used metals and nonmetals are tabulated in Tables 1 and 2, respectively. Insulating materials, which are used to prevent or reduce the transfer of heat between two substance or a substance and the surroundings, are listed in Tables 3 and 4, along with the thermal properties. The thermal conductivities for liquids, molten metals, and gasses are given in Tables 5, 6 and 7, respectively.

1.2 One-Dimensional Steady-State Heat Conduction

The steady-state rate of heat transfer resulting from heat conduction through a homogeneous material can be expressed in terms of the rate of heat transfer, q , or $q = \Delta T/R$, where ΔT is the temperature difference and R is the *thermal resistance*. This thermal resistance is the reciprocal of the *thermal conductance* ($C = 1/R$) and is related to the thermal conductivity by the cross-sectional area. Expressions for the thermal resistance, the temperature distribution, and the rate of heat transfer are given in Table 8 for a plane wall, a cylinder, and a sphere. For a plane wall, the heat transfer is typically assumed to be one dimensional (i.e., heat is conducted in only the x direction) and for a cylinder and sphere, only in the radial direction.

Aside from the heat transfer in these simple geometric configurations other common problems encountered in practical applications is that of heat transfer through layers or composite walls consisting of N layers, where the thickness of each layer is represented by Δx_n and the thermal conductivity by k_n for $n = 1, 2, \dots, N$. Assuming that the interfacial resistance is negligible (i.e., there is no thermal resistance at the contacting surfaces), the overall thermal resistance can be expressed as

$$R = \sum_{n=1}^N \frac{\Delta x_n}{k_n A}$$

Similarly, for conduction heat transfer in the radial direction through a number of N concentric cylinders with negligible interfacial resistance, the overall thermal resistance can be expressed as

$$R = \sum_{n=1}^N \frac{\ln(r_{n+1}/r_n)}{2\pi k_n L}$$

where r_1 = inner radius, r_{N+1} = outer radius.

For N concentric spheres with negligible interfacial resistance, the thermal resistance can be expressed as

$$R = \sum_{n=1}^N \frac{1/r_n - 1/r_{n+1}}{4\pi k}$$

where r_1 = inner radius, r_{N+1} = outer radius.

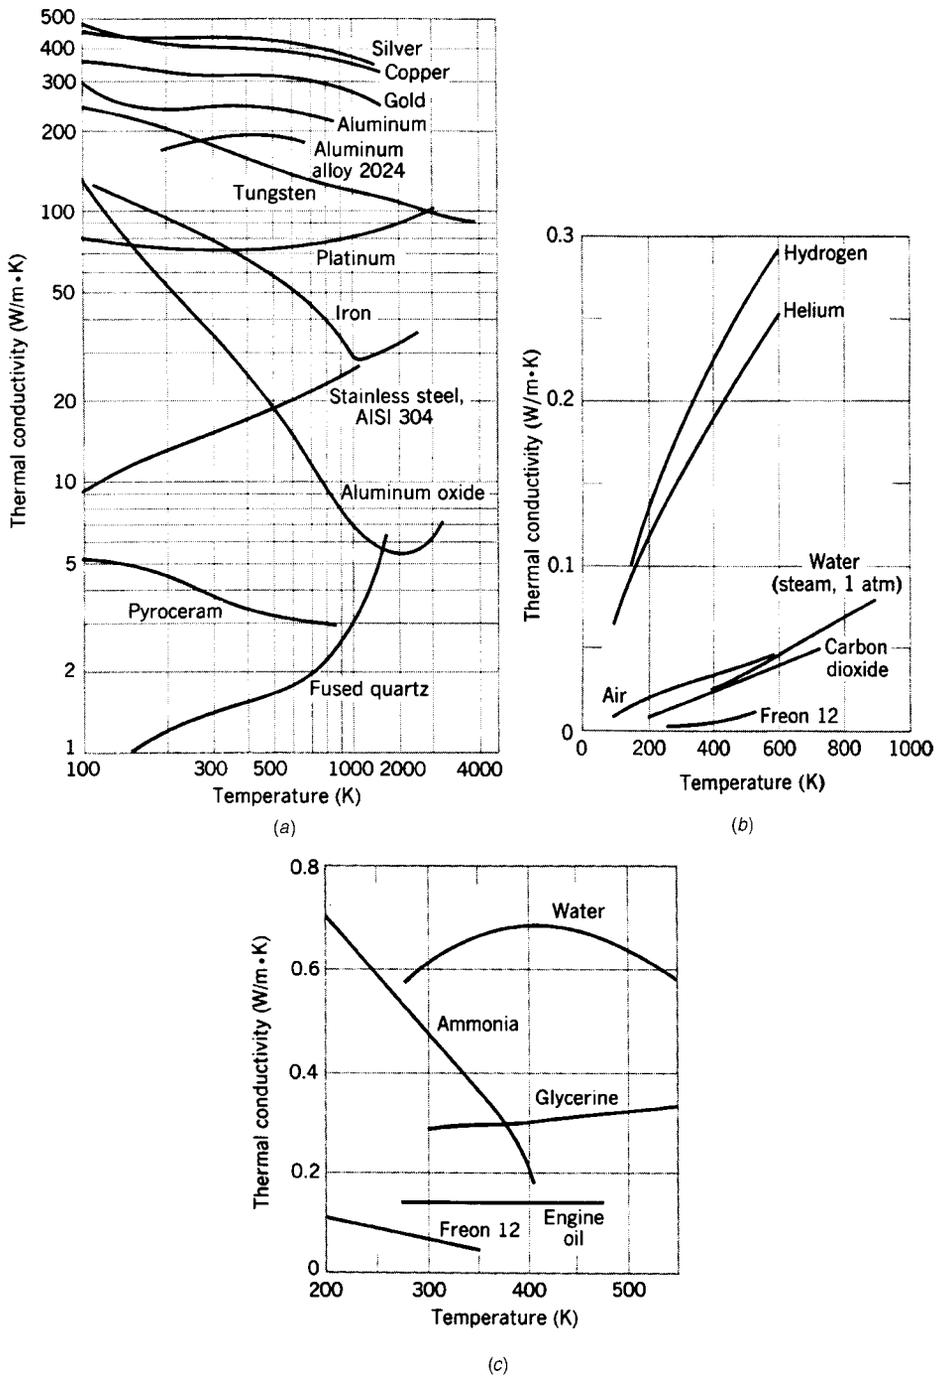

Fig. 1 Temperature dependence of thermal conductivity of (a) selected solids, (b) selected nonmetallic liquids under saturated conditions, and (c) selected gases at normal pressures.¹

1.3 Two-Dimensional Steady-State Heat Conduction

Two-dimensional heat transfer in an isotropic, homogeneous material with no internal heat generation requires solution of the heat diffusion equation of the form $\partial^2 T / \partial X^2 + \partial T / \partial y^2 = 0$, referred to as the *Laplace equation*. For certain geometries and a limited number of fairly simple combinations of boundary conditions, exact solutions can be obtained analytically. However, for anything but simple geometries or for simple geometries with complicated boundary conditions, development of an appropriate analytical solution can be difficult and other methods are

usually employed. Among these are solution procedures involving the use of *graphical* or *numerical* approaches. In the first of these, the rate of heat transfer between two isotherms, T_1 and T_2 , is expressed in terms of the conduction shape factor, defined by

$$q = kS(T_1 - T_2)$$

Table 9 illustrates the shape factor for a number of common geometric configurations. By combining these shape factors, the heat transfer characteristics for a wide variety of geometric configuration can be obtained.

^aAdapted from *Liquid Metals Handbook*, The Atomic Energy Commission, Department of the Navy, Washington, DC, 1952.

Prior to the development of high-speed digital computers, shape factor and analytical methods were the most prevalent methods utilized for evaluating steady-state and transient conduction problems. However, more recently, solution procedures for problems involving complicated geometries or boundary conditions utilize the finite-difference method (FDM). Using this approach, the solid object is divided into a number of distinct or discrete regions, referred to as *nodes*, each with a specific boundary condition. An energy balance is then written for each nodal region and these equations are solved simultaneously. For interior nodes in a two-dimensional system with no internal heat generation, the energy equation takes the form of the Laplace equation discussed earlier. However, because the system is characterized in terms of a nodal network, a finite-difference approximation must be used. This approximation is derived by substituting the following

equation for the x -direction rate of change expression

$$\left. \frac{\partial^2 T}{\partial x^2} \right|_{m,n} \approx \frac{T_{m+1,n} + T_{m-1,n} - 2T_{m,n}}{(\Delta x)^2}$$

and for the y -direction rate of change expression:

$$\left. \frac{\partial^2 T}{\partial y^2} \right|_{m,n} \approx \frac{T_{m,n+1} + T_{m,n-1} + T_{m,n}}{(\Delta y)^2}$$

Assuming $\Delta x = \Delta y$ and substituting into the Laplace equation and results in the following expression:

$$T_{m,n+1} + T_{m,n-1} + T_{m+1,n} + T_{m-1,n} - 4T_{m,n} = 0$$

which reduces the exact difference to an approximate algebraic expression.

^aAdapted from Ref. 2.

Combining this temperature difference with Fourier's law yields an expression for each internal node

$$T_{m,n+1} + T_{m,n-1} + T_{m-1,n} + T_{m+1,n} + \frac{\dot{q} \Delta x \Delta y}{k} - 4T_{m,n} = 0$$

Similar equations for other geometries (i.e., corners) and boundary conditions (i.e., convection) and combinations of the two are listed in Table 10. These equations must then be solved using some form of matrix inversion technique, Gauss–Seidel iteration method or other method for solving large numbers of simultaneous equations.

1.4 Heat Conduction with Convection Heat Transfer on Boundaries

In physical situations where a solid is immersed in a fluid or a portion of the surface is exposed to a liquid or gas, heat transfer will occur by convection (or when there is a large temperature difference, through some combination of convection and/or radiation). In these situations, the heat transfer is governed by *Newton's law of cooling*, which is expressed as

$$q = hA \Delta T$$

where h is the *convection heat transfer coefficient* (Section 2), ΔT is the temperature difference between

the solid surface and the fluid and A is the surface area in contact with the fluid. The resistance occurring at the surface bounding the solid and fluid is referred to as the *thermal resistance* and is given by $1/hA$, that is, the *convection resistance*. Combining this resistance term with the appropriate conduction resistance yields an *overall heat transfer coefficient* U . Usage of this term allows the overall heat transfer to be defined as $q = UA \Delta T$.

Table 8 shows the overall heat transfer coefficient for some simple geometries. Note that U may be based either on the inner surface (U_1) or on the outer surface (U_2) for the cylinders and spheres.

Critical Radius of Insulation for Cylinders A large number of practical applications involve the use of insulation materials to reduce the transfer of heat into or out of cylindrical surfaces. This is particularly true of steam or hot water pipes where concentric cylinders of insulation are typically added to the outside of the pipes to reduce the heat loss. Beyond a certain thickness, however, the continued addition of insulation may not result in continued reductions in the heat loss. To optimize the thickness of insulation required for these types of applications, a value typically referred to as the *critical radius*, defined as $r_{cr} = k/h$, is used. If the outer radius of the object to be insulated is less than r_{cr} then the addition of insulation will increase the heat loss, while for cases where the outer radius is greater than r_{cr} any additional increases in insulation thickness will result in a decrease in heat loss.

Table 8 One-Dimensional Heat Conduction

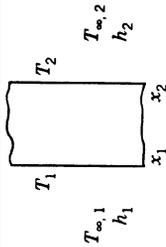

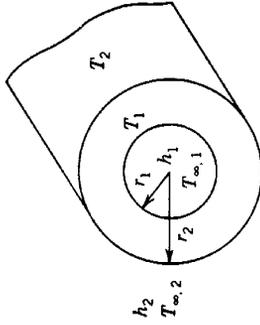

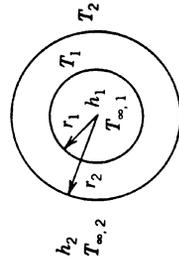

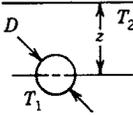

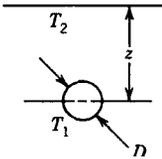

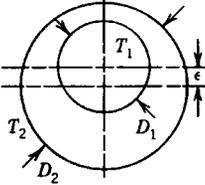

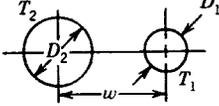

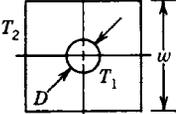

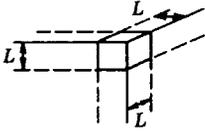

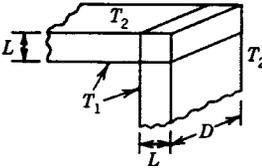

Geometry	Heat Transfer Rate and Temperature Distribution	Heat Transfer Rate and Overall Heat Transfer Coefficient with Convection at the Boundaries
Plane wall	 $q = \frac{T_1 - T_2}{(x_2 - x_1)/kA}$ $T = T_1 + \frac{T_2 - T_1}{x_x - x_1}(x - x_1)$ $R = (x_x - x_1)/kA$	$q = UA(T_{\infty,1} - T_{\infty,2})$ $U = \left(\frac{1}{h_1} + \frac{x_2 - x_1}{k} + \frac{1}{h_2} \right)^{-1}$
Hollow cylinder	 $q = \frac{T_1 - T_2}{[\ln(r_2/r_1)]/2\pi kL}$ $T = \frac{T_2 - T_1}{\ln(r_2/r_1)} \ln \frac{r}{r_1}$ $R = \frac{\ln(r_2/r_1)}{2\pi kL}$	$q = 2\pi r_1 L U_1 (T_{\infty,1} - T_{\infty,2})$ $= 2\pi r_1 L U_2 (T_{\infty,1} - T_{\infty,2})$ $U_1 = \left(\frac{1}{h_1} + \frac{r_1 \ln(r_2/r_1)}{k} + \frac{r_1}{r_2} \frac{1}{h_2} \right)^{-1}$ $U_2 = \left[\left(\frac{r_2}{r_1} \right) \frac{1}{h_1} + \frac{r_2 \ln(r_2/r_1)}{k} + \frac{1}{h_2} \right]^{-1}$
Hollow sphere	 $q = \frac{T_1 - T_2}{(1/r_1 - 1/r_2)/4\pi k}$ $T = \frac{1}{(1 - r_1/r_2)} \left[\frac{r_1}{r} (T_1 - T_2) + (T_2 - T_1 \frac{r_1}{r_2}) \right]$ $R = \frac{1/r_1 - 1/r_2}{4\pi k}$	$q = 4\pi r_1^2 U_1 (T_{\infty,1} - T_{\infty,2})$ $= 4\pi r_2^2 U_2 (T_{\infty,1} - T_{\infty,2})$ $U_1 = \left[\frac{1}{h_1} + \frac{r_1^2 (1/r_1 - 1/r_2)}{k} + \left(\frac{r_1}{r_2} \right)^2 \frac{1}{h_2} \right]^{-1}$ $U_2 = \left[\left(\frac{r_1}{r_2} \right)^2 \frac{1}{h_1} + \frac{r_2^2 (1/r_1 - 1/r_2)}{k} + \frac{1}{h_2} \right]^{-1}$

Table 9 Conduction Shape Factors

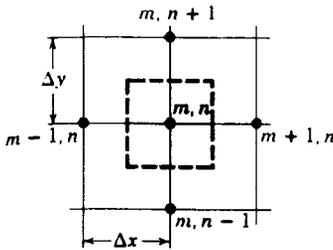

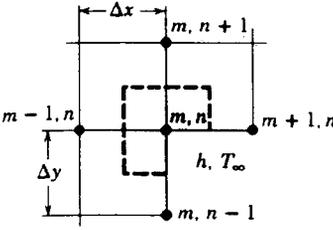

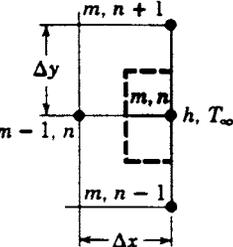

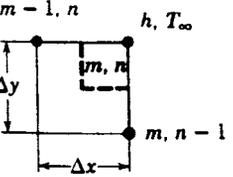

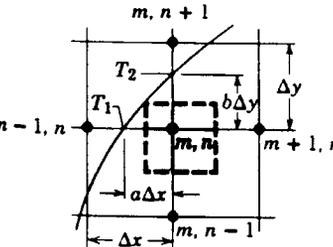

System	Schematic	Restrictions	Shape Factor
Isothermal sphere buried in a semi-infinite medium having isothermal surface		$z > D/2$	$\frac{2\pi D}{1 - D/4z}$
Horizontal isothermal cylinder of length L buried in a semi-infinite medium having isothermal surface		$L \gg D$ $L \gg D$ $z > 3D/2$	$\frac{2\pi L}{\cosh^{-1}(2z/D)}$ $\frac{2\pi L}{\ln(4z/D)}$
The cylinder of length L with eccentric bore		$L \gg D_1, D_2$	$\frac{2\pi L}{\cosh^{-1}\left(\frac{D_1^2 + D_2^2 - 4\epsilon^2}{2D_1D_2}\right)}$
Conduction between two cylinders of length L in infinite medium		$L \gg D_1, D_2$	$\frac{2\pi L}{\cosh^{-1}\left(\frac{4W^2 - D_1^2 - D_2^2}{2D_1D_2}\right)}$
Circular cylinder of length L in a square solid		$L \gg W$ $w > D$	$\frac{2\pi L}{\ln(1.08 w/D)}$
Conduction through the edge of adjoining walls		$D > L/5$	0.54 D
Conduction through corner of three walls with inside and outside temperature, respectively, at T_1 and T_2		$L \ll \text{length and width of wall}$	0.15 L

Extended Surfaces In examining Newton’s law of cooling, it is clear that the rate of heat transfer between a solid and the surrounding ambient fluid may be increased by increasing the surface area of the solid that is exposed to the fluid. This is typically done through the addition of extended surfaces or fin to the primary surface. Numerous examples often exist,

including the cooling fins on air-cooled engines, that is, motorcycles or lawn mowers or the fins attached to automobile radiators.

Figure 2 illustrates a common uniform cross-section extended surface, fin with a constant base temperature, T_b , a constant cross-sectional area, A , a circumference of $C = 2W + 2t$, and a length, L , which is much larger

Table 10 Summary of Nodal Finite-Difference Equations

Configuration	Finite-Difference Equation for $\Delta x = \Delta y$
Case 1. Interior node 	$T_{m,n+1} + T_{m,n-1} + T_{m-1,n} - 4T_{m,n} = 0$
Case 2. Node at an internal corner with convection 	$2(T_{m-1,n} + T_{m,n+1}) + (T_{m+1,n} + T_{m,n-1}) + 2\frac{h \Delta x}{k} T_{\infty} - 2\left(3 + \frac{h \Delta x}{k}\right) T_{m,n} = 0$
Case 3. Node at a plane surface with convection 	$2(T_{m-1,n} + T_{m,n+1} + T_{m,n-1}) + \frac{2h \Delta x}{k} T_{\infty} - 2\left(\frac{h \Delta x}{k} + 2\right) T_{m,n} = 0$
Case 4. Node at an external corner with convection 	$(T_{m,n-1} + T_{m-1,n}) + 2\frac{h \Delta x}{k} T_{\infty} - 2\left(\frac{h \Delta x}{k} + 1\right) T_{m,n} = 0$
Case 5. Node near a curved surface maintained at a nonuniform temperature 	$\frac{2}{a+1} T_{m+1,n} + \frac{2}{b+1} T_{m,n-1} + \frac{2}{a(a+1)} T_1 + \frac{2}{b(b+1)} T_2 - \left(\frac{2}{a} + \frac{2}{b}\right) T_{m,n} = 0$

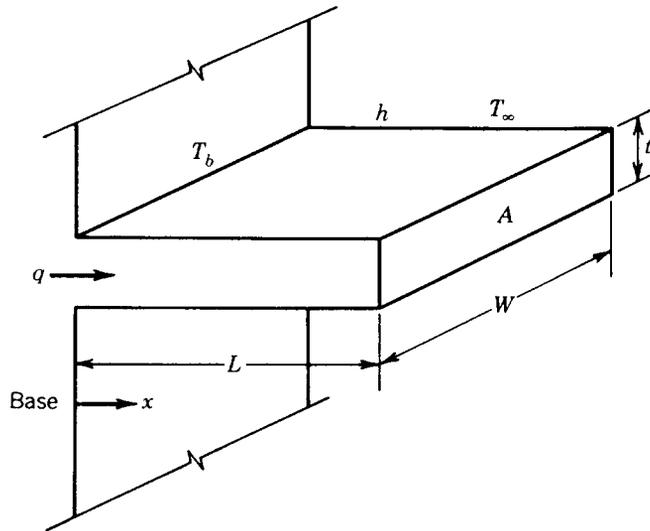

Fig. 2 Heat transfer by extended surfaces.

than the thickness, t . For these conditions, the temperature distribution in the fin must satisfy the following expression:

$$\frac{d^2T}{dx^2} - \frac{hC}{kA}(T - T_\infty) = 0$$

The solution of this equation depends on the boundary conditions existing at the tip, that is, at $x = L$. Table 11 shows the temperature distribution and heat transfer rate for fins of uniform cross section subjected to a number of different tip conditions, assuming a constant value for the heat transfer coefficient h .

Two terms are used to evaluate fins and their usefulness. The first of these is the *fin effectiveness*,

define as the ratio of the heat transfer rate with the fin to the heat transfer rate that would exist if the fin were not used. For most practical applications, the use of a fin is justified only when the fin effectiveness is significantly greater than 2. A second term used to evaluate the usefulness of a fin is the *fin efficiency*, η_f . This term represents the ratio of actual heat transfer rate from a fin to the heat transfer rate that would occur if the entire fin surface could be maintained at a uniform temperature equal to the temperature of the base of the fin. For this case, Newton's law of cooling can be written as

$$q = \eta_f h A_f (T_b - T_\infty)$$

Table 11 Temperature Distribution and Heat Transfer Rate at the Fin Base ($m = \sqrt{hc/kA}$)

Condition at $x = L$	$\frac{T - T_\infty}{T_b - T_\infty}$	Heat Transfer Rate $q/mkA(T_b - T_\infty)$
$h(T_{x=L} - T_\infty) = -k \left(\frac{dT}{dx} \right)_{x=L}$ (convection)	$\frac{\cosh m(L-x) + [h/(mk)] \sinh m(L-x)}{\cosh mL + [h/(mk)] \sinh mL}$	$\frac{\sinh mL + [h/(mk)] \cosh mL}{\cosh mL + [h/(mk)] \sinh mL}$
$\left(\frac{dT}{dx} \right)_{x=L} = 0$ (insulated)	$\frac{\cosh m(L-x)}{\cosh mL}$	$\tanh mL$
$T_{x=L} = T_L$ (prescribed temperature)	$\frac{(T_L - T_\infty)/(T_b - T_\infty) \sinh mx + \sinh m(L-x)}{\sinh mL}$	$\frac{\cosh mL - (T_L - T_\infty)/(T_b - T_\infty)}{\sinh mL}$
$T_{x=L} = T_\infty$ (infinitely long fin, $L \rightarrow \infty$)	e^{-mx}	1

where A_f is the total surface area of the fin and T_b is the temperature of the fin at the base. The application of fin for heat removal can be applied to either forced or natural convection of gases, and while some advantages can be gained in terms of increasing the liquid–solid or solid–vapor surface area, fin as such are not normally utilized for situations involving phase change heat transfer, such as boiling or condensation.

1.5 Transient Heat Conduction

Given a solid body, at a uniform temperature, $T_{\infty i}$, immersed in a fluid of different temperature T_{∞} , the surface of the solid body will be subject to heat losses (or gains) through convection from the surface to the fluid. In this situation, the heat lost (or gained) at the surface results from the conduction of heat from inside the body. To determine the significance of these two heat transfer modes, a dimensionless parameter referred to as the *Biot number* is used. This dimensionless number is defined as $Bi = hL/k$, where $L = V/A$ or the ratio of the volume of the solid to the surface area of the solid, and really represents a comparative relationship of the importance of convections from the outer surface to the conduction occurring inside. When this value is less than 0.1, the temperature of the solid may be assumed uniform and dependent on time alone. When this value is greater than 0.1, there is some spatial temperature variation that will affect the solution procedure.

For the first case, $Bi < 0.1$, an approximation referred to as the *lumped heat capacity* method may be used. In this method, the temperature of the solid is given by

$$\frac{T - T_{\infty}}{T_i - T_{\infty}} = \exp\left(\frac{-t}{\tau_i}\right) = \exp(-Bi Fo)$$

where τ_i is the *time constant* and is equal to $\rho C_p V/hA$. Increasing the value of the time constant, τ_i , will result in a decrease in the thermal response of the solid to the environment and hence, will increase the time required for it to reach thermal equilibrium (i.e., $T = T_{\infty}$). In this expression, Fo represents the dimensionless time and is called the *Fourier number*, the value of which is equal to $\alpha t A^2/V^2$. The Fourier number, along with the Biot number, can be used to characterize transient heat conduction problems. The total heat flow through the surface of the solid over the time interval from $t = 0$ to time t can be expressed as

$$Q = \rho V C_p (T_i - T_{\infty}) \left[1 - \exp\left(\frac{-t}{\tau_i}\right) \right]$$

Transient Heat Transfer for Infinite Plate, Infinite Cylinder, and Sphere Subjected to Surface Convection Generalized analytical solutions to transient heat transfer problems involving infinite plates, cylinders, and finite diameter spheres subjected

to surface convection have been developed. These solutions can be presented in graphical form through the use of the *Heisler charts*,³ illustrated in Figs. 3–11 for plane walls, cylinders, and spheres. In this procedure, the solid is assumed to be at a uniform temperature, T_i , at time $t = 0$ and then is suddenly subjected to or immersed in a fluid at a uniform temperature T_{∞} . The convection heat transfer coefficient h , is assumed to be constant, as is the temperature of the fluid. Combining Figs. 3 and 4 for plane walls, Figs. 6 and 7 for cylinders, and Figs. 9 and 10 for spheres allows the resulting time-dependent temperature of any point within the solid to be found. The total amount of energy, Q , transferred to or from the solid surface from time $t = 0$ to time t can be found from Figs. 5, 8, and 11.

1.6 Conduction at Microscale

The mean free path of electrons and the size of the volume involved has long been recognized as having a pronounced effect on electron transport phenomena. This is particularly true in applications involving thin metallic films or wires where the characteristic length may be close to the same order of magnitude as the scattering mean free path of the electrons.^{4a} The first notable work in this area was performed by Tien et al.,^{4b} where the thermal conductivity of thin metallic film and wires were calculated at cryogenic temperatures. Because the length of the mean free path in these types of applications is shortened near the surface, due to termination at the boundary, a reduction in transport coefficients such as electrical and thermal conductivities, was observed. Tests at cryogenic temperatures were first performed because the electron mean free path increases as temperature decreases, and the size effects were expected to become especially significant in this range. The primary purpose of this investigation was to outline in a systematic manner a method by which the thermal conductivity of such film and wires at cryogenic temperatures could be determined. The results indicated that, particularly in the case of thin metallic films, size effects may become an increasingly important part of the design and analysis required for application. Due to the increased use of thin films in optical components and solid-state devices and systems, there has been an increasing interest in the effect of decreasing size on the transport properties of thin solid films and wires.

The most common method for calculating the thermal conductivities in thin films and wires consists of three essential steps:

1. Identifying the appropriate expression for the electrical conductivity size effect
2. Determining the mean free path for electrical conductivity, which is essential in calculations of all electron transport properties
3. Applying the electrical–thermal transport analogy for calculating the thermal conductivity size effect^{4a}

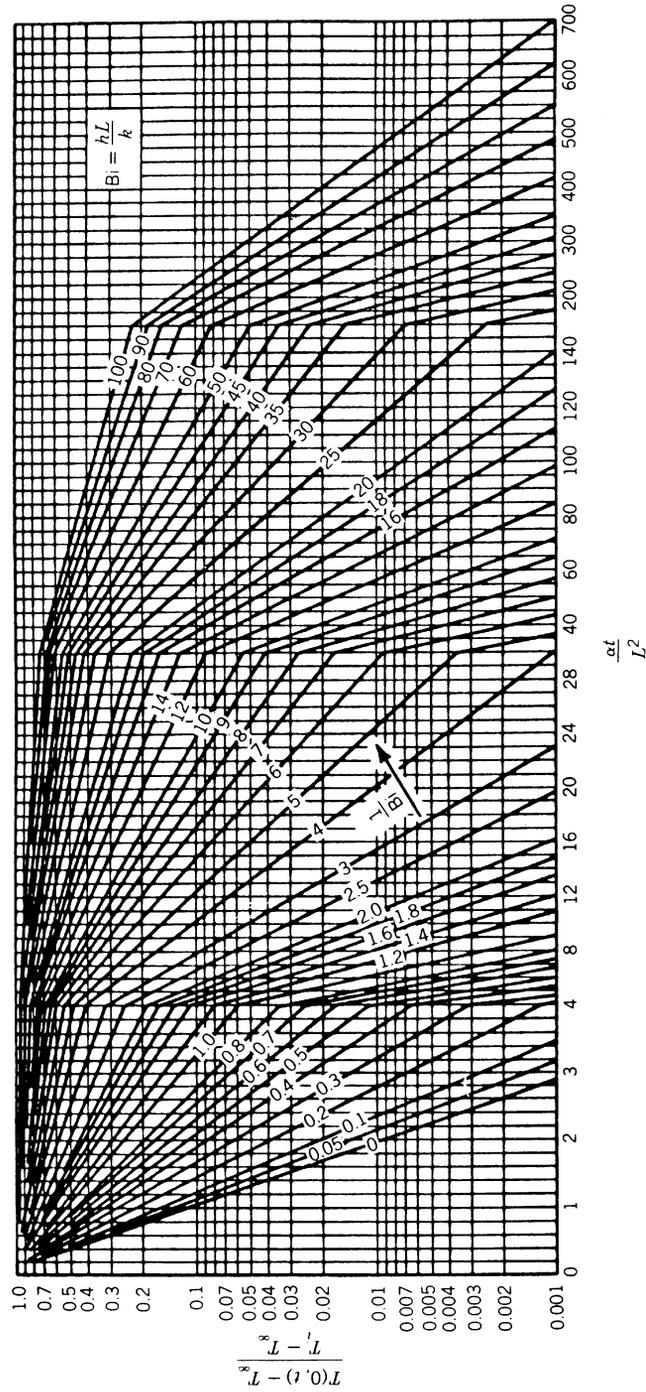

Fig. 3 Midplane temperature as a function of time for a plane wall of thickness $2L$. (Adapted from Ref. 3.)

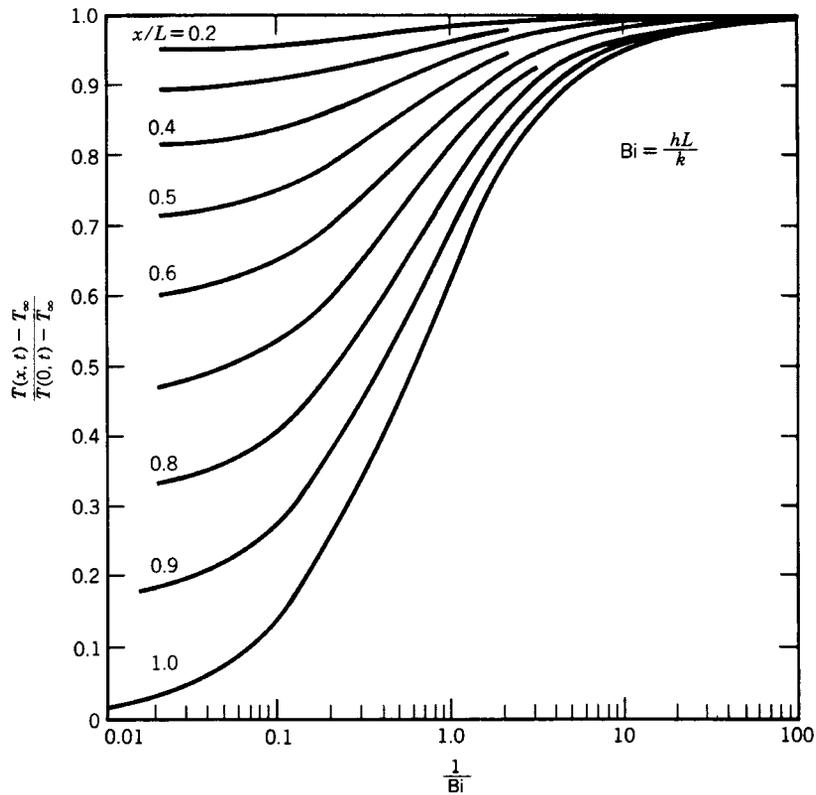

Fig. 4 Temperature distribution in a plane wall of thickness $2L$. (Adapted from Ref. 3.)

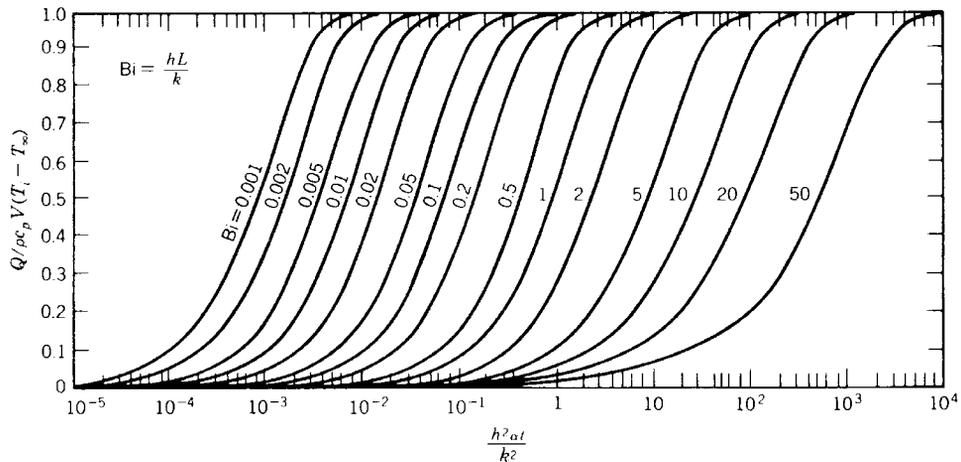

Fig. 5 Internal energy change as a function of time for a plane wall of thickness $2L$.⁴ (Used with the permission of McGraw-Hill Book Company.)

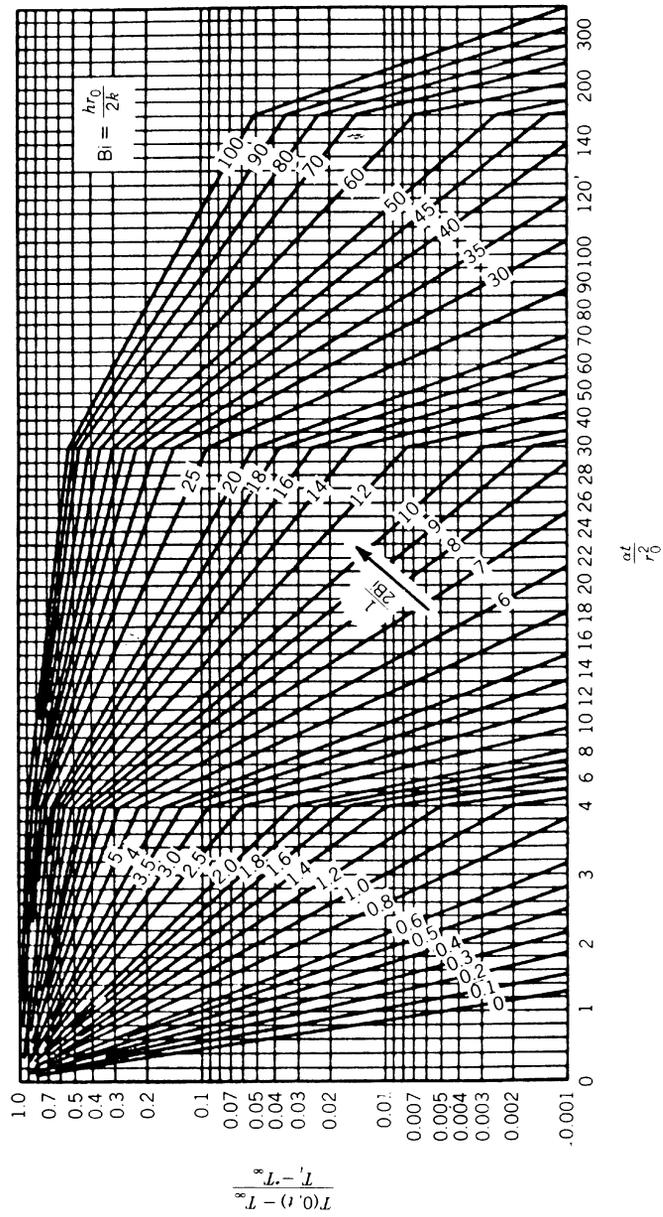

Fig. 6 Centerline temperature as function of time for an infinite cylinder of radius r_o . (Adapted from Ref. 3.)

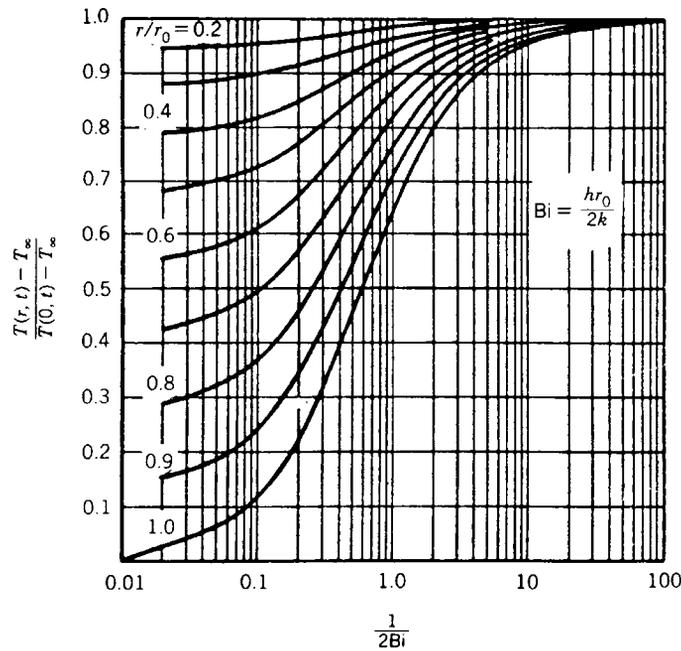

Fig. 7 Temperature distribution in an infinite cylinder of radius r_0 . (Adapted from Ref. 3.)

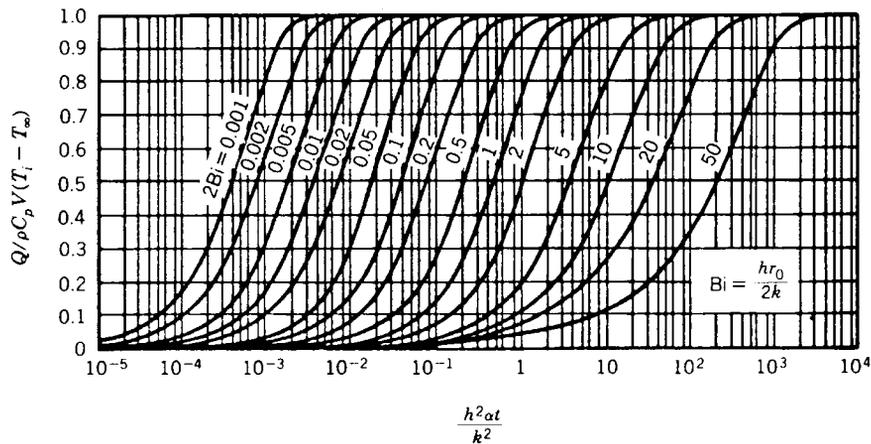

Fig. 8 Internal energy change as function of time for an infinite cylinder of radius r_0 .⁴ (Used with the permission of McGraw-Hill Book Company.)

For domain thicknesses on the order of the carrier mean free path, jump boundary conditions significantly affect the solution of the conduction problem. This problem can be resolved through the solution of the hyperbolic heat equation-based analysis, which is generally justifiable engineering applications.^{4c}

2 CONVECTION HEAT TRANSFER

As discussed earlier, convection heat transfer is the mode of energy transport in which the energy is transferred by means of fluid motion. This transfer can be the result of the random molecular motion or bulk motion of the fluid. If the fluid motion is

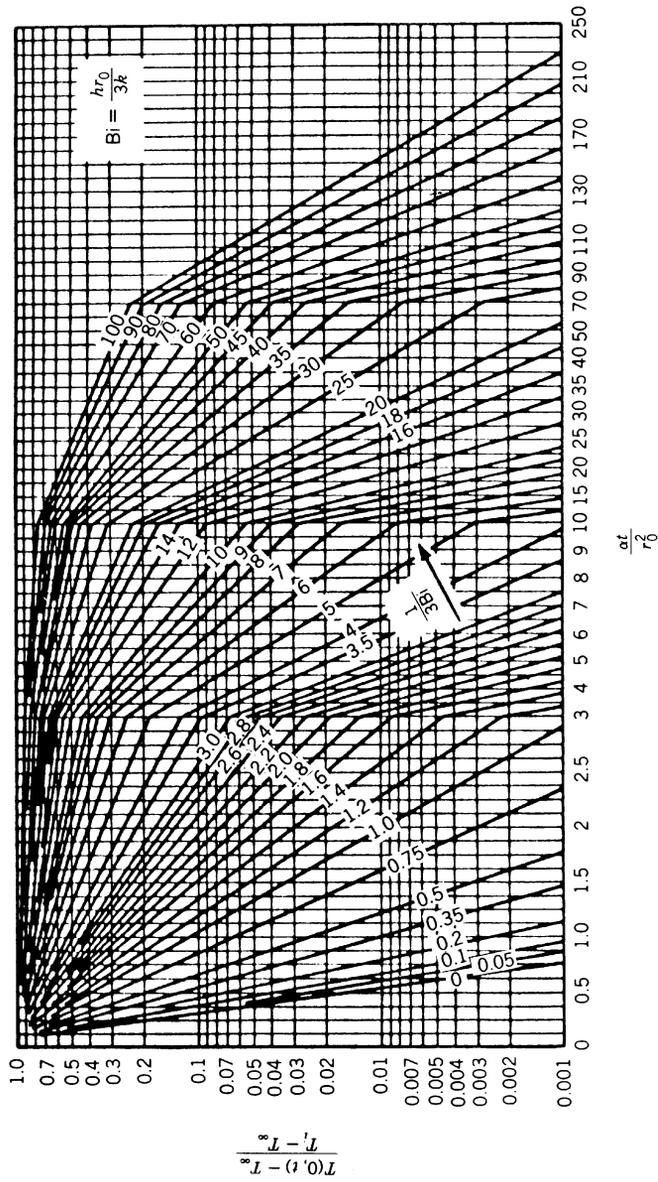

Fig. 9 Center temperature as function of time in a sphere of radius r_0 . (Adapted from Ref. 3.)

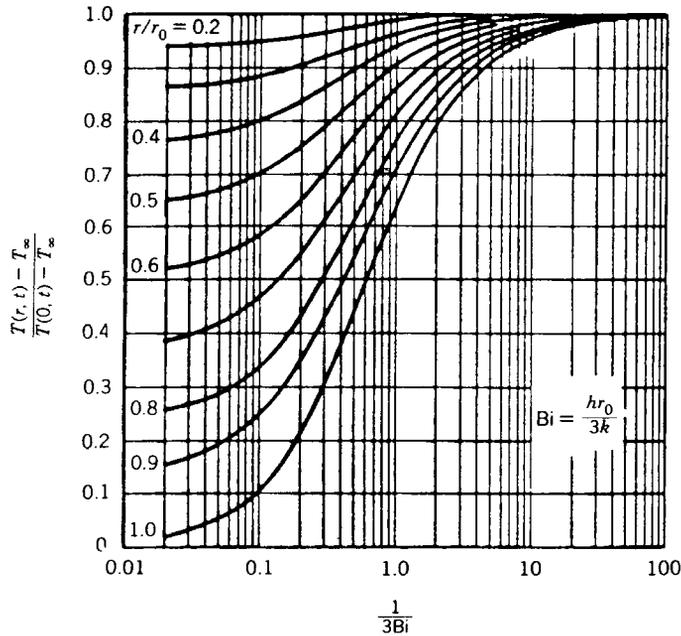

Fig. 10 Temperature distribution in sphere of radius r_0 . (Adapted from Ref. 3.)

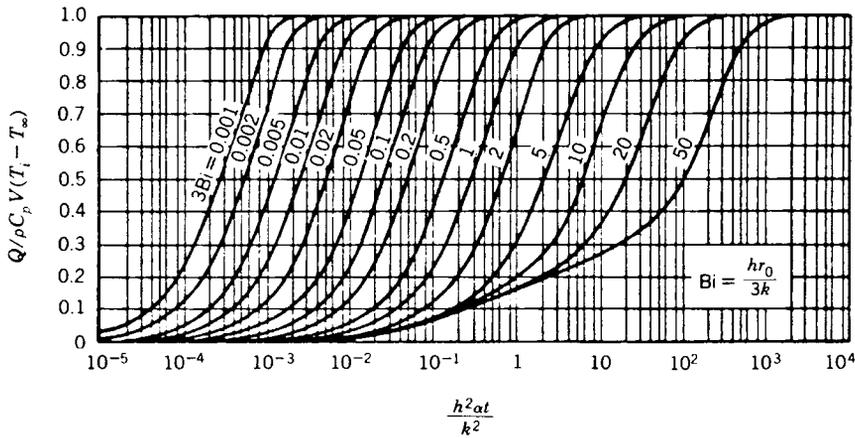

Fig. 11 Internal energy change as function of time for a sphere of radius r_0 .⁴ (Used with the permission of McGraw-Hill Book Company.)

caused by external forces, the energy transfer is called *forced convection*. If the fluid motion arises from a buoyancy effect caused by density differences, the energy transfer is called *free convection* or *natural convection*. For either case, the heat transfer rate, q , can be expressed in terms of the surface area, A , and the temperature difference, ΔT , by Newton's law of

cooling:

$$q = hA \Delta T$$

In this expression, h is referred to as the convection heat transfer coefficient or film coefficient and a function of the velocity and physical properties of the fluid, and the shape and nature of the surface. The

nondimensional heat transfer coefficient $Nu = hL/k$ is called the *Nusselt number*, where L is a characteristic length and k is the thermal conductivity of the fluid.

2.1 Forced Convection – Internal Flow

For internal flow in a tube or pipe, the convection heat transfer coefficient is typically defined as a function of the temperature difference existing between the temperature at the surface of the tube and the *bulk* or *mixing-cup temperature*, T_b , that is, $\Delta T = T_s - T_b$ can be defined as

$$T_b = \frac{\int C_p T \, d\dot{m}}{\int C_p \, d\dot{m}}$$

where \dot{m} is the axial flow rate. Using this value, heat transfer between the tube and the fluid can be written as $q = hA(T_s - T_b)$.

In the entrance region of a tube or pipe, the flow is quite different from that occurring downstream from the entrance. The rate of heat transfer differs significantly, depending on whether the flow is *laminar* or *turbulent*. From fluid mechanics, the flow is considered to be turbulent when $Re_D = V_m D/\nu > 2300$ for a smooth tube. This transition from laminar to turbulent, however, also depends on the roughness of tube wall and other factors. The generally accepted range for transition is $200 < Re_D < 4000$.

Laminar Fully Developed Flow For situations where both the thermal and velocity profile are fully developed, the Nusselt number is constant and depends only on the thermal boundary conditions. For *circular tubes* with $Pr \geq 0.6$, and $x/D \, Re_D \, Pr > 0.05$, the Nusselt numbers have been shown to be $Nu_D = 3.66$ and 4.36 , for constant temperature and constant heat flux conditions, respectively. Here, the fluid properties are based on the mean bulk temperature.

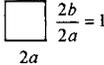

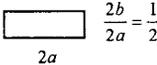

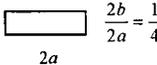

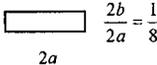

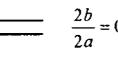

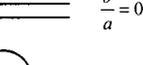

For *noncircular tubes*, the hydraulic diameter, $D_h = 4 \times$ the flow cross-sectional area/wetted perimeter, is used to define the Nusselt number Nu_D and the Reynolds number Re_D . Table 12 shows the Nusselt numbers based on hydraulic diameter for various cross-sectional shapes.

Laminar Flow for Short Tubes At the entrance of a tube, the Nusselt number is infinite and decreases asymptotically to the value for fully developed flow as the flow progresses down the tube. The Sieder–Tate equation⁵ gives good correlation for the combined entry length, that is, that region where the thermal and velocity profile are both developing or for short tubes:

$$\frac{\overline{Nu}_D = \bar{h}D}{k} = 1.86(Re_D \, Pr)^{1/3} \left(\frac{D}{L}\right)^{1/3} \left(\frac{\mu}{\mu_s}\right)^{0.14}$$

for $T_s = \text{constant}$, $0.48 < Pr < 16,700$, $0.0044 < \mu/\mu_s < 9.75$, and $(Re_D \, Pr \, D/L)^{1/3} (\mu/\mu_s)^{0.14} > 2$.

Table 12 Nusselt Numbers for Fully Developed Laminar Flow for Tubes of Various Cross Sections^a

Geometry ($L/DH > 100$)	Nu_{H1}	Nu_{H2}	Nu_r
 $\frac{2b}{2a} = 1$	3.608	3.091	2.976
 $\frac{2b}{2a} = \frac{1}{2}$	4.123	3.017	3.391
 $\frac{2b}{2a} = \frac{1}{4}$	5.099	4.35	3.66
 $\frac{2b}{2a} = \frac{1}{8}$	6.490	2.904	5.597
 $\frac{2b}{2a} = 0$	8.235	8.235	7.541
 $\frac{b}{a} = 0$	5.385	—	4.861
	4.364	4.364	3.657

^a Nu_{H1} = average Nusselt number for uniform heat flux in flow direction and uniform wall temperature at particular flow cross section.

Nu_{H2} = average Nusselt number for uniform heat flux both in flow direction and around periphery.

Nu_{Hr} = average Nusselt number for uniform wall temperature.

In this expression, all of the fluid properties are evaluated at the mean bulk temperature except for μ_s , which is evaluated at the wall surface temperature. The average convection heat transfer coefficient \bar{h} is based on the arithmetic average of the inlet and outlet temperature differences.

Turbulent Flow in Circular Tubes In turbulent flow the velocity and thermal entry lengths are much shorter than for a laminar flow. As a result, with the exception of short tubes, the fully developed flow values of the Nusselt number are frequently used directly in the calculation of the heat transfer. In general, the Nusselt number obtained for the constant heat flux case is greater than the Nusselt number obtained for the constant temperature case. The one exception to this is the case of liquid metals, where the difference is smaller than for laminar flow and becomes negligible for $Pr > 1.0$. The Dittus–Boelter equation⁶ is typically used if the difference between the pipe surface temperature and the bulk fluid temperature is less than 6°C (10°F) for liquids or 56°C (100°F) for gases:

$$Nu_D = 0.023 Re_D^{0.8} Pr^n$$

for $0.7 \leq Pr \leq 160$, $Re_D \geq 10,000$, and $L/D \geq 60$, where

$$\begin{aligned} n &= 0.4 \text{ for heating, } T_s > T_b \\ &= 0.3 \text{ for cooling, } T_s < T_b \end{aligned}$$

For temperature differences greater than specified above, use⁵

$$Nu_D = 0.027 Re_D^{0.8} Pr^{1/3} \left(\frac{\mu}{\mu_s} \right)^{0.14}$$

for $0.7 \leq Pr \leq 16,700$, $Re_D \geq 10,000$, and $L/D \geq 60$. In this expression, the properties are all evaluated at the mean bulk fluid temperature with the exception of μ_s , which is again evaluated at the tube surface temperature.

For *concentric tube annuli*, the hydraulic diameter $D_h = D_o - D_i$ (outer diameter – inner diameter) must be used for Nu_D and Re_D , and the coefficient h at either surface of the annulus must be evaluated from the Dittus–Boelter equation. Here, it should be noted that the foregoing equations apply for smooth surfaces and that the heat transfer rate will be larger for rough surfaces and are not applicable to liquid metals.

Fully Developed Turbulent Flow of Liquid Metals in Circular Tubes Because the Prandtl number for liquid metals is on the order of 0.01, the Nusselt number is primarily dependent on a dimensionless

parameter number referred to as the *Peclet number*, which in general is defined as $Pe = RePr$:

$$Nu_D = 5.0 + 0.025 Pe_D^{0.8}$$

which is valid for situations where T_s is a constant and $Pe_D > 100$ and $L/D > 60$.

For $q'' = \text{constant}$ and $3.6 \times 10^3 < Re_D < 9.05 \times 10^5$, $10^2 < Pe_D < 10^4$, and $L/D > 60$, the Nusselt number can be expressed as

$$Nu_D = 4.8 + 0.0185 Pe_D^{0.827}$$

2.2 Forced Convection – External Flow

In forced convection heat transfer, the heat transfer coefficient h , is based on the temperature difference between the wall surface temperature and the fluid temperature in the free stream outside the thermal boundary layer. The total heat transfer rate from the wall to the fluid is given by $q = hA(T_s - T_\infty)$. The Reynolds numbers are based on the free-stream velocity. The fluid properties are evaluated either at the free-stream temperature T_∞ or at the film temperature $T_f = (T_s + T_\infty)/2$.

Laminar Flow on a Flat Plate When the flow velocity along a constant temperature semi-infinite plate is uniform, the boundary layer originates from the leading edge and is laminar and the flow remains laminar until the local Reynolds number $Re_x = U_\infty x / \nu$ reaches the *critical Reynolds number*, Re_c . When the surface is smooth, the Reynolds number is generally assumed to be $Re_c = 5 \times 10^5$, but the value will depend on several parameters, including the surface roughness.

For a given distance x from the leading edge, the *local Nusselt number* and the *average Nusselt number* between $x = 0$ and $x = L$ are given below (Re_x and $Re_L \leq 5 \times 10^5$):

For $Pr \geq 0.6$:

$$Nu_x = \frac{hx}{k} = 0.332 Re_x^{0.5} Pr^{1/3}$$

$$\overline{Nu}_L = \frac{hL}{k} = 0.664 Re_L^{0.5} Pr^{1/3}$$

For $Pr \leq 0.6$:

$$Nu_x = 0.565(Re_x Pr)^{0.5} \quad \overline{Nu}_L = 1.13(Re_L Pr)^{0.5}$$

Here, all of the fluid properties are evaluated at the mean or average film temperature.

Turbulent Flow on Flat Plate When the flow over a flat plate is turbulent from the leading edge, expressions for the *local Nusselt number* can be written as

$$Nu_x = 0.0292 Re_x^{0.8} Pr^{1/3} \quad \overline{Nu}_L = 0.036 Re_L^{0.8} Pr^{1/3}$$

where the fluid properties are all based on the mean film temperature and $5 \times 10^5 \leq Re_x$ and $Re_L \leq 10^8$ and $0.6 \leq Pr \leq 60$.

Average Nusselt Number between $x = 0$ and $x = L$ with Transition For situations where transition occurs immediately once the critical Reynolds number Re_c has been reached⁷

$$\overline{Nu}_L = 0.036 Pr^{1/3} [Re_L^{0.8} - Re_c^{0.8} + 18.44 Re_c^{0.5}]$$

provided that $5 \times 10^5 \leq Re_L \leq 10^8$ and $0.6 \leq Pr \leq 60$. Specialized cases exist for this situation, that is,

$$\overline{Nu}_L = 0.036 Pr^{1/3} (Re_L^{0.8} - 18,700)$$

for $Re_c = 4 \times 10^5$, or

$$\overline{Nu}_L = 0.036 Pr^{1/3} (Re_L^{0.8} - 23,000)$$

for $Re_c = 5 \times 10^5$. Again, all fluid properties are evaluated at the mean film temperature.

Circular Cylinders in Cross Flow For circular cylinders in cross flow, the Nusselt number is based upon the diameter and can be expressed as

$$\overline{Nu}_D = (0.4 Re_D^{0.5} + 0.06 Re_D^{2/3}) Pr^{0.4} \left(\frac{\mu_\infty}{\mu_s} \right)^{0.25}$$

for $0.67 < Pr < 300$, $10 < Re_D < 10^5$, and $0.25 < \mu_\infty/\mu_s < 5.2$. Here, the fluid properties are evaluated at the free stream temperature except μ_s , which is evaluated at the surface temperature.⁸

Cylinders of Noncircular Cross Section in Cross Flow of Gases For noncircular cylinders in cross flow the Nusselt number is again based on the diameter, but is expressed as

$$\overline{Nu}_D = C (Re_D)^m Pr^{1/3}$$

where C and m are listed in Table 13, and the fluid properties are evaluated at the mean film temperature.⁹

Flow Past a Sphere For flow over a sphere, the Nusselt number is based on the sphere diameter and can be expressed as

$$\overline{Nu}_D = 2 + (0.4 Re_D^{0.5} + 0.06 Re_D^{2/3}) Pr^{0.4} \left(\frac{\mu_\infty}{\mu_s} \right)^{0.25}$$

for the case of $3.5 < Re_D < 8 \times 10^4$, $0.7 < Pr < 380$, and $1.0 < \mu_\infty/\mu_s < 3.2$. The fluid properties are calculated at the free-stream temperature except μ_s , which is evaluated at the surface temperature.⁸

Table 13 Constants and m for Noncircular Cylinders in Cross Flow

Geometry	Re_D	C	m
Square 	$5 \times 10^3 - 10^5$	0.246	0.588
	$5 \times 10^3 - 10^5$	0.102	0.675
Hexagon 	$5 \times 10^3 - 1.95 \times 10^4$	0.160	0.538
	$1.95 \times 10^4 - 10^5$	0.0385	0.782
Vertical plate 	$5 \times 10^3 - 10^5$	0.153	0.638
	$4 \times 10^3 - 1.5 \times 10^4$	0.228	0.731

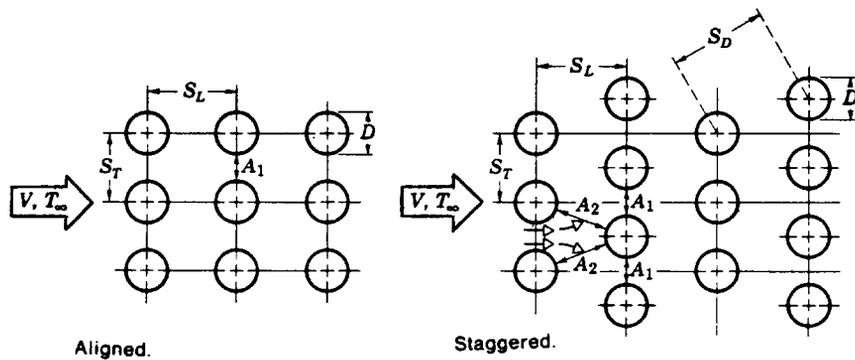

Fig. 12 Tube arrangement.

Flow across Banks of Tubes For banks of tubes, the tube arrangement may be either *staggered* or *aligned* (Fig. 12), and the heat transfer coefficient for the first row is approximately equal to that for a single tube.

In turbulent flow, the heat transfer coefficient for tubes in the first row is smaller than that of the subsequent rows. However, beyond the fourth or fifth row, the heat transfer coefficient becomes approximately constant. For tube banks with more than 20 rows, $0.7 < Pr < 500$, and $1000 < Re_{D,\max} < 2 \times 10^6$, the average Nusselt number for the entire tube bundle can be expressed as¹⁰

$$\overline{Nu}_D = C(Re_{D,\max})^m Pr^{0.36} \left(\frac{Pr_\infty}{Pr_s} \right)^{0.25}$$

where all fluid properties are evaluated at T_∞ except Pr_s , which is evaluated at the surface temperature. The constants C and m used in this expression are listed in Table 14, and the Reynolds number is based on the maximum fluid velocity occurring at the minimum free flow area available for the fluid. Using the nomenclature shown in Fig. 12, the maximum fluid velocity can be determined by

$$V_{\max} = \frac{S_T}{S_T - D} V$$

for the aligned or staggered configuration provided

$$\sqrt{S_L^2 + (S_T/2)^2} > \frac{S_T + D}{2}$$

or as

$$V_{\max} = \frac{S_T}{\sqrt{S_L^2 + (S_T/2)^2}} V$$

for staggered if

$$\sqrt{S_L^2 + (S_T/2)^2} < \frac{S_T + D}{2}$$

Liquid Metals in Cross Flow over Banks of Tubes

The average Nusselt number for tubes in the inner rows can be expressed as

$$\overline{Nu}_D = 4.03 + 0.228(Re_{D,\max} Pr)^{0.67}$$

which is valid for $2 \times 10^4 < Re_{D,\max} < 8 \times 10^4$ and $Pr < 0.03$ and the fluid properties are evaluated at the mean film temperature.¹¹

Table 14 Constants C and m of Heat Transfer Coefficient for the Banks in Cross Flow

Configuration	$Re_{D,\max}$	C	m
Aligned	$10^3 - 2 \times 10^5$	0.27	0.63
Staggered ($S_T/S_L < 2$)	$10^3 - 2 \times 10^5$	$0.35(S_T/S_L)^{1/5}$	0.60
Staggered ($S_G/S_L > 2$)	$10^3 - 2 \times 10^5$	0.40	0.60
Aligned	$2 \times 10^5 - 2 \times 10^6$	0.21	0.84
Staggered	$2 \times 10^5 - 2 \times 10^6$	0.022	0.84

High-Speed Flow over a Flat Plate When the free stream velocity is very high, the effects of viscous dissipation and fluid compressibility must be considered in the determination of the convection heat transfer. For these types of situations, the convection heat transfer can be described as $q = hA(T_s - T_{as})$, where T_{as} is the *adiabatic surface temperature* or *recovery temperature*, and is related to the *recovery factor* by $r = (T_{as} - T_\infty)/(T_0 - T_\infty)$. The value of the *stagnation temperature*, T_0 , is related to the free-stream static temperature, T_∞ , by the expression

$$\frac{T_0}{T_\infty} = 1 + \frac{\gamma - 1}{2} M_\infty^2$$

where γ is the specific heat ratio of the fluid and M_∞ is the ratio of the free-stream velocity and the acoustic velocity. For the case where $0.6 < \text{Pr} < 15$,

$$r = \begin{cases} \text{Pr}^{1/2} & \text{for laminar flow } (\text{Re}_x < 5 \times 10^5) \\ \text{Pr}^{1/3} & \text{for turbulent flow } (\text{Re}_x > 5 \times 10^5) \end{cases}$$

Here, all of the fluid properties are evaluated at the reference temperature $T_{\text{ref}} = T_\infty + 0.5(T_s - T_\infty) + 0.22(T_{as} - T_\infty)$. Expressions for the local heat transfer coefficients at a given distance x from the leading edge are given as²

$$\text{Nu}_x = \begin{cases} 0.332 \text{Re}_x^{0.5} \text{Pr}^{1/3} & \text{for } \text{Re}_x < 5 \times 10^5 \\ 0.0292 \text{Re}_x^{0.8} \text{Pr}^{1/3} & \text{for } 5 \times 10^5 < \text{Re}_x < 10^7 \\ 0.185 \text{Re}_x (\log \text{Re}_x)^{-2.584} & \text{for } 10^7 < \text{Re}_x < 10^9 \end{cases}$$

In the case of gaseous fluid flowing at very high free-stream velocities, dissociation of the gas may occur, and will cause large variations in the properties within the boundary layer. For these cases, the heat transfer coefficient must be defined in terms of the enthalpy difference, that is, $q = hA(i_s - i_{as})$, and the recovery factor will be given by $r = (i_s - i_{as})/(i_0 - i_\infty)$, where i_{as} represents the enthalpy at the adiabatic wall conditions. Similar expressions to those shown above for Nu_x can be used by substituting the properties evaluated at a reference enthalpy defined as $i_{\text{ref}} = i_\infty + 0.5(i_s - i_\infty) + 0.22(i_{as} - i_\infty)$.

High-Speed Gas Flow Past Cones For the case of high-speed gaseous flow over conical-shaped objects the following expressions can be used:

$$\text{Nu}_x = \begin{cases} 0.575 \text{Re}_x^{0.5} \text{Pr}^{1/3} & \text{for } \text{Re}_x < 10^5 \\ 0.0292 \text{Re}_x^{0.8} \text{Pr}^{1/3} & \text{for } \text{Re}_x > 10^5 \end{cases}$$

where the fluid properties are evaluated at T_{ref} as in the plate.¹²

Stagnation Point Heating for Gases When the conditions are such that the flow can be assumed to behave as *incompressible*, the Reynolds number is based on the free-stream velocity and \bar{h} is defined as $q = \bar{h}A(T_s - T_\infty)$.¹³ Estimations of the Nusselt can be made using the following relationship:

$$\text{Nu}_D = C \text{Re}_D^{0.5} \text{Pr}^{0.4}$$

where $C = 1.14$ for cylinders and 1.32 for spheres, and the fluid properties are evaluated at the mean film temperature. When the flow becomes *supersonic*, a bow shock wave will occur just off the front of the body. In this situation, the fluid properties must be evaluated at the stagnation state occurring behind the bow shock and the Nusselt number can be written as

$$\bar{\text{Nu}}_D = C \text{Re}_D^{0.5} \text{Pr}^{0.4} \left(\frac{\rho_\infty}{\rho_0} \right)^{0.25}$$

where $C = 0.95$ for cylinders and 1.28 for spheres; ρ_∞ is the free-stream gas density and ρ_0 is the stagnation density of stream behind the bow shock. The heat transfer rate for this case, is given by $q = \bar{h}A(T_s - T_0)$.

2.3 Free Convection

In free convection the fluid motion is caused by the buoyant force resulting from the density difference near the body surface, which is at a temperature different from that of the free fluid far removed from the surface where velocity is zero. In all free convection correlations, except for the enclosed cavities, the fluid properties are usually evaluated at the mean film temperature $T_f = (T_1 + T_\infty)/2$. The thermal expansion coefficient β , however, is evaluated at the free fluid temperature T_∞ . The convection heat transfer coefficient h is based on the temperature difference between the surface and the free fluid.

Free Convection from Flat Plates and Cylinders

For free convection from flat plates and cylinders, the average Nusselt number $\bar{\text{Nu}}_L$ can be expressed as⁴

$$\bar{\text{Nu}}_L = C(\text{Gr}_L \text{Pr})^m$$

where the constants C and m are given as shown in Table 15. The *Grashof Prandtl number* product, $(\text{Gr}_L \text{Pr})$ is called the *Rayleigh number* (Ra_L) and for certain ranges of this value, Figs. 13 and 14 are used instead of the above equation. Reasonable approximations for other types of *three-dimensional shapes*, such as short cylinders and blocks, can be made for $10^4 < \text{Ra}_L < 10^9$, by using this expression and $C = 0.6$, $m = 1/4$, provided that the characteristic length, L , is determined from $1/L = 1/L_{\text{hor}} + 1/L_{\text{ver}}$, where

Table 15 Constants for Free Convection from Flat Plates and Cylinders

Geometry	$Gr_L Pr$	C	m	L
Vertical flat plates and cylinders	$10^{-1} - 10^4$	Use Fig. 12	Use Fig. 12	Height of plates and cylinders; restricted to $D/L \geq 35/Gr_L^{1/4}$ for cylinders
Horizontal cylinders	$10^4 - 10^9$	0.59	$1/4$	Diameter D
	$10^9 - 10^{13}$	0.10	$1/3$	
	$0 - 10^{-5}$	0.4	0	
	$10^{-5} - 10^4$	Use Fig. 13	Use Fig. 13	
Upper surface of heated plates or lower surface of cooled plates	$10^4 - 10^9$	0.53	$1/4$	Length of a side for square plates, the average length of the two sides for rectangular plates
	$10^9 - 10^{13}$	0.13	$1/3$	
	$2 \times 10^4 - 8 \times 10^6$	0.54	$1/4$

	$10^5 - 10^{11}$	0.58	$1/5$	

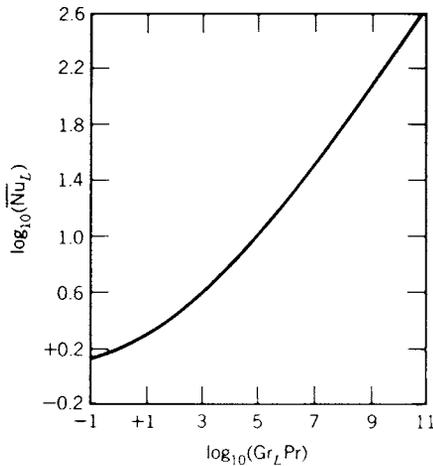

Fig. 13 Free-convection heat transfer correlation for heated vertical plates and cylinders. (Adapted from Ref. 14. Used with permission of McGraw-Hill Book Company.)

L_{ver} is the height and L_{hor} is the horizontal dimension of the object in question.

For *unsymmetrical horizontal* square, rectangular, or circular surfaces, the characteristic length L can be calculated from the expression $L = A/P$, where A is the area and P is the wetted perimeter of the surface.

Free Convection from Spheres For free convection from spheres, the following correlation has been developed:

$$\overline{Nu}_D = 2 + 0.43(Gr_D Pr)^{0.25} \quad \text{for } 1 < Gr_D < 10^5$$

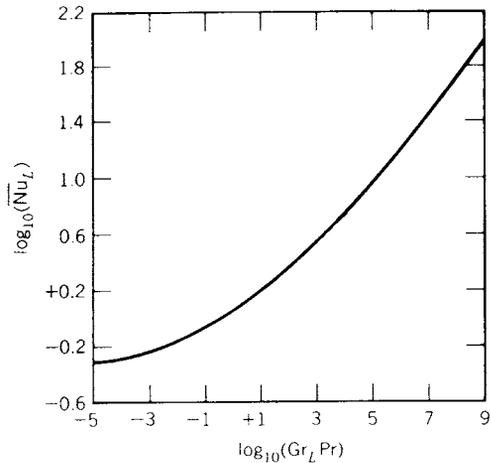

Fig. 14 Free-convection heat transfer correlation from heated horizontal cylinders. (Adapted from Ref. 14. Used with permission of McGraw-Hill Book Company.)

Although this expression was designed primarily for gases, $Pr \approx 1$, it may be used to approximate the values for liquids as well.¹⁵

Free Convection in Enclosed Spaces Heat transfer in an enclosure occurs in a number of different situations and with a variety of configurations. Then a temperature difference is imposed on two opposing walls that enclose a space filled with a fluid, convective heat transfer will occur. For small values of the Rayleigh number, the heat transfer may be dominated by conduction, but as the Rayleigh number increases, the contribution made by free convection will increase. Following are a number of correlations, each designed

for a specific geometry. For all of these, the fluid properties are evaluated at the average temperature of the two walls.

Cavities between Two Horizontal Walls at Temperatures T_1 and T_2 Separated by Distance δ (T_1 for Lower Wall, $T_1 > T_2$)

$$q'' = \bar{h}(T_1 - T_2)$$

$$\bar{Nu}_\delta = \begin{cases} 0.069 Ra_\delta^{1/3} Pr^{0.074} & \text{for } 3 \times 10^5 < Ra_\delta < 7 \times 10^9 \\ 1.0 & \text{for } Ra_\delta < 1700 \end{cases}$$

where $Ra_\delta = g\beta(T_1 - T_2)\delta^3/\alpha\nu$; δ is the thickness of the space.¹⁶

Cavities between Two Vertical Walls of Height H at Temperature by Distance T_Δ and T_Θ Separated by Distance δ ^{17,18}

$$q'' = \bar{h}(T_1 - T_2)$$

$$\bar{Nu}_\delta = 0.22 \left(\frac{Pr}{0.2 + Pr} Ra_\delta \right)^{0.28} \left(\frac{\delta}{H} \right)^{0.25}$$

for $2 < H/\delta < 10$, $Pr < 10^5$, $Ra_\delta < 10^{10}$;

$$\bar{Nu}_\delta = 0.18 \left(\frac{Pr}{0.2 + Pr} Ra_\delta \right)^{0.29}$$

for $1 < H/\delta < 2$, $10^3 < Pr < 10^5$, and $10^3 < Ra_\delta Pr / (0.2 + Pr)$; and

$$\bar{Nu}_\delta = 0.42 Ra_\delta^{0.25} Pr^{0.012} (\delta/H)^{0.3}$$

for $10 < H/\delta < 40$, $1 < Pr < 2 \times 10^4$, and $10^4 < Ra_\delta < 10^7$.

2.4 Log-Mean Temperature Difference

The simplest and most common type of heat exchanger is the *double-pipe heat exchanger* illustrated in Fig. 15. For this type of heat exchanger, the heat transfer between the two fluid can be found by assuming a constant overall heat transfer coefficient found from Table 8 and a constant fluid specific heat. For this type, the heat transfer is given by

$$q = UA \Delta T_m$$

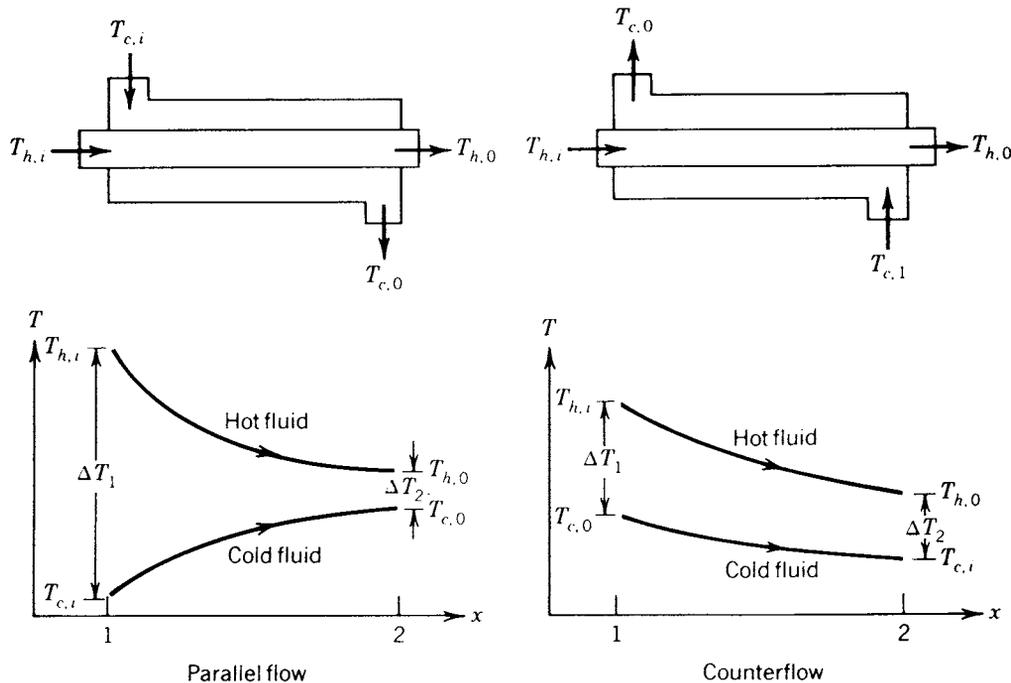

Fig. 15 Temperature profiles for parallel flow and counterflow in double-pipe heat exchanger.

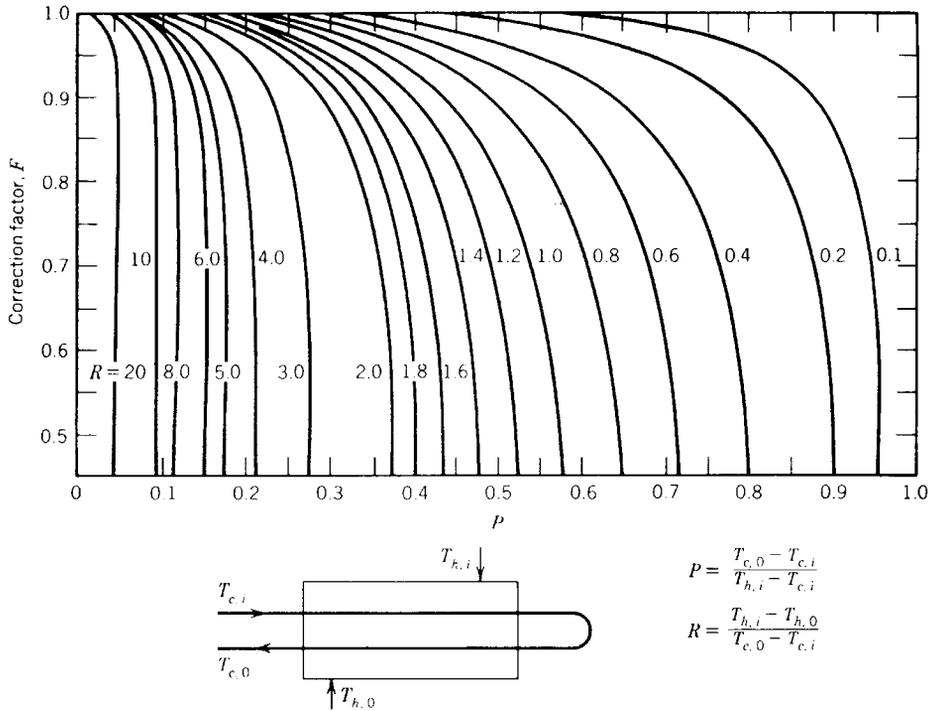

Fig. 16 Correction factor for shell-and-tube heat exchanger with one shell and any multiple of two tube passes (two, four, etc., tube passes.)

where

$$\Delta T_m = \frac{\Delta T_2 - \Delta T_1}{\ln(\Delta T_2/\Delta T_1)}$$

In this expression, the temperature difference, ΔT_m , is referred to as the *log-mean temperature difference* (LMTD); ΔT_1 represents the temperature difference between the two fluid at one end and ΔT_2 at the other end. For the case where the ratio $\Delta T_2/\Delta T_1$ is less than two, the *arithmetic mean temperature difference*, $(\Delta T_2 + \Delta T_1)/2$, may be used to calculate heat transfer rate without introducing any significant error. As shown in Fig. 15,

$$\Delta T_1 = T_{h,i} - T_{c,i} \quad \Delta T_2 = T_{h,o} - T_{c,o} \quad \text{for parallel flow}$$

$$\Delta T_1 = T_{h,i} - T_{c,o} \quad \Delta T_2 = T_{h,o} - T_{c,i} \quad \text{for counterflow}$$

Cross-Flow Coefficient In other types of heat exchangers, where the values of the overall heat transfer coefficient, U , may vary over the area of the surface, the LMTD may not be representative of the actual average temperature difference. In these cases, it is necessary to utilize a correction factor such that the

heat transfer, q , can be determined by

$$q = UAF \Delta T_m$$

Here the value of ΔT_m is computed assuming counterflow conditions, that is, $\Delta T_1 = T_{h,i} - T_{c,i}$ and $\Delta T_2 = T_{h,o} - T_{c,o}$. Figures 16 and 17 illustrate some examples of the *correction factor F* for various multiple-pass exchangers.

3 RADIATION HEAT TRANSFER

Heat transfer can occur in the absence of a participating medium through the transmission of energy by electromagnetic waves, characterized by a wavelength, λ , and frequency, ν , which are related by $c = \lambda\nu$. The parameter c represents the velocity of light, which in a vacuum is $c_0 = 2.9979 \times 10^8$ m/s. Energy transmitted in this fashion is referred to as *radiant energy* and the heat transfer process that occurs is called *radiation heat transfer* or simply *radiation*. In this mode of heat transfer, the energy is transferred through electromagnetic waves or through photons, with the energy of a photon being given by $h\nu$, where h represents Planck's constant.

In nature, every substance has a characteristic wave velocity that is smaller than that occurring in a vacuum.

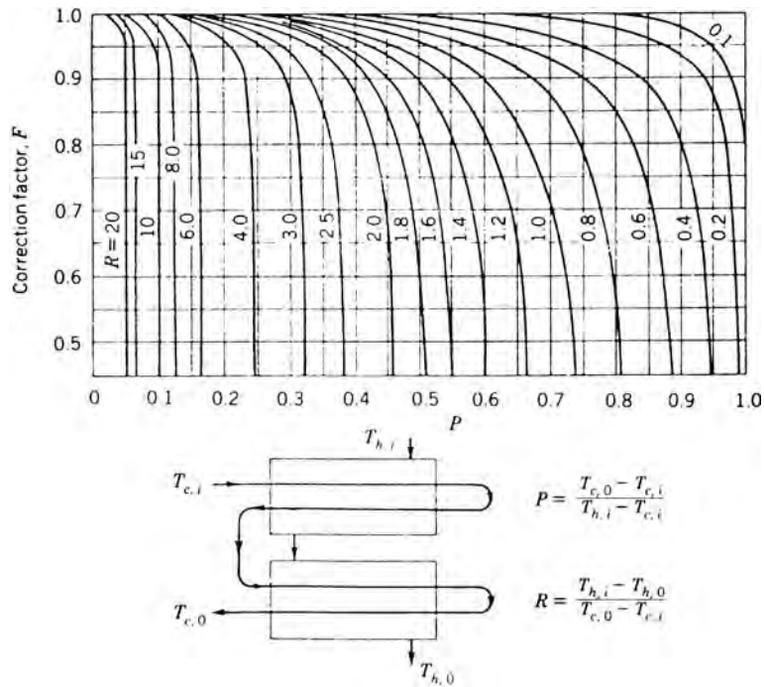

Fig. 17 Correction factor for shell-and-tube heat exchanger with two shell passes and any multiple of four tubes passes (four, eight, etc., tube passes.)

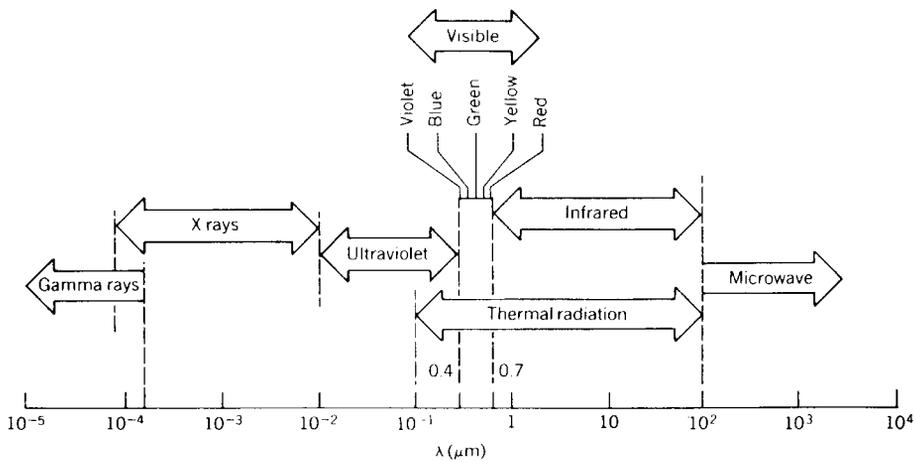

Fig. 18 Electromagnetic radiation spectrum.

These velocities can be related to c_o by $c = c_o/n$, where n indicates the refractive index. The value of the refractive index, n , for air is approximately equal to 1. The wavelength of the energy given or for the radiation that comes from a surface depends

on the nature of the source and various wavelengths sensed in different ways. For example, as shown in Fig. 18, the electromagnetic spectrum consists of a number of different types of radiation. Radiation in the visible spectrum occurs in the range $\lambda = 0.4\text{--}0.74 \mu\text{m}$,

while radiation in the wavelength range 0.1–100 μm is classified as *thermal radiation* and is sensed as heat. For radiant energy in this range, the amount of energy given off is governed by the temperature of the emitting body.

3.1 Blackbody Radiation

All objects in space are continuously being bombarded by radiant energy of one form or another and all of this energy is either absorbed, reflected or transmitted. An ideal body that absorbs all the radiant energy falling upon it, regardless of the wavelength and direction, is referred to as a *blackbody*. Such a body emits maximum energy for a prescribed temperature and wavelength. Radiation from a blackbody is independent of direction and is referred to as a *diffuse emitter*.

Stefan–Boltzmann Law The Stefan–Boltzmann law describes the rate at which energy is radiated from a blackbody and states that this radiation is proportional to the fourth power of the absolute temperature of the body,

$$e_b = \sigma T^4$$

where e_b is the *total emissive power* and σ is the Stefan–Boltzmann constant, which has the value $5.729 \times 10^{-8} \text{ W/m}^2 \cdot \text{K}^4$ ($0.173 \times 10^{-8} \text{ Btu/h} \cdot \text{ft}^2 \cdot \text{R}^4$).

Planck's Distribution Law The temperature amount of energy leaving a blackbody is described as the *spectral emissive power*, $e_{\lambda b}$, and is a function of wavelength. This function, which was derived from quantum theory by Planck, is

$$e_{\lambda b} = \frac{2\pi C_1}{\lambda^5 [\exp(C_2/\lambda T) - 1]}$$

where $e_{\lambda b}$ has a unit $\text{W/m}^2 \cdot \mu\text{m}$ ($\text{Btu/h} \cdot \text{ft}^2 \cdot \mu\text{m}$).

Values of the constants C_1 and C_2 are $0.59544 \times 10^{-16} \text{ W} \cdot \text{m}^2$ ($0.18892 \times 10^8 \text{ Btu} \cdot \mu\text{m}^4/\text{h} \cdot \text{ft}^2$) and $14,388 \mu\text{m} \cdot \text{K}$ ($25,898 \mu\text{m} \cdot \text{R}$), respectively. The distribution of the spectral emissive power from a blackbody at various temperatures is shown in Fig. 19, which shows that the energy emitted at all wavelengths increases as the temperature increases. The maximum or peak values of the constant temperature curves illustrated in Fig. 20 shift to the left for shorter wavelengths as the temperatures increase.

The fraction of the emissive power of a blackbody at a given temperature and in the wavelength interval between λ_1 and λ_2 can be described by

$$\begin{aligned} F_{\lambda_1 T - \lambda_2 T} &= \frac{1}{\sigma T^4} \left(\int_0^{\lambda_1} e_{\lambda b} d\lambda - \int_0^{\lambda_2} e_{\lambda b} d\lambda \right) \\ &= F_{0-\lambda_1 T} - F_{0-\lambda_2 T} \end{aligned}$$

where the function $F_{0-\lambda T} = (1/\sigma T^4) \int_0^\lambda e_{\lambda b} d\lambda$ is given in Table 16. This function is useful for the evaluation of total properties involving integration on the wavelength in which the spectral properties are piecewise constant.

Wien's Displacement Law The relationship between these peak or maximum temperatures can be described by *Wien's displacement law*,

$$\lambda_{\max} T = 2897.8 \mu\text{m} \cdot \text{K}$$

or

$$\lambda_{\max} T = 5216.0 \mu\text{m} \cdot \text{R}$$

3.2 Radiation Properties

While to some degree all surfaces follow the general trends described by the Stefan–Boltzmann and Planck laws, the behavior of real surfaces deviates somewhat from these. In fact, because blackbodies are ideal, all real surfaces emit and absorb less radiant energy than a blackbody. The amount of energy a body emits can be described in terms of the emissivity and is, in general, a function of the type of material, the temperature, and the surface conditions, such as roughness, oxide layer thickness, and chemical contamination. The emissivity is, in fact, a measure of how well a real body radiates energy as compared with a blackbody of the same temperature. The radiant energy emitted into the entire hemispherical space above a real surface element, including all wavelengths is given by $e = \epsilon \sigma T^4$, where ϵ is less than 1.0 and is called the *hemispherical emissivity* (or *total hemispherical emissivity* to indicate averaging over the total wavelength spectrum). For a given wavelength the *spectral hemispherical emissivity* e_λ of a real surface is defined as

$$e_\lambda = \frac{e_\lambda}{e_{\lambda b}}$$

where e_λ is the hemispherical emissive power of the real surface and $e_{\lambda b}$ is that of a blackbody at the same temperature.

Spectral irradiation, G_λ , ($\text{W/m}^2 \cdot \mu\text{m}$), is defined as the rate at which radiation is incident upon a surface per unit area of the surface, per unit wavelength about the wavelength λ , and encompasses the incident radiation from all directions.

Spectral hemispherical reflectivity, ρ_λ , is defined as the radiant energy reflected per unit time, per unit area of the surface, per unit wavelength per G_λ .

Spectral hemispherical absorptivity, α_λ , is defined as the radiant energy absorbed per unit area of the surface per unit wavelength about the wavelength per G_λ .

Spectral hemispherical transmissivity is defined as the radiant energy transmitted per unit area of the surface, per unit wavelength about the wavelength per G_λ .

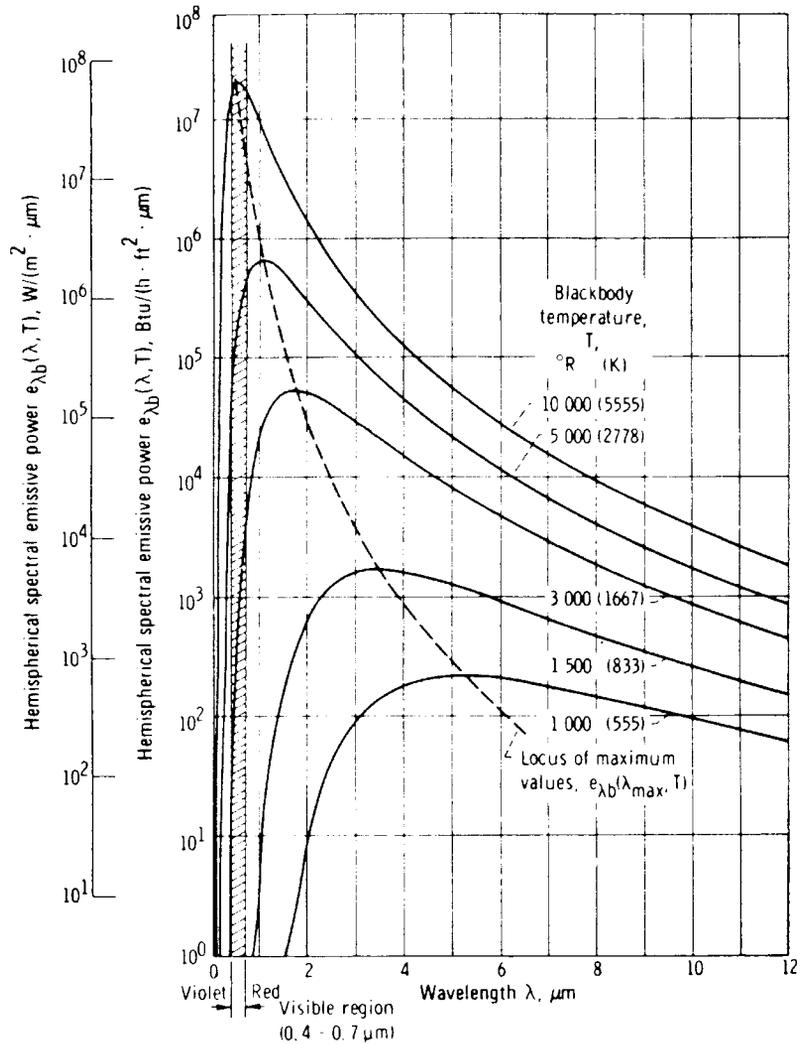

Fig. 19 Hemispherical spectral emissive power of a blackbody for various temperatures.

For any surface, the sum of the reflectivity absorptivity, and transmissivity must equal unit, that is,

$$\alpha_\lambda - \rho_\lambda \tau_\lambda = 1$$

When these values are averaged over the entire wavelength from $\lambda = 0$ to ∞ , they are referred to as total values. Hence, the total hemispherical reflectivity, total hemispherical absorptivity, and total hemispherical transmissivity can be written as

$$\rho = \int_0^\infty \rho_\lambda G_\lambda \frac{d\lambda}{G} \quad \alpha = \int_0^\infty \alpha_\lambda G_\lambda \frac{d\lambda}{G}$$

and

$$\tau = \int_0^\infty \tau_\lambda G_\lambda \frac{d\lambda}{G}$$

respectively, where

$$G = \int_0^\infty G_\lambda d\lambda$$

As was the case for the wavelength-dependent parameters, the sum of the total reflectivity total absorptivity,

$$dA_i dF_{di-dj} = dA_j dF_{dj-di}$$

$$dA_i F_{di-j} = A_j dF_{j-di}$$

$$A_i F_{i-j} = A_j F_{j-i}$$

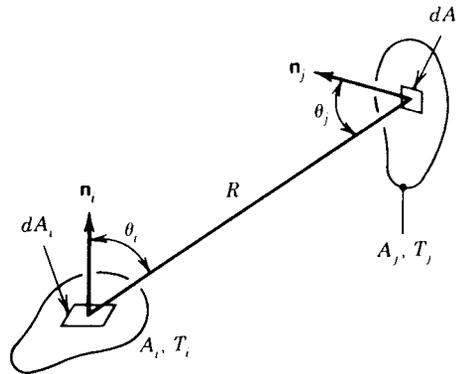

Fig. 20 Configuration factor for radiation exchange between surfaces of area dA_i and dA_j .

and total transmissivity must be equal to unity, that is,

$$\alpha + \rho + \tau = 1$$

It is important to note that while the emissivity is a function of the material, temperature, and surface conditions, the absorptivity and reflectivity depend on both the surface characteristics and the nature of the incident radiation.

The terms *reflectance*, *absorptance*, and *transmittance* are used by some authors for the real surfaces and the terms reflectivity, absorptivity, and transmissivity are reserved for the properties of the ideal surfaces (i.e., those optically smooth and pure substances perfectly uncontaminated). Surfaces that allow no radiation to pass through are referred to as *opaque*, that is, $\tau_\lambda = 0$, and all of the incident energy will be either reflected or absorbed. For such a surface,

$$\alpha_\lambda + \rho_\lambda = 1 \quad \alpha + \rho = 1$$

Light rays reflected from a surface can be reflected in such a manner that the incident and reflected rays are symmetric with respect to the surface normal at the point of incidence. This type of radiation is referred to as *specular*. The radiation is referred to as *diffuse* if the intensity of the reflected radiation is uniform over all angles of reflection and is independent of the incident direction, and the surface is called a *diffuse surface* if the radiation properties are independent of the direction. If they are independent of the wavelength, the surface is called a *gray surface*, and a *diffuse-gray surface* absorbs a fixed fraction of incident radiation from any direction and at any wavelength, and $\alpha_\lambda = \varepsilon_\lambda = \alpha = \varepsilon$.

Kirchhoff's Law of Radiation The directional characteristics can be specified by the addition of a prime to the value; for example, the spectral emissivity for radiation in a particular direction would be denoted by α'_λ . For radiation in a particular direction, the spectral emissivity is equal to the directional spectral absorptivity for the surface irradiated by a blackbody at the same temperature. The most general form of this expression states that $\alpha'_\lambda = \varepsilon'_\lambda$. If the incident radiation is independent of angle or if the surface is diffuse, then $\alpha_\lambda = \varepsilon_\lambda$ for the hemispherical properties. This relationship can have various conditions imposed on it, depending on whether spectral, total, directional, or hemispherical quantities are being considered.¹⁹

Emissivity of Metallic Surfaces The properties of pure smooth metallic surfaces are often characterized by low emissivity and absorptivity values and high values of reflectivity. The spectral emissivity of metals tends to increase with decreasing wavelength, and exhibits a peak near the visible region. At wavelengths $\lambda > \sim 5 \mu\text{m}$ the spectral emissivity increases with increasing temperature, but this trend reverses at

shorter wavelengths ($\lambda < \sim 1.27 \mu\text{m}$). Surface roughness has a pronounced effect on both the hemispherical emissivity and absorptivity, and large *optical roughnesses*, defined as the mean square roughness of the surface divided by the wavelength, will increase the hemispherical emissivity. For cases where the optical roughness is small, the directional properties will approach the values obtained for smooth surfaces. The presence of impurities, such as oxides or other nonmetallic contaminants, will change the properties significantly and increase the emissivity of an otherwise pure metallic body. A summary of the normal total emissivities for metals are given in Table 17. It should be noted that the hemispherical emissivity for metals is typically 10–30% higher than the values normally encountered for normal emissivity.

Emissivity of Nonmetallic Materials Large values of total hemispherical emissivity and absorptivity are typical for nonmetallic surfaces at moderate temperatures and, as shown in Table 18, which lists the normal total emissivity of some nonmetals, the temperature dependence is small.

Absorptivity for Solar Incident Radiation The spectral distribution of solar radiation can be approximated by blackbody radiation at a temperature of approximately 5800 K (10,000°R) and yields an average solar irradiation at the outer limit of the atmosphere of approximately 1353 W/m² (429 Btu/ft²·h). This solar irradiation is called the *solar constant* and is greater than the solar irradiation received at the surface of the earth, due to the radiation scattering by air molecules, water vapor, and dust, and the absorption by O₃, H₂O, and CO₂ in the atmosphere. The absorptivity of a substance depends not only on the surface properties but also on the sources of incident radiation. Since solar radiation is concentrated at a shorter wavelength, due to the high source temperature, the absorptivity for certain materials when exposed to solar radiation may be quite different from that which occurs for low-temperature radiation, where the radiation is concentrated in the longer wavelength range. A comparison of absorptivities for a number of different materials is given in Table 19 for both solar and low-temperature radiation.

3.3 Configuration Factor

The magnitude of the radiant energy exchanged between any two given surfaces is a function of the emissivity, absorptivity, and transmissivity. In addition, the energy exchange is a strong function of how one surface is viewed from the other. This aspect can be defined in terms of the *configuration factor* (sometimes called the *radiation shape factor*, *view factor*, *angle factor*, or *interception factor*). As shown in Fig. 20, the configuration factor, F_{i-j} , is defined as that fraction of the radiation leaving a black surface, i , that is intercepted by a black or gray surface, j , and is based on the relative geometry, position, and shape

Table 17 Normal Total Emissivity of Metals^a

Materials	Surface Temperature (K)	Normal Total Emissivity

of the two surfaces. The configuration factor can also be expressed in terms of the differential fraction of the energy or dF_{i-dj} , which indicates the differential fraction of energy from a finite area A_i that is intercepted by an infinitesimal area dA_j . Expressions for a number of different cases are given below for several common geometries:

Infinitesimal area dA_j to infinitesimal area dA_j :

$$dF_{di-dj} = \frac{\cos \theta_i \cos \theta_j}{\pi R^2} dA_j$$

Infinitesimal area dA_j to finite area A_j :

$$F_{di-j} = \int_{A_j} \frac{\cos \theta_i \cos \theta_j}{\pi R^2} dA_j$$

Finite area A_i to finite area A_j :

$$F_{i-j} = \frac{1}{A_i} \int_{A_j} \int_{A_j} \frac{\cos \theta_i \cos \theta_j}{\pi R^2} dA_i dA_j$$

Analytical expressions of other configuration factors have been found for a wide variety of simple geometries, and a number of these are presented in Figs. 21–24 for surfaces that emit and reflect diffusely.

Reciprocity Relations The configuration factors can be combined and manipulated using algebraic rules referred to as configuration factor geometry. These expressions take several forms, one of which is the reciprocal properties between different configuration

Table 18 Normal Total Emissivity of Nonmetals^a

factors, which allow one configuration factor to be determined from knowledge of the others:

$$dA_i dF_{di-j} = dA_j dF_{dj-di}$$

$$dA_i dF_{di-j} = A_j dF_{j-di}$$

$$A_i F_{i-j} = A_j F_{j-i}$$

These relationships can be combined with other basic rules to allow the determination of the configuration

of an infinite number of complex shapes and geometries form a few select, known geometries. These are summarized in the following sections.

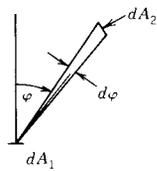

Additive Property For a surface A_i subdivided into N parts ($A_{i1}, A_{i2}, \dots, A_{iN}$) and a surface A_j subdivided into M parts ($A_{j1}, A_{j2}, \dots, A_{jM}$),

$$A_i F_{i-j} = \sum_{n=1}^N \sum_{m=1}^M A_{in} F_{in-jm}$$

Relation in an Enclosure When a surface is completely enclosed, the surface can be subdivided into \$N\$ parts having areas \$A_1, A_2, \dots, A_N\$, respectively, and

$$\sum_{j=1}^N F_{i-j} = 1$$

Blackbody Radiation Exchange For black surfaces \$A_i\$, and \$A_j\$ at temperatures \$T_i\$ and \$T_j\$, respectively, the net radiative exchange, \$q_{ij}\$, can be expressed as

$$q_{ij} = A_i F_{i-j} \sigma (T_i^4 - T_j^4)$$

and for a surface completely enclosed and subdivided into \$N\$ surfaces maintained at temperatures \$T_1, T_2, \dots, T_N\$, the net radiative heat transfer, \$q_i\$, to surface area \$A_i\$ is

$$q_i = \sum_{j=1}^N A_i F_{i-j} \sigma (T_i^4 - T_j^4) = \sum_{j=1}^N q_{ij}$$

3.4 Radiative Exchange among Diffuse Gray Surfaces in Enclosure

One method for solving for the radiation exchange between a number of surfaces or bodies is through the use of the *radiosity*, \$J\$, define as the total radiation

that leaves a surface per unit time and per unit area. For an opaque surface, this term is define as

$$J = \epsilon \sigma T^4 + (1 - \epsilon)G$$

For an enclosure consisting of \$N\$ surfaces, the irradiation on a given surface \$i\$ can be expressed as

$$G_i = \sum_{j=1}^N J_j F_{i-j}$$

and the net radiative heat transfer rate at given surface \$i\$ is

$$q_i = A_i (J_i - G_i) = \frac{\epsilon_i A_i}{1 - \epsilon_i} (\sigma T_i^4 - J_i)$$

For every surface in the enclosure, a uniform temperature or a constant heat transfer rate can be specified. If the surface temperature is given, the heat transfer rate can be determined for that surface and vice versa. Shown below are several specific cases that are commonly encountered.

Case I. The temperatures of the surfaces, \$T_i\$ (\$i = 1, 2, \dots, N\$), are known for each of the \$N\$ surfaces and the values of the radiosity, \$J_i\$, are solved from the expression

$$\sum_{j=1}^N \{\delta_{ij} - (1 - \epsilon_i) F_{i-j}\} J_j = \epsilon_i \sigma T_i^4 \quad 1 \leq i \leq N$$

The net heat transfer rate to surface i can then be determined from the fundamental relationship

$$q_i = A_i \frac{\varepsilon_i}{1 - \varepsilon_i} (\sigma T_i^4 - J_i) \quad 1 \leq i \leq N$$

where $\delta_{ij} = 0$ for $i \neq j$ and $\delta_{ij} = 1$ for $i = j$.

Case II. The heat transfer rates, q_i ($i = 1, 2, \dots, N$), to each of the N surfaces are known and the values of the radiosity, J_i , are determined from

$$\sum_{j=1}^N \{\delta_{ij} - F_{i-j}\} J_j = \frac{q_i}{A_i} \quad 1 \leq i \leq N$$

The surface temperature can then be determined from

$$T_i = \left[\frac{1}{\sigma} \left(\frac{1 - \varepsilon_i}{\varepsilon_i} \frac{q_i}{A_i} + J_i \right) \right]^{1/4} \quad 1 \leq i \leq N$$

Case III. The temperatures, T_i ($i = 1, \dots, N_1$), for N_1 surfaces and heat transfer rates q_i ($i = N_1 + 1, \dots, N$) for $(N - N_1)$ surfaces are known and

the radiosities are determined by

$$\sum_{j=1}^N \{\delta_{ij} - (1 - \varepsilon_i) F_{i-j}\} J_j = \varepsilon_i \alpha T_i^4 \quad 1 \leq i \leq N_1$$

$$\sum_{j=1}^N \{\delta_{ij} - F_{i-j}\} J_j = \frac{q_i}{A_i} \quad N_1 + 1 \leq i \leq N$$

The net heat transfer rates and temperatures can be found as

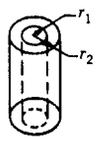

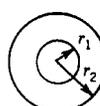

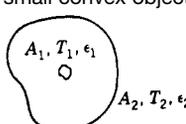

$$q_i = A_i \frac{\varepsilon_i}{1 - \varepsilon_i} (\sigma T_i^4 - J_i) \quad 1 \leq i \leq N_1$$

$$T_i = \left[\frac{1}{\sigma} \left(\frac{1 - \varepsilon_i}{\varepsilon_i} \frac{q_i}{A_i} + J_i \right) \right]^{1/4} \quad N_1 + 1 \leq i \leq N$$

Two Diffuse Gray Surfaces Forming an Enclosure The net radiative exchange, q_{12} , for two diffuse gray surfaces forming an enclosure are shown in Table 20 for several simple geometries.

Radiation Shields Often in practice, it is desirable to reduce the radiation heat transfer between two surfaces. This can be accomplished by placing a highly reflective surface between the two surfaces. For this configuration the ratio of the net radiative exchange

Table 20 Net Radiative Exchange between Two Surfaces Forming an Enclosure

Large (infinite) parallel planes $\frac{A_1, T_1, \varepsilon_1}{A_2, T_2, \varepsilon_2}$	$A_1 = A_2 = A$	$q_{12} = \frac{A\sigma(T_1^4 - T_2^4)}{\frac{1}{\varepsilon_1} + \frac{1}{\varepsilon_2} - 1}$
Long (infinite) concentric cylinders 	$\frac{A_1}{A_2} = \frac{r_1}{r_2}$	$q_{12} = \frac{\sigma A_1(T_1^4 - T_2^4)}{\frac{1}{\varepsilon_1} + \frac{1 - \varepsilon_2}{\varepsilon_2} \left(\frac{r_1}{r_2}\right)}$
Concentric sphere 	$\frac{A_1}{A_2} = \frac{r_1^2}{r_2^2}$	$q_{12} = \frac{\sigma A_1(T_1^4 - T_2^4)}{\frac{1}{\varepsilon_1} + \frac{1 - \varepsilon_2}{\varepsilon_2} \left(\frac{r_1}{r_2}\right)^2}$
Small convex object in a large cavity 	$\frac{A_1}{A_2} \approx 0$	$q_{12} = \sigma A_1 \varepsilon_1 (T_1^4 - T_2^4)$

with the shield to that without the shield can be expressed by the relationship

$$\frac{q_{12} \text{ with shield}}{q_{12} \text{ without shield}} = \frac{1}{1 + \chi}$$

Values for this ratio, χ , for shields between parallel plates, concentric cylinders, and concentric spheres are summarized in Table 21. For the special case of parallel plates involving more than one or N shields, where all of the emissivities are equal, the value of χ equals N .

Radiation Heat Transfer Coefficient The rate at which radiation heat transfer occurs can be expressed in a form similar to Fourier's law or Newton's law of cooling, by expressing it in terms of the temperature difference $T_1 - T_2$, or as

$$q = h_r A(T_1 - T_2)$$

where h_r is the radiation heat transfer coefficient or *radiation film coefficient*. For the case of radiation between two large parallel plates with emissivities, respectively, of ϵ_1 and ϵ_2 ,

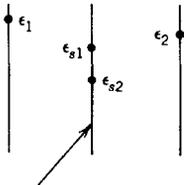

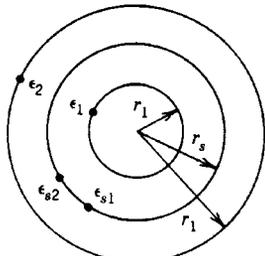

$$h_r \frac{\sigma(T_1^4 - T_2^4)}{T_1 - T_2(1/\epsilon_1 + 1/\epsilon_2 - 1)}$$

3.5 Thermal Radiation Properties of Gases

All of the previous expressions assumed that the medium present between the surfaces did not affect the radiation exchange. In reality, gases such as air, oxygen (O_2), hydrogen (H_2), and nitrogen (N_2) have a symmetrical molecular structure and neither emit nor absorb radiation at low to moderate temperatures. Hence, for most engineering applications, such *non-participating gases* can be ignored. However, polyatomic gases such as water vapor (H_2O), carbon dioxide (CO_2), carbon monoxide (CO), sulfur dioxide (SO_2), and various hydrocarbons emit and absorb significant amounts of radiation. These *participating gases* absorb and emit radiation in limited spectral ranges, referred to as spectral *bands*. In calculating the emitted or absorbed radiation for a gas layer, its thickness, shape, surface area, pressure, and temperature distribution must be considered. Although a precise method for calculating the effect of these participating media is quite complex, an approximate method developed by Hottel²¹ will yield results that are reasonably accurate.

The effective total emissivities of carbon dioxide and water vapor are a function of the temperature and the product of the partial pressure and the mean beam length of the substance as indicated in Figs. 25 and 26, respectively. The *mean beam length*, L_e , is the characteristic length that corresponds to the radius of a hemisphere of gas, such that the energy flux radiated to the center of the base is equal to the average flux radiated to the area of interest by the actual gas volume. Table 22 lists the mean beam lengths of several simple shapes. For a geometry for which L_e has not been determined, it is generally approximated

Table 21 Values of X for Radiative Shields

Geometry	X
	$\frac{\frac{1}{\epsilon_{s1}} + \frac{1}{\epsilon_{s2}} - 1}{\frac{1}{\epsilon_1} + \frac{1}{\epsilon_2} - 1}$
Shield	$\left(\frac{r_1}{r_2}\right)^2 \left(\frac{1}{\epsilon_{s1}} + \frac{1}{\epsilon_{s2}} - 1\right)$ $\frac{1}{\epsilon_1} + \left(\frac{1}{\epsilon_2} - 1\right) \left(\frac{r_1}{r_2}\right)^2$
	$n = 1$ for infinitely long concentric cylinders $n = 2$ for concentric spheres

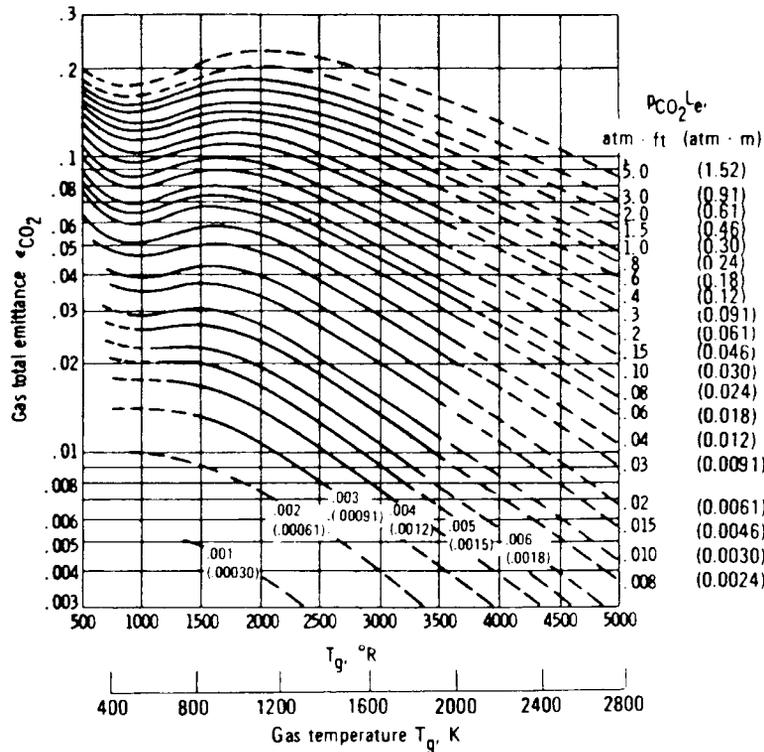

Fig. 25 Total emissivity of CO₂ in a mixture having a total pressure of 1 atm. (From Ref. 21. Used with the permission of McGraw-Hill Book Company.)

by $L_e = 3.6V/A$ for an entire gas volume V radiating to its entire boundary surface A . The data in Figs. 25 and 26 were obtained for a total pressure of 1 atm and zero partial pressure of the water vapor. For other total and partial pressures the emissivities are corrected by multiplying C_{CO_2} (Fig. 27) and C_{H_2O} (Fig. 28), respectively, to ϵ_{CO_2} and ϵ_{H_2O} which are found from Figs. 25 and 26.

These results can be applied when water vapor or carbon dioxide appear separately or in a mixture with other nonparticipating gases. For mixtures of CO₂ and water vapor in a nonparticipating gas, the total emissivity of the mixture, ϵ_g , can be estimated from the expression

$$\epsilon_g = C_{CO_2}\epsilon_{CO_2} + C_{H_2O}\epsilon_{H_2O} - \Delta\epsilon$$

where $\Delta\epsilon$ is a correction factor given in Fig. 29.

Radiative Exchange between Gas Volume and Black Enclosure of Uniform Temperature When radiative energy is exchanged between a gas volume and a black enclosure, the exchange per unit area, q'' , for a gas volume at uniform temperature, T_g , and a

uniform wall temperature, T_w , is given by

$$q'' = \epsilon_g(T_g)\sigma T_g^4 - \alpha_g(T_w)\sigma T_w^4$$

where $\epsilon_g(T_g)$ is the gas emissivity at a temperature T_g and $\alpha_g(T_w)$ is the absorptivity of gas for the radiation from the black enclosure at T_w . As a result of the nature of the band structure of the gas, the absorptivity, α_g , for black radiation at a temperature T_w is different from the emissivity, ϵ_g , at a gas temperature of T_g . When a mixture of carbon dioxide and water vapor is present, the empirical expression for α_g is

$$\alpha_g = \alpha_{CO_2} + \alpha_{H_2O} - \Delta\alpha$$

where

$$\alpha_{CO_2} = C_{CO_2}\epsilon'_{CO_2} \left(\frac{T_g}{T_w}\right)^{0.65}$$

$$\alpha_{H_2O} = C_{H_2O}\epsilon'_{H_2O} \left(\frac{T_g}{T_w}\right)^{0.45}$$

where $\Delta\alpha = \Delta\epsilon$ and all properties are evaluated at T_w .

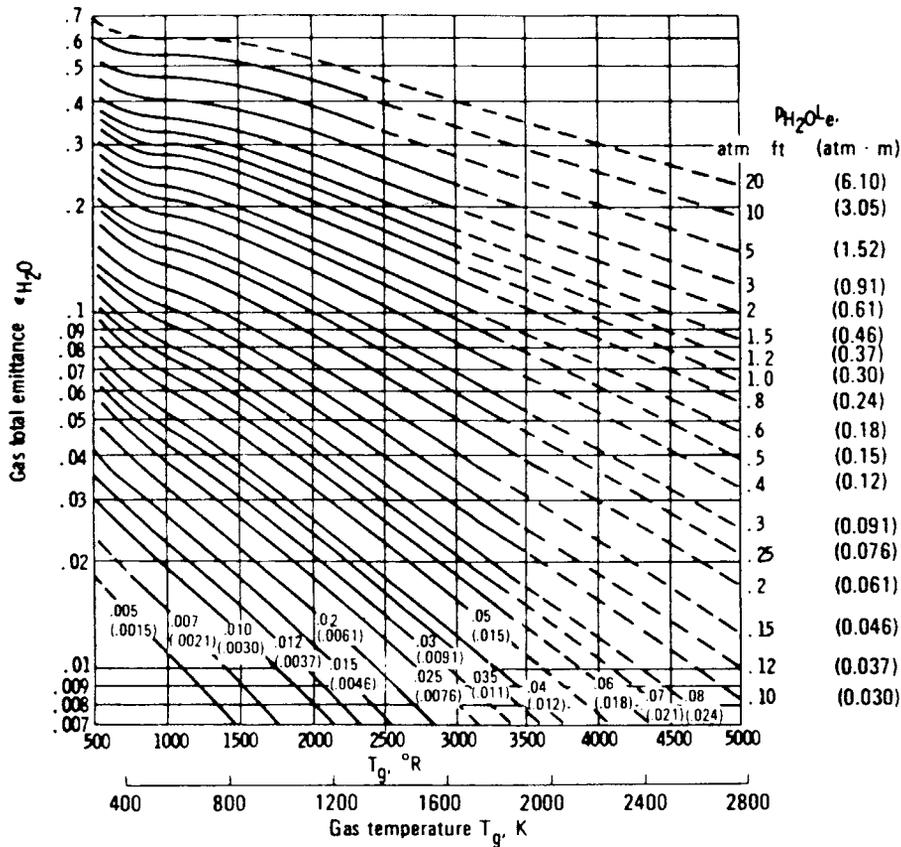

Fig. 26 Total emissivity of H_2O at 1 atm total pressure and zero partial pressure (From Ref. 21. Used with the permission of McGraw-Hill Book Company.)

In this expression, the values of ε'_{CO_2} and ε'_{H_2O} can be found from Figs. 25 and 26 using an abscissa of T_w , but substituting the parameters $p_{CO_2} L_e T_w / T_g$ and $p_{H_2O} L_e T_w / T_g$ for $p_{CO_2} L_e$ and $p_{H_2O} L_e$, respectively.

Radiative Exchange between a Gray Enclosure and a Gas Volume When the emissivity of the enclosure, ε_w , is larger than 0.8, the rate of heat transfer may be approximated by

$$q_{\text{gray}} = \left(\frac{\varepsilon_w + 1}{2} \right) q_{\text{black}}$$

where q_{gray} is the heat transfer rate for gray enclosure and q_{black} is that for black enclosure. For values of $\varepsilon_w < 0.8$, the band structures of the participating gas must be taken into account for heat transfer calculations.

4 BOILING AND CONDENSATION HEAT TRANSFER

Boiling and condensation are both forms of convection in which the fluid medium is undergoing a change of phase. When a liquid comes into contact with a solid surface maintained at a temperature above the saturation temperature of the liquid, the liquid may vaporize, resulting in boiling. This process is always accompanied by a change of phase, from the liquid to the vapor state, and results in large rates of heat transfer from the solid surface, due to the latent heat of vaporization of the liquid. The process of condensation is usually accomplished by allowing the vapor to come into contact with a surface at a temperature below the saturation temperature of the vapor, in which case the liquid undergoes a change in state from the vapor state to the liquid state, giving up the latent heat of vaporization.

The heat transfer coefficient for condensation and boiling are generally larger than that for convection

Table 22 Mean Beam Length^a

Geometry of Gas Volume	Characteristic Length	L_e
Hemisphere radiating to element at center of base	Radius R	R
Sphere radiating to its surface	Diameter D	$0.65D$
Circular cylinder of infinite height radiating to concave bounding surface	Diameter D	$0.95D$
Circular cylinder of semi-infinite height radiating to:		
Element at center of base	Diameter D	$0.90D$
Entire base	Diameter D	$0.65D$
Circular cylinder of height equal to diameter radiating to:		
Element at center of base	Diameter D	$0.71D$
Entire surface	Diameter D	$0.60D$
Circular cylinder of height equal to two diameters radiating to:		
Plane end	Diameter D	$0.60D$
Concave surface	Diameter D	$0.76D$
Entire surface	Diameter D	$0.73D$
Infinite slab of gas radiating to:		
Element on one face	Slab thickness D	$1.8D$
Both bounding planes	Slab thickness D	$1.8D$
Cube radiating to a face	Edge X	$0.6X$
Gas volume surrounding an infinite tube bundle and radiating to a single tube:		
Equilateral triangular array: $S = 2D$	Tube diameter D and spacing between tube centers, S	$3.0(S - D)$
$S = 3D$		$3.8(S - D)$
Square array: $S = 2D$		$3.5(S - D)$

^aAdapted from Ref. 19.

without phase change, sometimes by as much as several orders of magnitude. Application of boiling and condensation heat transfer may be seen in a closed-loop power cycle or in a device referred to as a *heat pipe*, which will be discussed in the following section.

In power cycles, the liquid is vaporized in a boiler at high pressure and temperature. After producing work by means of expansion through a turbine, the vapor is condensed to the liquid state in a condenser and then returned to the boiler where the cycle is repeated.

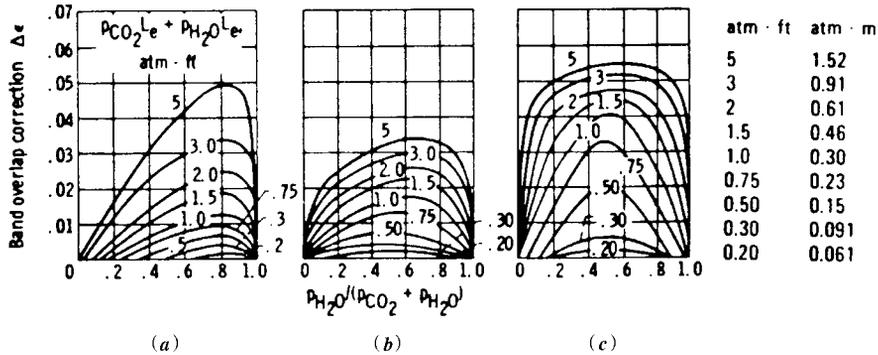

Fig. 29 Correction on total emissivity for band overlap when both CO_2 and water vapor are present: (a) gas temperature $T_g = 400$ K ($720^\circ R$); (b) gas temperature $T_g = 810$ K ($1460^\circ R$); (c) gas temperature $T_g = 1200$ K ($2160^\circ R$). (Adapted from Ref. 21. Used with the permission of McGraw-Hill Book Company.)

4.1 Boiling

The formation of vapor bubbles on a hot surface in contact with a quiescent liquid without external agitation is called *pool boiling*. This differs from *forced-convection boiling* in which forced convection occurs simultaneously with boiling. When the temperature of the liquid is below the saturation temperature, the process is referred to as *subcooled boiling*. When the liquid temperature is maintained or exceeds the saturation temperature, the process is referred to as *saturated or saturation boiling*. Figure 30 depicts the surface heat flux q'' , as a function of the excess temperature, $\Delta T_e = T_s - T_{sat}$, for typical pool boiling of water using an electrically heated wire. In the region $0 < \Delta T_e < \Delta T_{e,A}$ bubbles occur only on selected spots of

the heating surface, and the heat transfer occurs primarily through free convection. This process is called *free-convection boiling*. When $\Delta T_{e,A} < \Delta T_e < \Delta T_{e,C}$, the heated surface is densely populated with bubbles, and the bubble separation and eventual rise due to buoyancy induce a considerable stirring action in the fluid near the surface. This stirring action substantially increases the heat transfer from the solid surface. This process or region of the curve is referred to as *nucleate boiling*. When the excess temperature is raised to $\Delta T_{e,C}$, the heat flux reaches a maximum value, and further increases in the temperature will result in a decrease in the heat flux. The point at which the heat flux is at a maximum value, is called the *critical heat flux*.

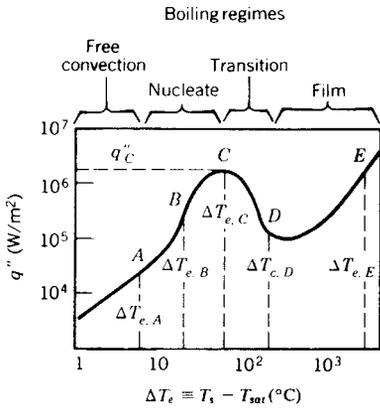

Fig. 30 Typical boiling curve for a wire in a pool of water at atmospheric pressure.

Film boiling occurs in the region where $\Delta T_e > \Delta T_{e,D}$, and the entire heating surface is covered by a vapor film. In this region the heat transfer to the liquid is caused by conduction and radiation through the vapor. Between points C and D, the heat flux decreases with increasing ΔT_e . In this region, part of the surface is covered by bubbles and part by a film. The vaporization in this region is called *transition boiling* or *partial film boiling*. The point of maximum heat flux point C, is called the *burnout point* or the *Linden frost point*. Although it is desirable to operate the vapor generators at heat fluxes close to q''_c , to permit the maximum use of the surface area, in most engineering applications it is necessary to control the heat flux and great care is taken to avoid reaching this point. The primary reason for this is that, as illustrated, when the heat flux is increased gradually, the temperature rises steadily until point C is reached. Any increase of heat flux beyond the value of q''_c , however, will dramatically change the surface temperature to $T_s = T_{sat} + T_{e,E}$, typically exceeding the solid melting point and leading to failure of the material in which the liquid is held or from which the heater is fabricated.

Nucleate Pool Boiling The heat flux data are best correlated by²⁶

$$q'' = \mu_l h_{fg} \left[\frac{g(\rho_l - \rho_v)}{g_c \sigma} \right]^{1/2} \left(\frac{c_{p,l} \Delta T_e}{Ch_{fg} Pr_l^{1.7}} \right)^3$$

where the subscripts *l* and *v* denote saturated liquid and vapor, respectively. The surface tension of the liquid is σ (N/m). The quantity g_c is the proportionality constant equal to $1 \text{ kg}\cdot\text{m}/\text{N}\cdot\text{s}^2$. The quantity g is the local gravitational acceleration in m/s^2 . The values of C are given in Table 23. The above equation may be applied to different geometries, such as plates, wire, or cylinders.

The *critical heat flux* (point C of Fig. 30) is given by²⁸

$$q''_c = \frac{\pi}{24} h_{fg} \rho_v \left[\frac{\sigma g g_c (\rho_l - \rho_v)}{\rho_v^2} \right]^{0.25} \left(1 + \frac{\rho_v}{\rho_l} \right)^{0.5}$$

For a water–steel combination, $q''_c \approx 1290 \text{ kW}/\text{m}^2$ and $\Delta T_{e,c} \approx 30^\circ\text{C}$. For water–chrome-plated copper, $q''_c \approx 940\text{--}1260 \text{ kW}/\text{m}^2$ and $\Delta T_{e,c} \approx 23\text{--}28^\circ\text{C}$.

Film Pool Boiling The heat transfer from the surface to the liquid is due to both convection and radiation. A total heat transfer coefficient is defined by the combination of convection and radiation heat transfer coefficient of the following form²⁹ for the outside surfaces of horizontal tubes:

$$h^{4/3} = h_c^{4/3} + h_r h^{1/3}$$

where

$$h_c = 0.62 \left[\frac{k_v^3 \rho_v (\rho_l - \rho_v) g (h_{fg} + 0.4 c_{p,v} \Delta T_e)}{\mu_v D \Delta T_e} \right]^{1/4}$$

and

$$h_r = \frac{5.73 \times 10^{-8} \epsilon (T_s^4 - T_{sat}^4)}{T_s - T_{sat}}$$

The vapor properties are evaluated at the film temperature $T_f = (T_s + T_{sat})/2$. The temperatures T_s and T_{sat} are in kelvins for the evaluation of h_r . The emissivity of the metallic solids can be found from Table 17. Note that $q = hA (T_s - T_{sat})$.

Nucleate Boiling in Forced Convection The total heat transfer rate can be obtained by simply superimposing the heat transfer due to nucleate boiling and forced convection:

$$q'' = q''_{\text{boiling}} + q''_{\text{forced convection}}$$

Table 23 Values of the Constant C for Various Liquid–Surface Combinations

Fluid-Heating Surface Combinations	C
Water with polished copper, platinum, or mechanically polished stainless steel	0.0130
Water with brass or nickel	0.006
Water with ground and polished stainless steel	0.008
Water with Teflon-plated stainless steel	0.008

For forced convection, it is recommended that the coefficient 0.023 be replaced by 0.014 in the Dittus–Boelter equation (Section 2.1). The above equation is generally applicable to forced convection where the bulk liquid temperature is subcooled (*local forced convection boiling*).

Simplified Relations for Boiling in Water For *nucleate boiling*,³⁰

$$h = C(\Delta T_e)^n \left(\frac{p}{p_a} \right)^{0.4}$$

where p and p_a are, respectively, the system pressure and standard atmospheric pressure. The constants C and n are listed in Table 24.

For *local forced convection boiling inside vertical tubes*, valid over a pressure range of 5–170 atm,³¹

$$h = 2.54(\Delta T_e)^3 e^{p/1.551}$$

where h has the unit $\text{W/m}^2 \cdot ^\circ\text{C}$, ΔT_e is in $^\circ\text{C}$, and p is the pressure in 10^6 N/m^2 .

4.2 Condensation

Depending on the surface conditions, the condensation may be a *film condensation* or a *dropwise condensation*. Film condensation usually occurs when a vapor, relatively free of impurities, is allowed to condense on a clean, uncontaminated surface. Dropwise condensation occurs on highly polished surfaces or on surfaces coated with substances that inhibit wetting. The condensate provides a resistance to heat transfer between the vapor and the surface. Therefore, it is desirable to use short vertical surfaces or horizontal cylinders to prevent the condensate from growing too thick. The heat transfer rate for dropwise condensation is usually an order of magnitude larger than that for film condensation under similar conditions. Silicones, Teflon and certain fatty acids can be used to coat the surfaces to promote dropwise condensation. However, such coatings may lose their effectiveness owing to oxidation or outright removal. Thus, except under carefully controlled conditions, film condensation may be expected to occur in most instances, and the condenser design calculations are often based on the assumption of film condensation.

For condensation on the surface at temperature T_s , the total heat transfer rate to the surface is given by $q = \bar{h}_L A (T_{\text{sat}} - T_s)$, where T_{sat} is the saturation temperature of the vapor. The mass flow rate is determined by $\dot{m} = q/h_{fg}$; h_{fg} is the latent heat of vaporization of the fluid (see Table 25 for saturated water). Correlations are based on the evaluation of liquid properties at $T_f = (T_s + T_{\text{sat}})/2$, except h_{fg} , which is to be taken at T_{sat} .

Film Condensation on a Vertical Plate The Reynolds number for *condensate flow* is defined by $\text{Re}_\Gamma = \rho_l V_m D_h / \mu_l$, where ρ_l and μ_l are the density and viscosity of the liquid, V_m is the average velocity of condensate, and D_h is the hydraulic diameter defined by $D_h = 4 \times$ condensate film cross-sectional area/wetted perimeter. For the condensation on a vertical plate $\text{Re}_\Gamma = 4\Gamma / \mu_l$, where Γ is the mass flow rate of condensate per unit width evaluated at the lowest point on the condensing surface. The condensate flow is generally considered to be laminar for $\text{Re}_\Gamma < 1800$, and turbulent for $\text{Re}_\Gamma > 1800$. The average Nusselt number is given by²²

$$\overline{\text{Nu}}_L = \begin{cases} 1.13 \left[\frac{g\rho_l(\rho_l - \rho_v)h_{fg}L^3}{\mu_l k_l (T_{\text{sat}} - T_s)} \right]^{0.25} & \text{for } \text{Re}_\Gamma < 1800 \\ 0.0077 \left[\frac{g\rho_l(\rho_l - \rho_v)L^3}{\mu_l^2} \right]^{1/3} \text{Re}_\Gamma^{0.4} & \text{for } \text{Re}_\Gamma > 1800 \end{cases}$$

Film Condensation on the Outside of Horizontal Tubes and Tube Banks

$$\overline{\text{Nu}}_D = 0.725 \left[\frac{g\rho_l(\rho_l - \rho_v)h_{fg}D^3}{N\mu_l k_l (T_{\text{sat}} - T_s)} \right]^{0.25}$$

where N is the number of horizontal tubes placed one above the other; $N = 1$ for a single tube.²³

Film Condensation Inside Horizontal Tubes For low vapor velocities such that Re_D based on the vapor velocities at the pipe inlet is less than 3500²⁴

$$\overline{\text{Nu}}_D = 0.555 \left[\frac{g\rho_l(\rho_l - \rho_v)h'_{fg}D^3}{\mu_l k_l (T_{\text{sat}} - T_s)} \right]^{0.25}$$

where $h'_{fg} + \frac{3}{8}C_{p,l}(T_{\text{sat}} - T_s)$. For higher flow rate,²⁵ $\text{Re}_G > 5 \times 10^4$,

$$\overline{\text{Nu}}_D = 0.0265 \text{Re}_G^{0.8} \text{Pr}^{1/3}$$

where the Reynolds number $\text{Re}_G = GD/\mu_l$ is based on the equivalent mass velocity $G = G_l + G_v(\rho_l/\rho_v)^{0.5}$. The mass velocity for the liquid G_l and that for vapor G_v are calculated as if each occupied the entire flow area.

Effect of Noncondensable Gases If noncondensable gas such as air is present in a vapor, even in a small amount, the heat transfer coefficient for condensation may be greatly reduced. It has been found that the presence of a few percent of air by volume in steam reduces the coefficient by 50% or more. Therefore, it is desirable in the condenser design to vent the noncondensable gases as much as possible.

4.3 Heat Pipes

Heat pipes are two-phase heat transfer devices that operate on a closed two-phase cycle³² and come in a wide variety of sizes and shapes.^{33,34} As shown in Fig. 31, they typically consist of three distinct regions: the evaporator or heat addition region, the condenser or heat rejection region, and the adiabatic or isothermal region. Heat added to the evaporator region of the container causes the working fluid in the evaporator wicking structure to be vaporized. The

high temperature and corresponding high pressure in this region result in flow of the vapor to the other, cooler end of the container where the vapor condenses, giving up its latent heat of vaporization. The capillary forces existing in the wicking structure then pump the liquid back to the evaporator section. Other similar devices, referred to as two-phase thermosyphons have no wick, and utilize gravitational forces to provide the liquid return. Thus, the heat pipe functions as a nearly isothermal device, adjusting the evaporation rate to accommodate a wide range of power inputs, while maintaining a relatively constant source temperature.

Transport Limitations The transport capacity of a heat pipe is limited by several important mechanisms. Among these are the capillary wicking limit, viscous limit, sonic limit, entrainment, and boiling limits. The capillary wicking limit and viscous limits deal with the pressure drops occurring in the liquid and vapor phases, respectively. The sonic limit results from the occurrence of choked flow in the vapor passage, while the entrainment limit is due to the high liquid vapor shear forces developed when the vapor passes in counterflow over the liquid saturated wick. The boiling limit is reached when the heat flux applied in the evaporator portion is high enough that nucleate boiling occurs in the evaporator wick, creating vapor bubbles that partially block the return of liquid.

To function properly, the net capillary pressure difference between the condenser and the evaporator in a heat pipe must be greater than the pressure losses throughout the liquid and vapor flow paths. This

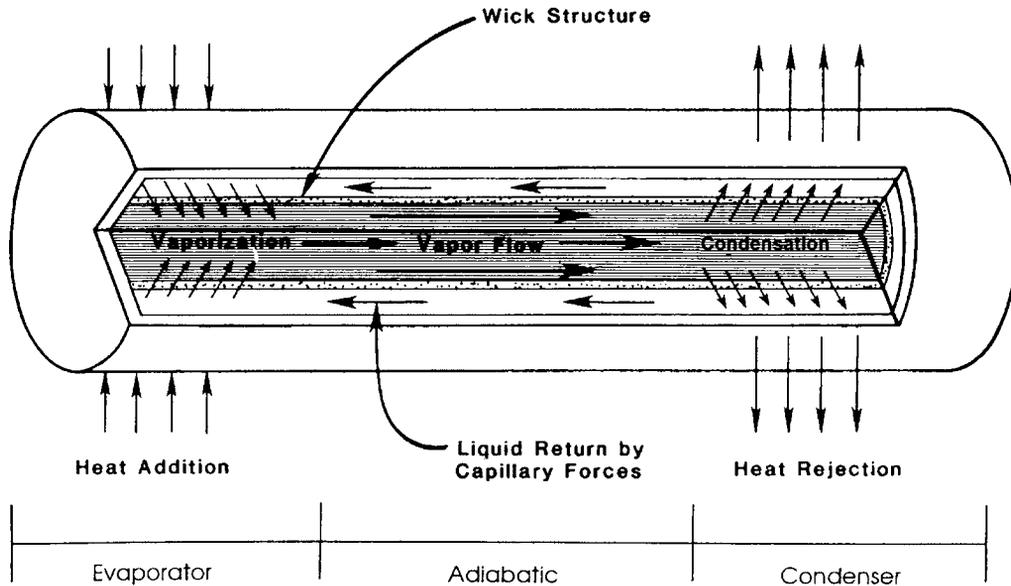

Fig. 31 Typical heat pipe construction and operation.³⁵

relationship can be expressed as

$$\Delta P_c \geq \Delta P_+ + \Delta P_- + \Delta P_l + \Delta P_v$$

- where ΔP_c = net capillary pressure difference
- ΔP_+ = normal hydrostatic pressure drop
- ΔP_- = axial hydrostatic pressure drop
- ΔP_l = viscous pressure drop occurring in the liquid phase
- ΔP_v = viscous pressure drop occurring in the vapor phase

If these conditions are not met, the heat pipe is said to have reached the *capillary limitation*.

Expressions for each of these terms have been developed for steady-state operation, and are summarized below.

Capillary pressure:
$$\Delta P_{c,m} = \left(\frac{2\sigma}{r_{c,e}} \right)$$

Values for the effective capillary radius, r_c , can be found theoretically for simple geometries or experimentally for pores or structures of more complex geometry. Table 26 gives values for some common wicking structures.

Normal and axial hydrostatic pressure drop

$$\Delta P_+ + \rho_l g d_v \cos \psi$$

$$\Delta P_- = \rho_l g L \sin \psi$$

In a gravitational environment, the axial hydrostatic pressure term may either assist or hinder the capillary pumping process, depending on whether the tilt of the heat pipe promotes or hinders the flow of liquid back to the evaporator (i.e., the evaporator lies either below or above the condenser). In a zero-g environment, both this term and the normal hydrostatic pressure drop term can be neglected because of the absence of body forces.

Liquid pressure drop
$$\Delta P_l = \left(\frac{\mu_l}{K A_w h_{fg} \rho_l} \right) L_{\text{eff}} q$$

where L_{eff} is the effective heat pipe length defined as

$$L_{\text{eff}} = 0.5L_e + L_a + 0.5L_c$$

and K is the liquid permeability as shown in Table 27.

Vapor pressure drop
$$\Delta P_v = \left[\frac{C(f_v \text{Re}_v) \mu_v}{2(r_{h,v})^2 A_v \rho_v h_{fg}} \right] L_{\text{eff}} q$$

Although during steady-state operation the liquid flow regime is always laminar, the vapor flow may be either laminar or turbulent. It is therefore necessary to determine the vapor flow regime as a function of the heat flux. This can be accomplished by evaluating the local axial Reynolds and Mach numbers and substituting the values as shown below:

$$\text{Re}_v < 2300 \quad \text{Ma}_v < 0.2$$

$$(f_v \text{Re}_v) = 16$$

$$C = 1.00$$

$$\text{Re}_v < 2300 \quad \text{Ma}_v > 0.2$$

$$(f_v \text{Re}_v) = 16$$

$$C = \left[1 + \left(\frac{\gamma_v - 1}{2} \right) \text{Ma}_v^2 \right]^{1/2}$$

$$\text{Re}_v > 2300 \quad \text{Ma}_v < 0.2$$

$$(f_v \text{Re}_v) = 0.038 \left[\frac{2(r_{h,v})q}{A_v \mu_v h_{fg}} \right]^{3/4}$$

$$C = 1.00$$

$$\text{Re}_v > 2300 \quad \text{Ma}_v > 0.2$$

$$(f_v \text{Re}_v) = 0.038 \left[\frac{2(r_{h,v})q}{A_v \mu_v h_{fg}} \right]^{3/4}$$

$$C = \left[1 + \left(\frac{\gamma_v - 1}{2} \right) \text{Ma}_v^2 \right]^{-1/2}$$

Table 26 Expressions for the Effective Capillary Radius for Several Wick Structures

Structure	r_c	Data
Circular cylinder (artery or tunnel wick)	r	r = radius of liquid flow passage
Rectangular groove	ω	ω = groove width
Triangular groove	$\omega / \cos \beta$	ω = groove width β = half-included angle
Parallel wires	ω	ω = wire spacing
Wire screens	$(\omega + d_\omega) / 2 = \frac{1}{2} N$	d = wire diameter N = screen mesh number
Packed spheres	$0.41 r_s$	ω = wire spacing r_s = sphere radius

Table 27 Wick Permeability for Several Wick Structures

Structure	K	Data
Circular cylinder (artery or tunnel wick)	$r^2/8$	$r =$ radius of liquid flow passage
Open rectangular grooves	$2\varepsilon(r_{h,i})^2/(f_l Re_l) = \omega/s$	$\varepsilon =$ wick porosity $\omega =$ groove width $s =$ groove pitch $\delta =$ groove depth $(r_{h,i}) = 2\omega\delta/(\omega + 2\delta)$
Circular annular wick	$2(r_{h,i})^2/(f_l Re_l)$	$(r_{h,i}) = r_1 - r_2$
Wrapped screen wick	$1/22 d_\omega^2 \varepsilon^3 / (1 - \varepsilon)^2$	$d_\omega =$ wire diameter $\varepsilon = 1 - (1.05\pi N d_\omega / 4)$ $N =$ mesh number
Packed sphere	$1/37.5 r_s^2 \varepsilon^3 / (1 - \varepsilon)^2$	$r_s =$ sphere radius $\varepsilon =$ porosity (dependent on packing mode)

Since the equations used to evaluate both the Reynolds number and the Mach number are functions of the heat transport capacity, it is necessary to first assume the conditions of the vapor flow. Using these assumptions, the maximum heat capacity, $q_{c,m}$, can be determined by substituting the values of the individual pressure drops into Eq. (1) and solving for $q_{c,m}$. Once the value of $q_{c,m}$ is known, it can then be substituted into the expressions for the vapor Reynolds number and Mach number to determine the accuracy of the original assumption. Using this iterative approach, accurate values for the capillary limitation as a function of the operating temperature can be determined in units of W-m or watts for $(qL)_{c,m}$ and $q_{c,m}$, respectively.

The *viscous limitation* in heat pipes occurs when the viscous forces within the vapor region are dominant and limit the heat pipe operation:

$$\frac{\Delta P_v}{P_v} < 0.1$$

for determining when this limit might be of a concern. Due to the operating temperature range, this limitation will normally be of little consequence in the design of heat pipes for use in the thermal control of electronic components and devices.

The *sonic limitation* in heat pipes is analogous to the sonic limitation in a converging-diverging nozzle and can be determined from

$$q_{s,m} = A_v \rho_v h_{fg} \left[\frac{\gamma_v R_v T_v}{2(\gamma_v + 1)} \right]^{1/2}$$

where T_v is the mean vapor temperature within the heat pipe.

Since the liquid and vapor flow in opposite directions in a heat pipe, at high enough vapor velocities, liquid droplets may be picked up or entrained in the vapor flow. This entrainment results in excess liquid

accumulation in the condenser and, hence, dryout of the evaporator wick. Using the Weber number, We , define We as the ratio of the viscous shear force to the force resulting from the liquid surface tension, an expression for the *entrainment limit* can be found as

$$q_{e,m} = A_v h_{fg} \left[\frac{\sigma \rho_v}{2(r_{h,w})} \right]^{1/2}$$

where $(r_{h,w})$ is the hydraulic radius of the wick structure, define We as twice the area of the wick pore at the wick-vapor interface divided by the wetted perimeter at the wick-vapor interface.

The *boiling limit* occurs when the input heat flux is so high that nucleate boiling occurs in the wicking structure and bubbles may become trapped in the wick, blocking the liquid return and resulting in evaporator dryout. This phenomenon, referred to as the boiling limit, differs from the other limitations previously discussed in that it depends on the evaporator heat flux as opposed to the axial heat flux. This expression, which is a function of the fluid properties, can be written as

$$q_{b,m} = \left[\frac{2\pi L_{\text{eff}} k_{\text{eff}} T_v}{h_{fg} \rho_v \ln(r_i/r_n)} \right] \left(\frac{2\sigma}{r_n} - \Delta P_{c,m} \right)$$

where k_{eff} is the effective thermal conductivity of the liquid-wick combination, given in Table 28, r_i is the inner radius of the heat pipe wall, and r_n is the nucleation site radius. After the power level associated with each of the four limitations is established, determination of the maximum heat transport capacity is only a matter of selecting the lowest limitation for any given operating temperature.

Heat Pipe Thermal Resistance The *heat pipe thermal resistance* can be found using an analogous electrothermal network. Figure 32 illustrates the

Table 28 Effective Thermal Conductivity for Liquid-Saturated Wick Structures

Wick Structures	k_{eff}
Wick and liquid in series	$\frac{k_l k_w}{\epsilon k_w + k_l(1 - \epsilon)}$
Wick and liquid in parallel	$\epsilon k_l + k_w(1 - \epsilon)$
Wrapped screen	$\frac{k_l[(k_l + k_w) - (1 - \epsilon)(k_l - k_w)]}{(k_l + k_w) + (1 - \epsilon)(k_l - k_w)}$
Packed spheres	$\frac{k_l[(2k_l + k_w) - 2(1 - \epsilon)(k_l - k_w)]}{(2k_l + k_w) + (1 - \epsilon)(k_l - k_w)}$
Rectangular grooves	$\frac{(w_f k_l k_w \delta) + w k_l (0.185 w_f k_w + \delta k_l)}{(w + w_f)(0.185 w_f k_f + \delta k_l)}$

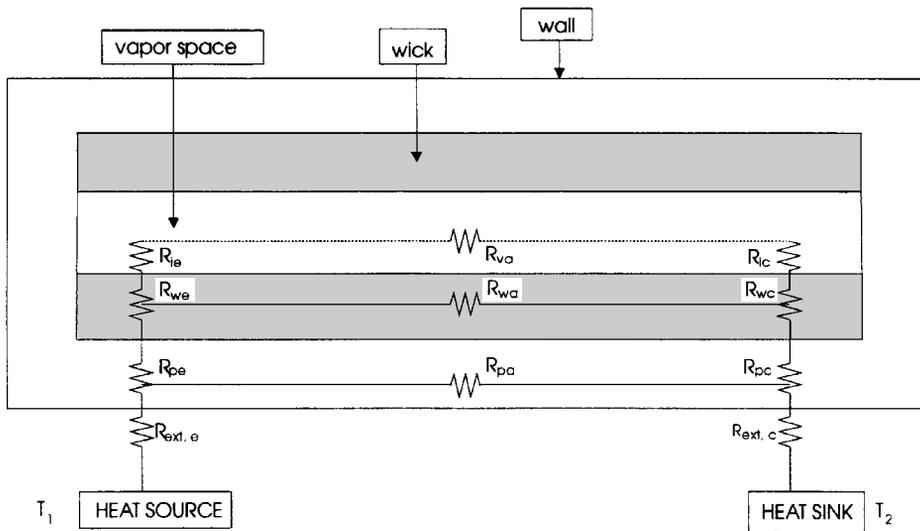

Fig. 32 Equivalent thermal resistance of heat pipe.

electrothermal analog for the heat pipe illustrated in Fig. 31. As shown, the overall thermal resistance is composed of nine different resistances arranged in a series/parallel combination, which can be summarized as follows:

- R_{pe} Radial resistance of pipe wall at evaporator
- R_{we} Resistance of liquid–wick combination at evaporator
- R_{ie} Resistance of liquid–vapor interface at evaporator
- R_{ya} Resistance of adiabatic vapor section
- R_{pa} Axial resistance of pipe wall
- R_{wa} Axial resistance of liquid–wick combination
- R_{ic} Resistance of liquid–vapor interface at condenser

- R_{wc} Resistance of liquid–wick combination at condenser
- R_{pc} Radial resistance of pipe wall at condenser

Because of the comparative magnitudes of the resistance of the vapor space and the axial resistances of the pipe wall and liquid–wick combinations, the axial resistance of both the pipe wall and the liquid–wick combination may be treated as open circuits and neglected. Also, because of the comparative resistances, the liquid–vapor interface resistances and the axial vapor resistance can, in most situations, be assumed to be negligible. This leaves only the pipe wall radial resistances and the liquid–wick resistances at both the evaporator and condenser. The radial resistances at the pipe wall can be computed from Fourier’s

law as

$$R_{pe} = \frac{\delta}{k_p A_e}$$

for f at plates, where δ is the plate thickness and A_e is the evaporator area, or

$$R_{pe} = \frac{\ln(D_o/D_i)}{2\pi L_e k_p}$$

for cylindrical pipes, where L_e is the evaporator length. An expression for the equivalent thermal resistance of the liquid-wick combination in circular pipes is

$$R_{we} = \frac{\ln(D_o/D_i)}{2\pi L_e k_{\text{eff}}}$$

where values for the effective conductivity, k_{eff} , can be found in Table 28. The adiabatic vapor resistance, although usually negligible, can be found as

$$R_{va} = \frac{T_v(P_{v,e} - P_{v,c})}{\rho_v h_{fg} q}$$

where $P_{v,e}$ and $P_{v,c}$ are the vapor pressures at the evaporator and condenser. Combining these individual resistances provides a mechanism by which the overall thermal resistance can be computed and hence the temperature drop associated with various axial heat fluxes can be computed.

1 INTRODUCTION

1.1 Overview

The purpose of this chapter is to introduce the analysis and design of linear circuits. Circuits are important in electrical engineering because they process electrical signals that carry energy and information. For the present a *circuit* is defined as an interconnection of electrical devices and a *signal* as a time-varying electrical quantity. A modern technological society is intimately dependent on the generation, transfer, and conversion of electrical energy. Recording media like CDs, DVDs, thumb drives, hard drives, and tape-based products; communication systems like radar, cell phones, radio, television, and the Internet; information systems like computers and the world wide web; instrumentation and control systems; and the national electrical power grid all involve circuits that process

and transfer signals carrying either energy or information or both.

This chapter will focus on *linear circuits*. An important feature of a linear circuit is that the amplitude of the output signal is proportional to the input signal amplitude. The proportionality property of linear circuits greatly simplifies the process of circuit analysis and design. Most circuits are only linear within a restricted range of signal levels. When driven outside this range, they become nonlinear and proportionality no longer applies. Hence only circuits operating within their linear range will be studied.

An important aspect of this study involves interface circuits. An *interface* is defined as a pair of accessible terminals at which signals may be observed or specified. The interface concept is especially important with integrated circuit (IC) technology. Integrated circuits involve many thousands of interconnections, but only

Table 1 Some Important Quantities, Symbols, and Unit Abbreviations

Quantity	Symbol	Unit	Unit Abbreviation
Time	t	Second	s
Frequency	f	Hertz	Hz
Radian frequency	ω	Radians per second	rad/s
Phase angle	θ, φ	Degree or radian	$^\circ$ or rad
Energy	w	Joule	J
Power	p	Watt	W
Charge	q	Coulomb	C
Current	i	Ampere	A
Electric field	\mathcal{E}	Volt per meter	V/m
Voltage	v	Volt	V

a small number are accessible to the user. Creating systems using ICs involves interconnecting large circuits at a few accessible terminals in such a way that the circuits are compatible. Ensuring compatibility often involves relatively small circuits whose purpose is to change signal levels or formats. Such interface circuits are intentionally introduced to ensure that the appropriate signal conditions exist at the connections between two larger circuits.

In terms of signal processing, *analysis* involves determining the output signals of a given circuit with known input signals. Analysis has the compelling feature that a unique solution exists in linear circuits. Circuit analysis will occupy the bulk of the study of linear circuits, since it provides the foundation for understanding the interaction of signals and circuits. *Design* involves devising circuits that perform a prescribed signal-processing function. In contrast to analysis, a design problem may have no solution or several solutions. The latter possibility leads to *evaluation*. Given several circuits that perform the same basic function, the alternative designs are rank ordered using factors such as cost, power consumption, and part counts. In reality the engineer's role involves analysis, design, and evaluation, and the boundaries between these functions are often blurred.

There are some worked examples to help the reader understand how to apply the concepts needed to master the concepts covered. These examples describe in detail the steps needed to obtain the final answer. They usually treat analysis problems, although design examples and application notes are included where appropriate.

Symbols and Units This chapter uses the International System (SI) of units. The SI units include six fundamental units: meter (m), kilogram (kg), second (s), ampere (A), kelvin (K), and candela (cd). All the other units can be derived from these six. Table 1 contains the quantities important to this chapter.

Numerical values encountered in electrical engineering range over many orders of magnitude. Consequently, the system of standard decimal prefixes in Table 2 is used. These prefixes on the unit abbreviation of a quantity indicate the power of 10 that is applied to the numerical value of the quantity.

Circuit Variables The underlying physical quantities in the study of electronic systems are two basic

Table 2 Standard Decimal Prefixes

Multiplier	Prefix	Abbreviation
10^{18}	Exa	E
10^{15}	Peta	P
10^{12}	Tera	T
10^9	Giga	G
10^6	Mega	M
10^3	Kilo	k
10^{-1}	Deci	d
10^{-2}	Centi	c
10^{-3}	Milli	m
10^{-6}	Micro	μ
10^{-9}	Nano	n
10^{-12}	Pico	p
10^{-15}	Femto	f
10^{-18}	Atto	a

variables, *charge* and *energy*. The concept of electrical charge explains the very strong electrical forces that occur in nature. To explain both attraction and repulsion, we say there are two kinds of charge—positive and negative. Like charges repel while unlike charges attract. The symbol q is used to represent charge. If the amount of charge is varying with time, we emphasize the fact by writing $q(t)$. In SI charge is measured in *coulombs* (abbreviated C). The smallest quantity of charge in nature is an electron's charge ($q_E = 1.6 \times 10^{-19}$ C). There are 6.24×10^{18} electrons in 1 C.

Electrical charge is a rather cumbersome variable to work with in practice. Moreover, in many situations the charges are moving, and so it is more convenient to measure the amount of charge passing a given point per unit time. To do this in differential form, a signal variable i called *current* is defined as follows:

$$i = \frac{dq}{dt} \quad (1)$$

Current is a measure of the flow of electrical charge. It is the time rate of change of charge passing a given point. The physical dimensions of current are coulombs per second. The unit of current is the *ampere* (abbreviated A). That is,

$$1 \text{ coulomb per second} = 1 \text{ ampere}$$

In electrical engineering it is customary to define the direction of current as the direction of the net flow of *positive* charges, that is, the opposite of electron flow.

A second signal variable called *voltage* is related to the change in energy that would be experienced by a charge as it passes through a circuit. The symbol w is commonly used to represent energy. Energy carries the units of *joules* (abbreviated J). If a small charge dq were to experience a change in energy dw in passing from point A to point B , then the voltage v between A and B is defined as the change in energy per unit charge. One can express this definition in differential form as

$$v = \frac{dw}{dq} \quad (2)$$

Voltage does not depend on the path followed by the charge dq in moving from point A to point B . Furthermore, there can be a voltage between two points even if there is no charge motion (i.e., no current), since voltage is a measure of how much energy dw would be involved if a charge dq were moved. The dimensions of voltage are joules per coulomb. The unit of voltage is the *volt* (abbreviated V). That is,

$$1 \text{ joule per coulomb} = 1 \text{ volt}$$

A third signal variable, *power*, is defined as the time rate of change of energy:

$$p = \frac{dw}{dt} \quad (3)$$

The dimensions of power are joules per second, which is called a *watt* (abbreviated W). In electrical situations, it is useful to have power expressed in terms of current and voltage. Using the chain rule, Eq. (3) and Eqs. (1) and (2) can be combined as

$$p = \left(\frac{dw}{dq} \right) \left(\frac{dq}{dt} \right) = v \cdot i \quad (4)$$

This shows that the electrical power associated with a situation is determined by the product of voltage and current.

Signal References The three signal variables (current, voltage, and power) are defined in terms of two basic variables (charge and energy). Charge and energy, like mass, length, and time, are basic concepts of physics that provide the scientific foundation for electrical engineering. However, engineering problems rarely involve charge and energy directly but are usually stated in terms of the signal variables because current and voltage are much easier to measure.

A signal can be either a current or a voltage, but it is essential that the reader recognize that current and voltage, while interrelated, are quite different variables. Current is a measure of the time rate of charge passing a point. Since current indicates the direction of the flow of electrical charge, one thinks of current as a *through* variable. Voltage is best thought of as an *across* variable because it inherently involves two points. Voltage is a measure of the net change in energy involved in moving a charge from one point to another. Voltage is measured not at a single point but rather between two points or across an element.

Figure 1 shows the notation used for assigning reference directions to current and voltage. The reference mark for current [the arrow below $i(t)$] does not indicate the actual direction of the current. The actual direction may be reversing a million times per second. However, when the actual direction coincides with the reference direction, the current is positive. When the opposite occurs, the current is negative. If the net flow of positive charge in Fig. 1 is to the right, the current $i(t)$ is positive. Conversely, if the current $i(t)$ is

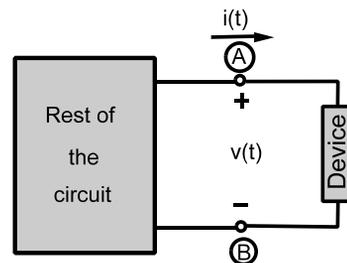

Fig. 1 Voltage and current reference marks for two-terminal device.¹

positive, then the net flow of positive charge is to the right.

Similarly, the voltage reference marks (+ and B symbols) in Fig. 1 do not imply that the potential at the positive terminal is always higher than the potential at the B terminal. However, when this is true, the voltage across the device is positive. When the opposite is true, the voltage is negative.

The importance of relating the reference directions (the plus and minus voltage signs and the current arrows) to the actual direction of the current (in and out) and voltage (high and low) can be used to determine the power associated with a device. That is, if the actual direction of the current is the same as the reference arrow drawn on the device, the current goes “in” and comes “out” of the device in the same direction as the reference arrow. Also, the voltage is “high” at the positive reference and “low” at the negative reference. If the actual and reference directions agree and i and v have the same sign, the power associated with this device is positive since the product of the current and voltage is positive. A positive sign for the associated power indicates that the device absorbs or consumes power. If the actual and reference direction disagrees for either voltage or current so i and v have opposite signs, $p = i \cdot v$ is negative and the device provides power. This definition of reference marks is called the *passive-sign convention*. Certain devices such as heaters (e.g., a toaster) can only absorb power. On the other hand, the power associated with a battery is positive when it is charging (absorbing power) and negative when it is discharging (delivering power). The passive-sign convention is used throughout electrical engineering. It is also the convention used by computer circuit simulation programs.

Ground Voltage as an across variable is defined and measured between two points. It is convenient to identify one of the points as a reference point commonly called *ground*. This is similar to measuring elevation with respect to mean sea level. The heights of mountains, cities, and so on, are given relative to sea level. Similarly, the voltages at all other points in a circuit are defined with respect to ground. Circuit references are denoted using one of the “ground” symbols shown in Fig. 2. The voltage at the ground point is always taken to be 0 V.

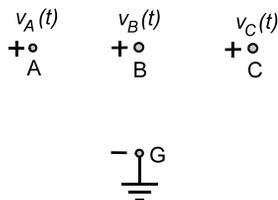

Fig. 2 Ground symbol indicates a common voltage reference point.¹

1.2 Fundamentals

A *circuit* is a collection of interconnected electrical devices that performs a useful function. An electrical *device* is a component that is treated as a distinct entity.

Element Constraints A two-terminal device is described by its i - v *characteristic*, that is, the relationship between the voltage across and current through the device. In most cases the relationship is complicated and nonlinear so we use simpler linear models which adequately approximate the dominant features of a device.

Resistor A resistor is a linear device described by a simple i - v characteristic as follows:

$$v = Ri \quad \text{or} \quad i = Gv \quad (5)$$

where R and G are positive constants related as $G = 1/R$. The power rating of the resistor determines the range over which the i - v characteristic can be represented by this linear relation. Equations (5) are collectively known as *Ohm's law*. The parameter R is called *resistance* and has the unit *ohms* (Ω). The parameter G is called *conductance* with the unit *siemens* (S).

The power associated with the resistor can be found from $p = v \cdot i$. Using Eqs. (5) to eliminate v or i from this relationship yields

$$p = i^2 R = v^2 G = \frac{v^2}{R} \quad (6)$$

Since the parameter R is positive, these equations state that the power is always nonnegative. Under the passive-sign convention this means the resistor always absorbs power.

Example 1. A resistor functions as a linear element as long as the voltage and current are within the limits defined by its power rating. Determine the maximum current and voltage that can be applied to a 47-k Ω resistor with a power rating of 0.25 W and remain within its linear operating range.

Solution. Using Eq. (6) to relate power and current, we obtain

$$I_{\text{MAX}} = \sqrt{\frac{P_{\text{MAX}}}{R}} = \sqrt{\frac{0.25}{47 \times 10^3}} = 2.31 \text{ mA}$$

Similarly, using Eq. (6) to relate power and voltage,

$$V_{\text{MAX}} = \sqrt{R P_{\text{MAX}}} = \sqrt{47 \times 10^3 \times 0.25} = 108 \text{ V}$$

A resistor with infinite resistance, that is, $R = \infty \Omega$, is called an *open circuit*. By Ohm's law no current can flow through such a device. Similarly, a resistor with

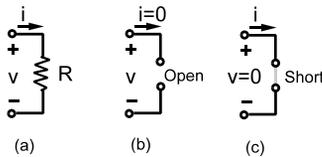

Fig. 3 (a) Resistor symbol; (b) open circuit; (c) short circuit.

no resistance, that is, $R = 0 \Omega$, is called a *short circuit*. The voltage across a short circuit is always zero. In circuit analysis the devices in a circuit are assumed to be interconnected by zero-resistance wire, that is, by short circuits. Figure 3 shows the circuit symbols for a resistor and open and short circuits.

Ideal Sources The signal and power sources required to operate electronic circuits are modeled using two elements: voltage sources and current sources. These sources can produce either constant or time-varying signals. The circuit symbols of an ideal voltage source and an ideal current source are shown in Fig. 4.

The i - v characteristic of an *ideal voltage source* in Fig. 4 is described by the element equations

$$v = v_S \quad \text{and} \quad i = \text{any value} \quad (7)$$

The element equations mean the ideal voltage source produces v_S volts across its terminals and will supply whatever current may be required by the circuit to which it is connected.

The i - v characteristic of an *ideal current source* in Fig. 4 is described by the element equations

$$i = i_S \quad \text{and} \quad v = \text{any value} \quad (8)$$

The ideal current source supplies i_S amperes in the direction of its arrow symbol and will furnish whatever voltage is required by the circuit to which it is connected.

In practice, circuit analysis involves selecting an appropriate model for the actual device. Figure 5 shows the practical models for the voltage and current sources. These models are called practical because they more accurately represent the properties of real-world

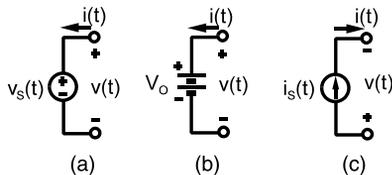

Fig. 4 (a) Voltage source; (b) battery (traditional symbol); (c) current source.

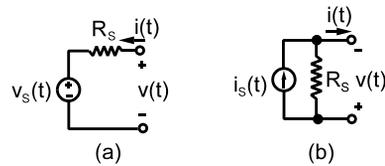

Fig. 5 Circuit symbols for practical independent sources: (a) practical voltage source; (b) practical current source.¹

sources than do the ideal models. The resistances R_S in the practical source models in Fig. 5 do not represent physical resistors but represent circuit elements used to account for resistive effects within the devices being modeled.

Connection Constraints The previous section dealt with individual devices and models while this section considers the constraints introduced by interconnections of devices to form circuits. *Kirchhoff's laws* are derived from conservation laws as applied to circuits and are called *connection constraints* because they are based only on the circuit connections and not on the specific devices in the circuit.

The treatment of Kirchhoff's laws uses the following definitions

A *circuit* is any collection of devices connected at their terminals.

A *node* is an electrical juncture of two or more devices.

A *loop* is a closed path formed by tracing through a sequence of devices without passing through any node more than once.

While it is customary to designate a juncture of two or more elements as a node, it is important to realize that a node is not confined to a point but includes all the wire from the point to each element.

Kirchhoff's Current Law Kirchhoff's first law is based on the principle of conservation of charge. *Kirchhoff's current law* (KCL) states that the algebraic sum of the currents entering a node is zero at every instant. In forming the algebraic sum of currents, one must take into account the current reference directions associated with the devices. If the current reference direction is into the node, a positive sign is assigned to the algebraic sum of the corresponding current. If the reference direction is away from the node, a negative sign is assigned.

There are two signs associated with each current in the application of KCL. The first is the sign given to a current in writing a KCL connection equation. This sign is determined by the orientation of the current reference direction relative to a node. The second sign is determined by the actual direction of the current relative to the reference direction.

The following general principle applies to writing KCL equations: *In a circuit containing N nodes there are only $N - 1$ independent KCL connection equations.* In general, to write these equations, we select one node as the reference or ground node and then write KCL equations at the remaining $N - 1$ non-reference nodes.

Kirchhoff's Voltage Law The second of Kirchhoff's circuit laws is based on the principle of conservation of energy. *Kirchhoff's voltage law (KVL)* states that the algebraic sum of all of the voltages around a loop is zero at every instant. There are two signs associated with each voltage. The first is the sign given the voltage when writing the KVL connection equation. The second is the sign determined by the actual polarity of a voltage relative to its assigned reference polarity.

The following general principle applies to writing KVL equations: *In a circuit containing E two-terminal elements and N nodes there are only $E - N + 1$ independent KVL connection equations.* Voltage equations written around $E - N + 1$ different loops contain all of the independent connection constraints that can be derived from KVL. A sufficient condition for loops to be different is that each contains at least one element that is not contained in any other loop.

Parallel and Series Connections Two types of connections occur so frequently in circuit analysis that they deserve special attention. Elements are said to be connected in *parallel* when they share two common nodes. In a parallel connection KVL forces equal voltages across the elements. The parallel connection is not restricted to two elements.

Two elements are said to be connected in *series* when they have one common node to which no other current-drawing element is connected. A series connection results in equal current through each element. Any number of elements can be connected in series.

Combined Constraints The usual goal of circuit analysis is to determine the currents or voltages at various places in a circuit. This analysis is based on constraints of two distinctly different types. The element constraints are based on the models of the specific devices connected in the circuit. The connection constraints are based on Kirchhoff's laws and the circuit connections. The element equations are independent of the circuit in which the device is connected. Likewise, the connection equations are independent of the specific devices in the circuit. But taken together, the *combined constraints* from the element and connection equations provide the data needed to analyze a circuit.

The study of combined constraints begins by considering the simple but important example in Fig. 6. This circuit is driven by the current source i_S and the resulting responses are current/voltage pairs (i_X, v_X) and (i_O, v_O). The reference marks for the response pairs have been assigned using the passive-sign convention.

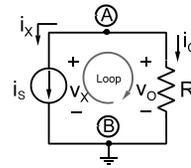

Fig. 6 Circuit used to demonstrate combined constraints.¹

To solve for all four responses, four equations are required. The first two are the element equations:

$$\begin{aligned} \text{Current source: } i_X &= i_S \\ \text{Resistor: } v_O &= R \cdot i_O \end{aligned} \quad (9)$$

The first element equation states that the response current i_X and the input driving force i_S are equal in magnitude and direction. The second element equation is Ohm's law relating v_O and i_O under the passive-sign convention.

The connection equations are obtained by applying Kirchhoff's laws. The circuit in Fig. 6 has two elements ($E = 2$) and two nodes ($N = 2$); hence for a total solution $E - N + 1 = 1$ KVL equation and $N - 1 = 1$ KCL equation are required. Selecting node B as the reference or ground node, a KCL at node A and a KVL around the loop yield

$$\begin{aligned} \text{KCL: } -i_X - i_O &= 0 \\ \text{KVL: } -v_X + v_O &= 0 \end{aligned} \quad (10)$$

With four equations and four unknowns all four responses can be found. Combining the KCL connection equation and the first element equations yields $i_O = -i_X = -i_S$. Substituting this result into the second element equations (Ohm's law) produces $v_O = -Ri_S$. The minus sign in this equation does not mean v_O is always negative. Nor does it mean the resistance is negative since resistance is always positive. It means that when the input driving force i_S is positive, the response v_O is negative, and vice versa.

Example 2. Find all of the element currents and voltages in Fig. 7 for $V_O = 10$ V, $R_1 = 2$ k Ω , and $R_2 = 3$ k Ω .

Solution. Substituting the element constraints into the KVL connection constraint produces

$$-V_O + R_1 i_1 + R_2 i_2 = 0$$

This equation can be used to solve for i_1 since the second KCL connection equation requires that $i_2 = i_1$. Hence

$$i_1 = \frac{V_O}{R_1 + R_2} = \frac{10}{2000 + 3000} = 2 \text{ mA}$$

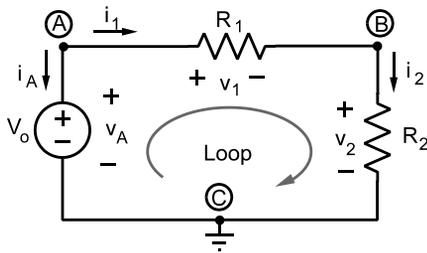

Fig. 7 (From Ref. 1.)

By finding the current i_1 , all currents can be found from

$$-i_A = i_1 = i_2$$

since all three elements are connected in series. Substituting all of the known values into the element equations gives

$$v_A = 10 \text{ V} \quad v_1 = R_1 i_1 = 4 \text{ V} \quad v_2 = R_2 i_2 = 6 \text{ V}$$

Assigning Reference Marks In all previous examples and exercises the reference marks for the element currents (arrows) and voltages (+ and -) were given. When reference marks are not shown on a circuit diagram, they must be assigned by the person solving the problem. Beginners sometimes wonder how to assign reference marks when the actual voltage polarities and current directions are as yet unknown. It is important to remember that reference marks do not indicate the actual polarities and directions. They are benchmarks assigned in an arbitrary way at the beginning of the analysis. If it turns out the actual direction and reference direction agree, then the numerical value of the response will be positive. If they disagree, the numerical value will be negative. In other words, the sign of the answer together with arbitrarily assigned reference marks tells us the actual voltage polarity or current direction. When assigning reference marks in this chapter the passive-sign convention will always be used. By always following the passive-sign convention any confusion about the direction of power flow in a device will be avoided. In addition, Ohm's law and other device $i-v$ characteristics assume the voltage and current reference marks follow the passive-sign convention. Always using this convention follows the practice used in all SPICE-based computer circuit analysis programs.

Equivalent Circuits The analysis of a circuit can often be simplified by replacing part of the circuit with one which is equivalent but simpler. The underlying basis for two circuits to be equivalent is contained in their $i-v$ relationships: *Two circuits are said to be equivalent if they have identical $i-v$ characteristics at a specified pair of terminals.*

Equivalent Resistance Resistances connected in series simply add, while conductances connected in parallel also simply add. Since conductance is not normally used to describe a resistor, two resistors R_1 and R_2 connected in parallel result in the expression

$$\begin{aligned} R_1 || R_2 = R_{EQ} &= \frac{1}{G_{EQ}} = \frac{1}{G_1 + G_2} = \frac{1}{1/R_1 + 1/R_2} \\ &= \frac{R_1 R_2}{R_1 + R_2} \end{aligned} \quad (11)$$

where the symbol $||$ is shorthand for "in parallel." The expression on the far right in Eq. (11) is called the product over the sum rule for two resistors in parallel. The product-over-the-sum rule only applies to two resistors connected in parallel. When more than two resistors are in parallel, the following must be used to obtain the equivalent resistance:

$$R_{EQ} = \frac{1}{G_{EQ}} = \frac{1}{1/R_1 + 1/R_2 + 1/R_3 + \dots} \quad (12)$$

Example 3. Given the circuit in Fig. 8:

- Find the equivalent resistance R_{EQ1} connected between terminals A and B.
- Find the equivalent resistance R_{EQ2} connected between terminals C and D.

Solution. First resistors R_2 and R_3 are connected in parallel. Applying Eq. (11) results in

$$R_2 || R_3 = \frac{R_2 R_3}{R_2 + R_3}$$

- The equivalent resistance between terminals A and B equals R_1 and the equivalent resistance

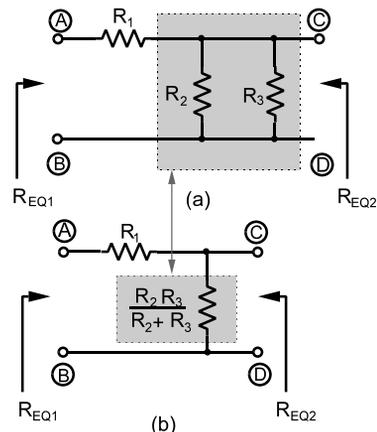

Fig. 8 (From Ref. 1.)

$R_2 || R_3$ connected in series. The total equivalent resistance R_{EQ1} between terminals A and B thus is

$$R_{EQ1} = R_1 + (R_2 || R_3)$$

$$R_{EQ1} = R_1 + \frac{R_2 R_3}{R_2 + R_3}$$

$$R_{EQ1} = \frac{R_1 R_2 + R_1 R_3 + R_2 R_3}{R_2 + R_3}$$

- (b) Looking into terminals C and D yields a different result. In this case R_1 is not involved, since there is an open circuit (an infinite resistance) between terminals A and B. Therefore only $R_2 || R_3$ affects the resistance between terminals C and D. As a result R_{EQ2} is simply

$$R_{EQ2} = R_2 || R_3 = \frac{R_2 R_3}{R_2 + R_3}$$

This example shows that equivalent resistance depends upon the pair of terminals involved.

Equivalent Sources The practical source models shown in Fig. 9 consist of an ideal voltage source in series with a resistance and an ideal current source in parallel with a resistance.

If $R_1 = R_2 = R$ and $v_S = i_S R$, the two practical sources have the same $i-v$ relationship, making the two sources equivalent. When equivalency conditions are met, the rest of the circuit is unaffected regardless if driven by a practical voltage source or a practical current source.

The source transformation equivalency means that either model will deliver the same voltage and current

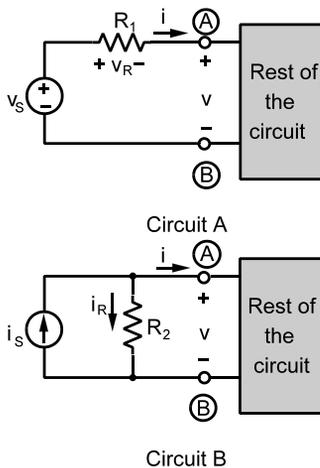

Fig. 9 Equivalent practical source models.¹

to the rest of the circuit. It does not mean the two models are identical in every way. For example, when the rest of the circuit is an open circuit, there is no current in the resistance of the practical voltage source and hence no $i^2 R$ power loss. But the practical current source model has a power loss because the open-circuit voltage is produced by the source current in the parallel resistance.

Y-Δ Transformations The Y-Δ connections shown in Fig. 10 occasionally occur in circuits and are especially prevalent in three-phase power circuits. One can transform from one configuration to the other by the following set of transformations:

$$R_A = \frac{R_1 R_2 + R_2 R_3 + R_1 R_3}{R_1} \quad R_1 = \frac{R_B R_C}{R_A + R_B + R_C}$$

$$R_B = \frac{R_1 R_2 + R_2 R_3 + R_1 R_3}{R_2} \quad R_2 = \frac{R_A R_C}{R_A + R_B + R_C}$$

$$R_C = \frac{R_1 R_2 + R_2 R_3 + R_1 R_3}{R_3} \quad R_3 = \frac{R_B R_A}{R_A + R_B + R_C} \quad (13)$$

Solving Eqs. (13) for R_1 , R_2 , and R_3 yields the equations for a Δ-to-Y transformation while solving Eqs. (13) for R_A , R_B , and R_C yields the equations for a Y-to-Δ transformation. The Y and Δ subcircuits are said to be *balanced* when $R_1 = R_2 = R_3 = R_Y$ and $R_A = R_B = R_C = R_Δ$. Under balanced conditions the transformation equations reduce to $R_Y = R_Δ/3$ and $R_Δ = 3R_Y$.

Voltage and Current Division These two analysis tools find wide application in circuit analysis and design.

Voltage Division Voltage division allows us to solve for the voltage across each element in a series circuit. Figure 11 shows a circuit that lends itself to solution by voltage division. Applying KVL around the loop in Fig. 11 yields $v_S = v_1 + v_2 + v_3$. Since all resistors are connected in series, the same current i exists in all three. Using Ohm's law yields $v_S = R_1 i + R_2 i + R_3 i$. Solving for i yields $i = v_S / (R_1 + R_2 + R_3)$. Once the current in the series circuit is

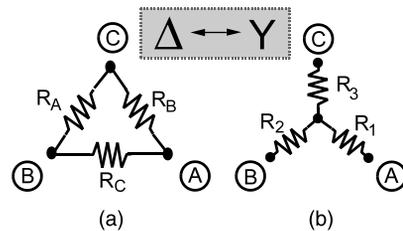

Fig. 10 Y-Δ transformation.²

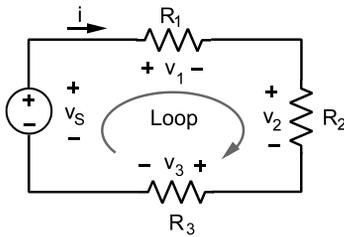

Fig. 11 Voltage divider circuit.¹

found, the voltage across each resistor is found using Ohm's law:

$$\begin{aligned} v_1 &= R_1 i = \left(\frac{R_1}{R_1 + R_2 + R_3} \right) v_s \\ v_2 &= R_2 i = \left(\frac{R_2}{R_1 + R_2 + R_3} \right) v_s \\ v_3 &= R_3 i = \left(\frac{R_3}{R_1 + R_2 + R_3} \right) v_s \end{aligned} \quad (14)$$

In each case the element voltage is equal to its resistance divided by the equivalent series resistance in the circuit times the total voltage across the series circuit. Thus, the general expression of the *voltage division rule* is

$$v_k = \left(\frac{R_k}{R_{EQ}} \right) v_{total} \quad (15)$$

The operation of a potentiometer is based on the voltage division rule. The device is a three-terminal element which uses voltage (potential) division to meter out a fraction of the applied voltage. Figure 12 shows the circuit symbol of a potentiometer. Simply stated, a potentiometer is an adjustable voltage divider.

The voltage v_O in Fig. 12 can be adjusted by turning the shaft on the potentiometer to move the wiper arm contact. Using the voltage division rule, v_O is found as

$$v_O = \left(\frac{R_{total} - R_1}{R_{total}} \right) v_s \quad (16)$$

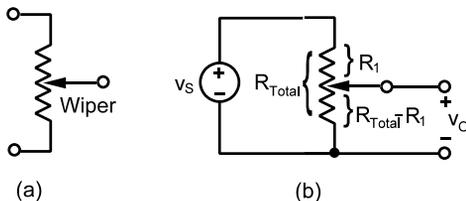

Fig. 12 Potentiometer: (a) circuit symbol; (b) an application.

Moving the movable wiper arm all the way to the top makes R_1 zero, and voltage division yields v_s . In other words, 100% of the applied voltage is delivered to the rest of the circuit. Moving the wiper to the other extreme delivers zero voltage. By adjusting the wiper arm position we can obtain an output voltage anywhere between zero and the applied voltage v_s . Applications of a potentiometer include volume control, voltage balancing, and frequency-tuning adjustment.

Current Division Current division is the dual of voltage division. By duality current division allows for the solution of the current through each element in a parallel circuit. Figure 13 shows a parallel circuit that lends itself to solution by current division. Applying KCL at node A yields $i_s = i_1 + i_2 + i_3$. The voltage v appears across all three conductances since they are connected in parallel. So using Ohm's law we can write $i_s = vG_1 + vG_2 + vG_3$ and solve for v as $v = i_s / (G_1 + G_2 + G_3)$. Given the voltage v , the current through any element is found using Ohm's law as

$$\begin{aligned} i_1 &= vG_1 = \left(\frac{G_1}{G_1 + G_2 + G_3} \right) i_s \\ i_2 &= vG_2 = \left(\frac{G_2}{G_1 + G_2 + G_3} \right) i_s \\ i_3 &= vG_3 = \left(\frac{G_3}{G_1 + G_2 + G_3} \right) i_s \end{aligned}$$

These results show that the source current divides among the parallel resistors in proportion to their conductances divided by the equivalent conductances in the parallel connection. Thus, the general expression for the *current division rule* is

$$i_k = \left(\frac{G_k}{G_{EQ}} \right) i_{total} = \frac{1/R_k}{1/R_{EQ}} i_{total} \quad (17)$$

Circuit Reduction The concepts of series/parallel equivalence, voltage/current division, and source transformations can be used to analyze *ladder circuits* of the type shown in Fig. 14. The basic analysis strategy is to reduce the circuit to a simpler equivalent in which the desired voltage or current is easily found using voltage and/or current division and/or source transformation and/or Ohm's law. There is no fixed pattern to

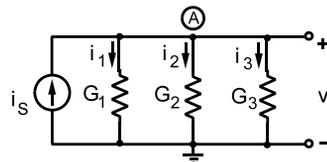

Fig. 13 Current divider circuit.¹

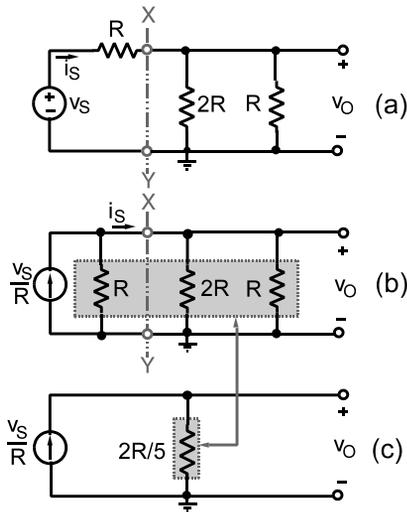

Fig. 14 (From Ref. 1.)

the reduction process, and much depends on the insight of the analyst.

When using circuit reduction it is important to remember that the unknown voltage exists between two nodes and the unknown current exists in a branch. The reduction process must not eliminate the required node pair or branch; otherwise the unknown voltage or current cannot be found. The next example will illustrate circuit reduction.

Example 4. Find the output voltage v_O and the input current i_S in the ladder circuit shown in Fig. 14a.

Solution. Breaking the circuit at points X and Y produces voltage source v_S in series with a resistor R : Using source transformation this combination can be replaced by an equivalent current source in parallel with the same resistor, as shown in Fig. 14b. Using current division the input current i_S is

$$i_S = \frac{R}{(2/3)R + R} \times \frac{v_S}{R} = \frac{v_S}{(5/3)R} = \frac{3}{5} \frac{v_S}{R}$$

The three parallel resistances in Fig. 14b can be combined into a single equivalent resistance without eliminating the node pair used to define the output voltage v_O :

$$R_{EQ} = \frac{1}{1/R + 1/(2R) + 1/R} = \frac{2R}{5}$$

which yields the equivalent circuit in Fig. 14c. The current source v_S/R determines the current through the

equivalent resistance in Fig. 14c. The output voltage is found using Ohm's law:

$$v_O = \left(\frac{v_S}{R}\right) \times \left(\frac{2R}{5}\right) = \frac{2}{5} v_S$$

Several other analysis approaches are possible.

2 DIRECT-CURRENT (DC) CIRCUITS

This section reviews basic DC analysis using traditional circuits theorems with application to circuit analysis and design.

2.1 Node Voltage Analysis

Using node voltage instead of element voltages as circuit variables can greatly reduce the number of equations that must be treated simultaneously. To define a set of node voltages, a reference node or ground is first selected. The *node voltages* are then defined as the voltages between the remaining nodes and the reference node. Figure 15 shows a reference node indicated by the ground symbol as well as the notation defining the three nonreference node voltages. The node voltages are identified by a voltage symbol adjacent to the nonreference nodes. This notation means that the positive reference mark for the node voltage is located at the node in question while the negative mark is at the reference node. Any circuit with N nodes involves $N - 1$ node voltages.

The following is a fundamental property of node voltages: *If the K th two-terminal element is connected*

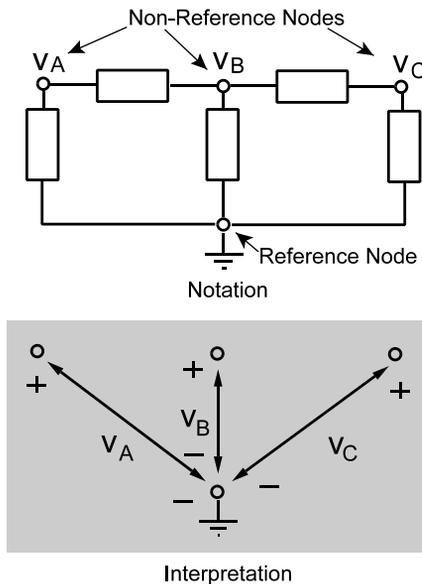

Fig. 15 Node voltage definition and notation.¹

between nodes X and Y , then the element voltage can be expressed in terms of the two node voltages as

$$v_K = v_X - v_Y \quad (18)$$

where X is the node connected to the positive reference for element voltage v_K .

Equation (18) is a KVL constraint at the element level. If node Y is the reference node, then by definition $v_Y = 0$ and Eq. (18) reduces to $v_K = v_X$. On the other hand, if node X is the reference node, then $v_X = 0$ and therefore $v_K = -v_Y$. The minus sign here comes from the fact that the positive reference for the element is connected to the reference node. In any case, the important fact is that the voltage across any two-terminal element can be expressed as the difference of two node voltages, one of which may be zero.

To formulate a circuit description using node voltages, device and connection analysis is used, except that the KVL connection equations are not explicitly written down. Instead the fundamental property of node analysis is used to express the element voltages in terms of the node voltages.

The circuit in Fig. 16 will demonstrate the formulation of node voltage equations. The ground symbol identifies the reference node, six element currents ($i_0, i_1, i_2, i_3, i_4,$ and i_5), and three node voltages ($v_A, v_B,$ and v_C).

The KCL constraints at the three nonreference nodes are

$$\begin{aligned} \text{Node A:} \quad & -i_0 + i_1 + i_2 = 0 \\ \text{Node B:} \quad & -i_1 + i_3 - i_5 = 0 \\ \text{Node C:} \quad & -i_2 + i_4 + i_5 = 0 \end{aligned}$$

Using the fundamental property of node analysis, device equations are used to relate the element currents to the node voltages:

$$\begin{aligned} R_1: \quad i_1 &= \frac{v_A - v_B}{R_1} & R_2: \quad i_2 &= \frac{v_A - v_C}{R_2} \\ \text{Voltage source:} \quad & v_S &= & v_A \end{aligned}$$

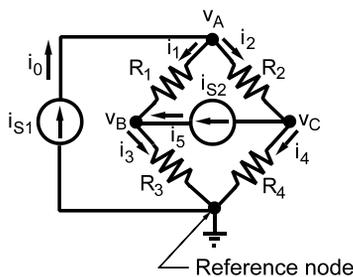

Fig. 16 Bridge circuit for node voltage example.¹

$$\begin{aligned} R_3: \quad i_3 &= \frac{v_B - 0}{R_3} & R_4: \quad i_4 &= \frac{v_C - 0}{R_4} \\ \text{Current source:} \quad & i_5 &= & i_{S2} \end{aligned}$$

Substituting the element currents into the KCL equations yields

$$\begin{aligned} \text{Node A:} \quad & -i_0 + \frac{v_A - v_B}{R_1} + \frac{v_A - v_C}{R_2} = 0 \\ \text{Node B:} \quad & \frac{v_B - v_A}{R_1} + \frac{v_B}{R_3} - i_{S2} = 0 \\ \text{Node C:} \quad & \frac{v_C - v_A}{R_2} + \frac{v_C}{R_4} + i_{S2} = 0 \end{aligned}$$

But since the reference is connected to the negative side of the voltage source, $v_A = v_S$. Thus at node A the voltage is already known and this reduces the number of equations that need to be solved. The equation written above can be used to solve for the current through the voltage source if that is desired. Writing these equations in standard form with all of the unknown node voltages grouped on one side and the independent sources on the other yields

$$\begin{aligned} \text{Node A:} \quad & v_A = v_S \\ \text{Node B:} \quad & v_B \left(\frac{1}{R_1} + \frac{1}{R_3} \right) = i_S + \frac{v_S}{R_1} \\ \text{Node C:} \quad & v_C \left(\frac{1}{R_2} + \frac{1}{R_4} \right) = -i_S + \frac{v_S}{R_2} \end{aligned}$$

Using node voltage analysis there are only two equations and two unknowns (v_B and v_C) to be solved. The coefficients in the equations on the left side depend only on circuit parameters, while the right side contains the known input driving forces.

Supernodes When neither node of a voltage source can be selected as the reference, a *supernode* must be used. The fact that KCL applies to the currents penetrating a boundary can be used to write a node equation at the supernode. Then node equations at the remaining nonreference nodes are written in the usual way. This process reduces the number of available node equations to $N - 3$ plus one supernode equation, leaving us one equation short of the $N - 1$ required. The voltage source inside the supernode constrains the difference between the node voltages to be the value of the voltage source. The voltage source constraint provides the additional relationship needed to write $N - 1$ independent equations in the $N - 1$ node voltages.

Example 5. For the circuit in Fig. 17:

- Formulate node voltage equations.
- Solve for the output voltage v_O using $R_1 = R_4 = 2 \text{ k}\Omega$ and $R_2 = R_3 = 4 \text{ k}\Omega$.

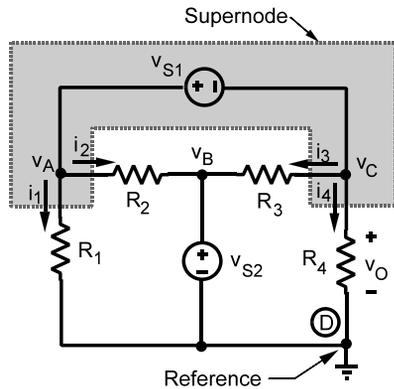

Fig. 17 (From Ref. 1.)

Solution. (a) The voltage sources in Fig. 17 do not have a common node so a reference node that includes both sources cannot be selected. Choosing node D as the reference forces the condition $v_B = v_{S2}$ but leaves the other source v_{S1} ungrounded. The ungrounded source and all wires leading to it are encompassed by a supernode boundary as shown in the figure. Kirchhoff's current law applies to the four-element currents that penetrate the supernode boundary and we can write

$$i_1 + i_2 + i_3 + i_4 = 0$$

These currents can easily be expressed in terms of the node voltages:

$$\frac{v_A}{R_1} + \frac{v_A - v_B}{R_2} + \frac{v_C - v_B}{R_3} + \frac{v_C}{R_4} = 0$$

But since $v_B = v_{S2}$, the standard form of this equation is

$$v_A \left(\frac{1}{R_1} + \frac{1}{R_2} \right) + v_C \left(\frac{1}{R_3} + \frac{1}{R_4} \right) = v_{S2} \left(\frac{1}{R_2} + \frac{1}{R_3} \right)$$

We have one equation in the two unknown node voltages v_A and v_C . Applying the fundamental property of node voltages inside the supernode, we can write

$$v_A - v_C = v_{S1}$$

That is, the ungrounded voltage source constrains the difference between the two unknown node voltages inside the supernode and thereby supplies the relationship needed to obtain two equations in two unknowns.

(b) Substituting in the given numerical values yields

$$(7.5 \times 10^{-4}) v_A + (7.5 \times 10^{-4}) v_C = (5 \times 10^{-4}) v_{S2}$$

$$v_A - v_C = v_{S1}$$

To find the output v_O , we need to solve these equations for v_C . The second equation yields $v_A = v_C + v_{S1}$, which when substituted into the first equation yields the required output:

$$v_O = v_C = \frac{1}{3} v_{S2} - \frac{1}{2} v_{S1}$$

Node voltage equations are very useful in the analysis of a variety of electronic circuits. These equations can always be formulated using KCL, the element constraints, and the fundamental property of node voltages. The following guidelines summarize this approach:

1. Simplify the circuit by combining elements in series and parallel wherever possible.
2. If not specified select a reference node so that as many dependent and independent voltage sources as possible are directly connected to the reference.
3. Label a node voltage adjacent to each nonreference node.
4. Create supernodes for dependent and independent voltage sources that are not directly connected to the reference node.
5. Node equations are required at supernodes and all other nonreference nodes except on amp outputs and nodes directly connected to the reference by a voltage source.
6. Write symmetrical node equations by treating dependent sources as independent sources and using the inspection method.
7. Write expressions relating the node and source voltages for voltage sources included in supernodes.
8. Substitute the expressions from step 7 into the node equations from step 6 and place the result in standard form.

2.2 Mesh Current Analysis

Mesh currents are an alternative set of analysis variables that are useful in circuits containing many elements connected in series. To review terminology, a loop is a sequence of circuit elements that forms a closed path that passes through each element just once. A mesh is a special type of loop that does not enclose any elements.

The following development of mesh analysis is restricted to planar circuits. A *planar circuit* can be drawn on a flat surface without crossovers in a "window pane" fashion. To define a set of variables, a *mesh current* (i_A, i_B, i_C, \dots) is associated with each window pane and a reference direction assigned customarily in a clockwise sense. There is no momentous reason for this except perhaps tradition.

Mesh currents are thought of as circulating through the elements in their respective meshes; however, this

viewpoint is not based on the physics of circuit behavior. There are not different types of electrons flowing that somehow get assigned to mesh currents i_A or i_B . Mesh currents are variables used in circuit analysis. They are only somewhat abstractly related to the physical operation of a circuit and may be impossible to measure directly. Mesh currents have a unique feature that is the dual of the fundamental property of node voltages. In a planar circuit any given element is contained in at most two meshes. When an element is in two meshes, the two mesh currents circulate through the element in opposite directions. In such cases KCL declares that the net element current through the element is the difference of the two mesh currents.

These observations lead to the fundamental property of mesh currents: *If the K th two-terminal element is contained in meshes X and Y , then the element current can be expressed in terms of the two mesh currents as*

$$i_K = i_X - i_Y \quad (19)$$

where X is the mesh whose reference direction agrees with the reference direction of i_K .

Equation (19) is a KCL constraint at the element level. If the element is contained in only one mesh, then $i_K = i_X$ or $i_K = -i_Y$ depending on whether the reference direction for the element current agrees or disagrees with the mesh current. The key fact is that the current through every two-terminal element in a planar circuit can be expressed as the difference of at most two mesh currents.

Mesh currents allow circuit equations to be formulated using device and connection constraints, except that the KCL constraints are not explicitly written down. Instead, the fundamental property of mesh currents is used to express the device constraints in terms of the mesh currents, thereby avoiding using the element currents and working only with the element voltages and mesh currents.

For example, the planar circuit in Fig. 18 can be analyzed using the mesh current method. In the figure two mesh currents are shown as well as the voltages across each of the five elements. The KVL constraints around each mesh using the element voltages yield

$$\text{Mesh A: } -v_0 + v_1 + v_3 = 0$$

$$\text{Mesh B: } -v_3 + v_2 + v_4 = 0$$

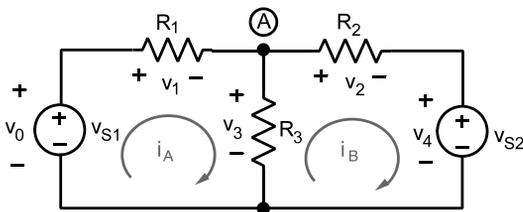

Fig. 18 Circuit demonstrating mesh current analysis.¹

Using the fundamental property of mesh currents, the element voltages in terms of the mesh currents and input voltages are written as

$$v_1 = R_1 i_A \quad v_0 = v_{S1}$$

$$v_2 = R_2 i_B \quad v_4 = v_{S2}$$

$$v_3 = R_3 (i_A - i_B)$$

Substituting these element equations into the KVL connection equations and arranging the result in standard form yield

$$(R_1 + R_3) i_A - R_3 i_B = v_{S1}$$

$$-R_3 i_A + (R_2 + R_3) i_B = -v_{S2}$$

This results in two equations in two unknown mesh currents. The KCL equations $i_1 = i_A$, $i_2 = i_B$ and $i_3 = i_A - i_B$ are implicitly used to write mesh equations. In effect, the fundamental property of mesh currents ensures that the KCL constraints are satisfied. Any general method of circuit analysis must satisfy KCL, KVL, and the device i - v relationships. Mesh current analysis appears to focus on the latter two but implicitly satisfies KCL when the device constraints are expressed in terms of the mesh currents.

Solving for the mesh currents yields

$$i_A = \frac{(R_2 + R_3) v_{S1} - R_3 v_{S2}}{R_1 R_2 + R_1 R_3 + R_2 R_3} \quad \text{and}$$

$$i_B = \frac{R_3 v_{S1} - (R_1 + R_3) v_{S2}}{R_1 R_2 + R_1 R_3 + R_2 R_3}$$

The results for i_A and i_B can now be substituted into the device constraints to solve for every voltage in the circuit. For instance, the voltage across R_3 is

$$v_A = v_3 = R_3 (i_A - i_B) = \frac{R_2 R_3 v_{S1} + R_1 R_3 v_{S2}}{R_1 R_2 + R_1 R_3 + R_2 R_3}$$

Example 6. Use mesh current equations to find i_O in the circuit in Fig. 19a.

Solution. The current source in this circuit can be handled by a source transformation. The 2-mA source in parallel with the 4-k Ω resistor in Fig. 19a can be replaced by an equivalent 8-V source in series with the same resistor as shown in Fig. 19b. In this circuit the total resistance in mesh A is 6 k Ω , the total resistance in mesh B is 11 k Ω , and the resistance contained in both meshes is 2 k Ω . By inspection the mesh equations for this circuit are

$$(6000) i_A - (2000) i_B = 5$$

$$-(2000) i_A + (11000) i_B = -8$$

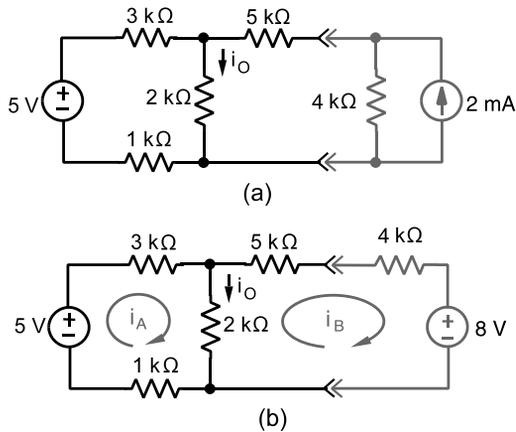

Fig. 19 (From Ref. 1.)

Solving for the two mesh currents yields

$$i_A = 0.6290 \text{ mA} \quad \text{and} \quad i_B = 0.6129 \text{ mA}$$

By KCL the required current is

$$i_0 = i_A - i_B = 1.2419 \text{ mA}$$

Supermesh If a current source is contained in two meshes and is not connected in parallel with a resistance, then a *supermesh* is created by excluding the current source and any elements connected in series with it. One mesh equation is written around the supermesh using the currents i_A and i_B . Then mesh equations of the remaining meshes are written in the usual way. This leaves the solution one equation short because parts of meshes A and B are included in the supermesh. However, the fundamental property of mesh currents relates the currents i_S , i_A , and i_B as

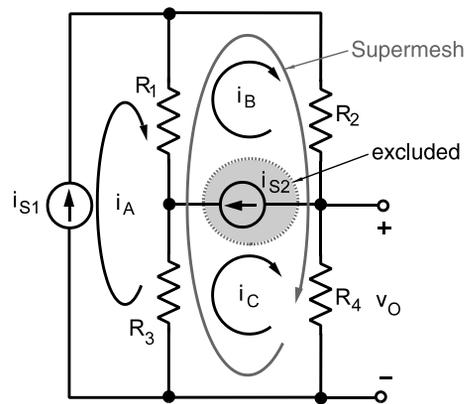

$$i_S = i_A - i_B$$

This equation supplies the additional relationship needed to get the requisite number of equations in the unknown mesh currents. This approach is obviously the dual of the supernode method for modified node analysis. The following example demonstrates the use of a supermesh.

Example 7. Use mesh current equations to find the v_O in Fig. 20.

Solution. The current source i_{S2} is in both mesh B and mesh C, so we exclude this element and create the supermesh shown in the figure. The sum of voltages around the supermesh is

$$R_1(i_B - i_A) + R_2(i_B) + R_4(i_C) + R_3(i_C - i_A) = 0$$

Fig. 20 Example of supermesh.¹

The supermesh voltage constraint yields one equation in the three unknown mesh currents. Applying KCL to each of the current sources yields

$$i_A = i_{S1} \quad i_B - i_C = i_{S2}$$

Because of KCL, the two current sources force constraints that supply two more equations. Using these two KCL constraints to eliminate i_A and i_B from the supermesh KVL constraint yields

$$(R_1 + R_2 + R_3 + R_4)i_C = (R_1 + R_3)i_{S1} - (R_1 + R_2)i_{S2}$$

Hence, the required output voltage is

$$v_O = R_4 i_C = R_4 \times \left[\frac{(R_1 + R_3)i_{S1} - (R_1 + R_2)i_{S2}}{R_1 + R_2 + R_3 + R_4} \right]$$

Mesh current equations can always be formulated from KVL, the element constraints, and the fundamental property of mesh currents. The following guidelines summarize an approach to formulating mesh equations for resistance circuits:

1. Simplify the circuit by combining elements in series or parallel wherever possible.
2. Assign a clockwise mesh current to each mesh.
3. Create a supermesh for dependent and independent current sources that are contained in two meshes.
4. Write symmetrical mesh equations for all meshes by treating dependent sources as independent sources and using the inspection method.
5. Write expressions relating the mesh and source currents for current sources contained in only one mesh.

6. Write expressions relating the mesh and source currents for current sources included in supermeshes.
7. Substitute the expressions from steps 5 and 6 into the mesh equations from step 4 and place the result in standard form.

2.3 Linearity Properties

This chapter treats the analysis and design of *linear circuits*. A circuit is said to be linear if it can be adequately modeled using only linear elements and independent sources. The hallmark feature of a linear circuit is that outputs are linear functions of the inputs. Circuit *inputs* are the signals produced by independent sources and *outputs* are any other designated signals. Mathematically a function is said to be linear if it possesses two properties—homogeneity and additivity. In terms of circuit responses, *homogeneity* means the output of a linear circuit is proportional to the input. *Additivity* means the output due to two or more inputs can be found by adding the outputs obtained when each input is applied separately. Mathematically these properties are written as follows:

$$f(Kx) = Kf(x) \quad \text{and}$$

$$f(x_1 + x_2) = f(x_1) + f(x_2) \quad (20)$$

where K is a scalar constant. In circuit analysis the homogeneity property is called *proportionality* while the additivity property is called *superposition*.

Proportionality Property The *proportionality property* applies to linear circuits with one input. For linear resistive circuits proportionality states that every input–output relationship can be written as

$$y = K \cdot x$$

where x is the input current or voltage, y is an output current or voltage, and K is a constant. The block diagram in Fig. 21 describes a relationship in which the input x is multiplied by the scalar constant K to produce the output y . Examples of proportionality abound. For instance, using voltage division in Fig. 22 produces

$$v_O = \left(\frac{R_2}{R_1 + R_2} \right) v_S$$

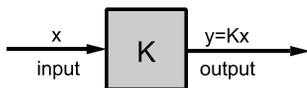

Fig. 21 Block diagram representation of proportionality property.¹

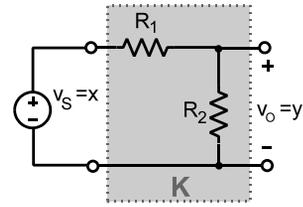

Fig. 22 Example of circuit exhibiting proportionality.¹

which means

$$x = v_S \quad y = v_O$$

$$K = \frac{R_2}{R_1 + R_2}$$

In this example the proportionality constant K is dimensionless because the input and output have the same units. In other situations K could carry the units of ohms or siemens when the input or output does not have the same units.

Example 8. Given the bridge circuit of Fig. 23:

- (a) Find the proportionality constant K in the input–output relationship $v_O = K v_S$.
- (b) Find the sign of K when $R_2 R_3 > R_1 R_4$, $R_2 R_3 = R_1 R_4$, and $R_2 R_3 < R_1 R_4$.

Solution. (a) Note that the circuit consists of two voltage dividers. Applying the voltage division rule to each side of the bridge circuit yields

$$v_A = \frac{R_3}{R_1 + R_3} v_S \quad v_B = \frac{R_4}{R_2 + R_4} v_S$$

The fundamental property of node voltages allows us to write $v_O = v_A - v_B$. Substituting the equations for v_A and v_B into this KVL equation yields

$$v_o = \begin{cases} \left(\frac{R_3}{R_1 + R_3} - \frac{R_4}{R_2 + R_4} \right) v_S \\ \left(\frac{R_2 R_3 - R_1 R_4}{(R_1 + R_3)(R_2 + R_4)} \right) v_S \\ (K) v_S \end{cases}$$

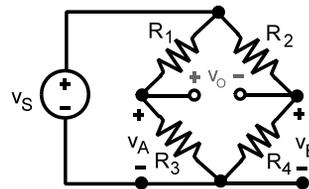

Fig. 23 (From Ref. 1.)

(b) The proportionality constant K can be positive, negative, or zero. Specifically

If $R_2 R_3 > R_1 R_2$, then $K > 0$.

If $R_2 R_3 = R_1 R_2$, then $K = 0$.

If $R_2 R_3 < R_1 R_2$, then $K < 0$.

When the product of the resistances in opposite legs of the bridge are equal, $K = 0$ and the bridge is said to be balanced.

Superposition Property The *additivity property*, or superposition, states that any output current or voltage of a linear resistive circuit with multiple inputs can be expressed as a linear combination of several inputs:

$$y = K_1 x_1 + K_2 x_2 + K_3 x_3 + \dots$$

where x_1, x_2, x_3, \dots are current or voltage inputs and K_1, K_2, K_3, \dots are constants that depend on the circuit parameters.

Since the output y above is a linear combination, the contribution of each input source is independent of all other inputs. This means that the output can be found by finding the contribution from each source acting alone and then adding the individual response to obtain the total response. This suggests that the output of a multiple-input linear circuit can be found by the following steps:

Step 1: “Turn off” all independent input signal sources except one and find the output of the circuit due to that source acting alone.

Step 2: Repeat the process in step 1 until each independent input source has been turned on and the output due to that source found.

Step 3: The total output with all sources turned on is then a linear combination (algebraic sum) of the contributions of the individual independent sources.

A voltage source is turned off by setting its voltage to zero ($v_S = 0$) and replacing it with a short circuit. Similarly, turning off a current source ($i_S = 0$) entails replacing it with an open circuit. Figure 24a shows that the circuit has two input sources. Figure 24b shows the circuit with the current source set to zero. The output of the circuit v_{O1} represents that part of the total output caused by the voltage source. Using voltage division yields

$$v_{O1} = \frac{R_2}{R_1 + R_2} v_S$$

Next the voltage source is turned off and the current source is turned on, as shown in Fig. 24c. Using Ohm’s law, $v_{O2} = i_{O2} R_2$. Then using current division to express i_{O2} in terms of i_S yields

$$v_{O2} = i_{O2} \times R_2 = \left[\frac{R_1}{R_1 + R_2} i_S \right] R_2 = \frac{R_1 R_2}{R_1 + R_2} i_S$$

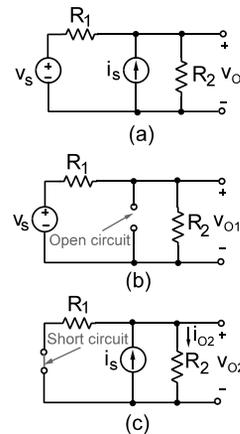

Fig. 24 Circuit analysis using superposition: (a) current source off; (b) voltage source off.¹

Applying the superposition theorem, the response with both sources “turned on” is found by adding the two responses v_{O1} and v_{O2} :

$$v_O = v_{O1} + v_{O2}$$

$$v_O = \left[\frac{R_2}{R_1 + R_2} \right] v_S + \left[\frac{R_1 R_2}{R_1 + R_2} \right] i_S$$

Superposition is an important property of linear circuits and is used primarily as a conceptual tool to develop other circuit analysis and design techniques. It is useful, for example, to determine the contribution to a circuit by a certain source.

2.4 Thevenin and Norton Equivalent Circuits

An *interface* is a connection between circuits that perform different functions. Circuit interfaces occur frequently in electrical and electronic systems so special analysis methods are used to handle them. For the two-terminal interface shown in Fig. 25, one circuit can be considered as the source S and the other as the load L . Signals are produced by the source circuit and delivered to the load. The source–load interaction at an interface is one of the central problems of circuit analysis and design.

The Thevenin and Norton equivalent circuits shown in Fig. 25 are valuable tools for dealing with circuit interfaces. The conditions under which these equivalent circuits exist can be stated as a theorem: *If the source circuit in a two-terminal interface is linear, then the interface signals v and i do not change when the source circuit is replaced by its Thevenin or Norton equivalent circuit.*

The equivalence requires the source circuit to be linear but places no restriction on the linearity of

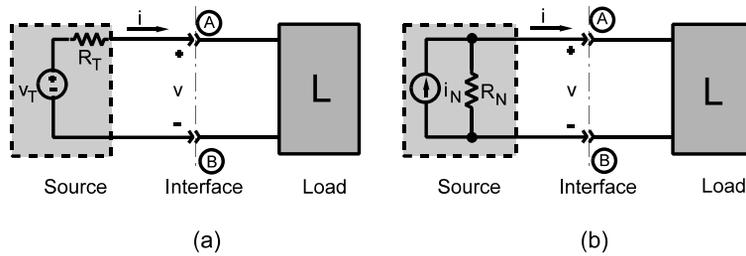

Fig. 25 Equivalent circuits for source circuit: (a) Thevenin equivalent; (b) Norton equivalent.¹

the load circuit. The Thevenin equivalent circuit consists of a voltage source (v_T) in series with a resistance (R_T). The Norton equivalent circuit is a current source (i_N) in parallel with a resistance (R_N). The Thevenin and Norton equivalent circuits are equivalent to each other since replacing one by the other leaves the interface signals unchanged. In essence the Thevenin and Norton equivalent circuits are related by the source transformation covered earlier under equivalent circuits.

The two parameters can often be obtained using open-circuit and short-circuit loads. If the actual load is disconnected from the source, an open-circuit voltage v_{OC} appears between terminals A and B. Connecting an open-circuit load to the Thevenin equivalent produces $v_{OC} = v_T$ since the open circuit causes the current to be zero, resulting in no voltage drop across R_T . Similarly, disconnecting the load and connecting a short circuit as shown produce a current i_{SC} . Connecting a short-circuit load to the Norton equivalent produces $i_{SC} = i_N$ since all of the source current i_N is diverted through the short-circuit load.

In summary, the parameters of the Thevenin and Norton equivalent circuits at a given interface can be found by determining the open-circuit voltage and the short-circuit current:

$$v_T = v_{OC} \quad i_N = i_{SC} \quad R_N = R_T = \frac{v_{OC}}{i_{SC}} \quad (21)$$

General Applications Since even complex linear circuits can be replaced by their Thevenin or Norton equivalent, the chore of designing circuits that interface with these complex circuits is greatly simplified. Suppose a load resistance in Fig. 26a needs to be chosen so the source circuit to the left of the interface A–B delivers 4 V to the load.

The Thevenin and Norton equivalents v_{OC} and i_{SC} are first found. The open-circuit voltage v_{OC} is found by disconnecting the load at terminals A–B as shown in Fig. 26b. The voltage across the 15- Ω resistor is zero because the current through it is zero due to the open circuit. The open-circuit voltage at the interface is the same as the voltage across the 10- Ω resistor.

Using voltage division, this voltage is

$$v_T = v_{OC} = \frac{10}{10 + 5} \times 5 = 10 \text{ V}$$

Then the short-circuit current i_{SC} is calculated using the circuit in Fig. 26c. The total current i_X delivered by the 15-V source is $i_X = 15/R_{EQ}$, where R_{EQ} is the equivalent resistance seen by the voltage source with a short circuit at the interface:

$$R_{EQ} = 5 + \frac{10 \times 15}{10 + 15} = 11 \Omega$$

The source current i_X can now be found: $i_X = 15/11 = 1.36$ A. Given i_X , current division is used to obtain the short-circuit current,

$$i_N = i_{SC} = \frac{10}{10 + 15} \times i_X = 0.545 \text{ A}$$

Finally, we compute the Thevenin and Norton resistances:

$$R_T = R_N = \frac{v_{OC}}{i_{SC}} = 18.3 \Omega$$

The resulting Thevenin and Norton equivalent circuits are shown in Figs. 26d,e.

It now is an easy matter to select a load R_L so 4 V is supplied to the load. Using the Thevenin equivalent circuit, the problem reduces to a voltage divider,

$$4 \text{ V} = \frac{R_L}{R_L + R_T} \times v_T = \frac{R_L}{R_L + 18.3} \times 10$$

Solving for R_L yields $R_L = 12.2 \Omega$.

The Thevenin or Norton equivalent can always be found from the open-circuit voltage and short-circuit current at the interface. Often they can be measured using a multimeter to measure the open-circuit voltage and the short-circuit current.

Application to Nonlinear Loads An important use of Thevenin and Norton equivalent circuits is

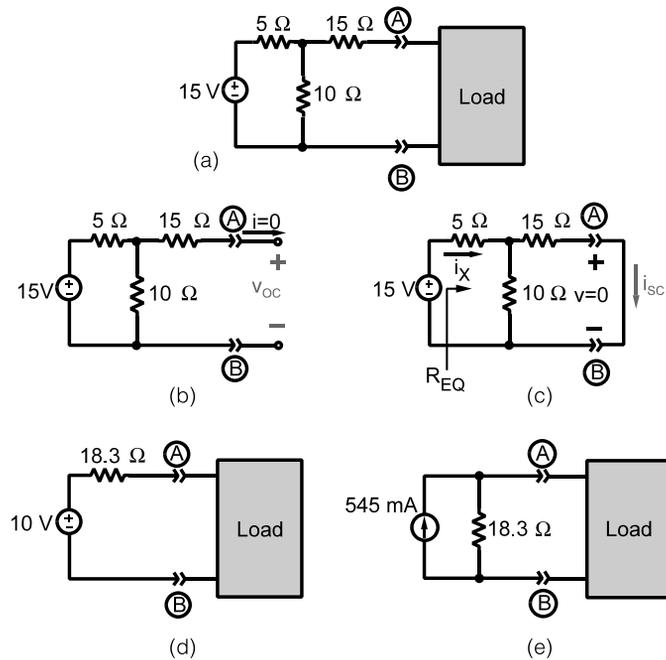

Fig. 26 Example of finding Thevenin and Norton equivalent circuits: (a) given circuit; (b) open circuit yields Thevenin voltage; (c) short circuit yields Norton current; (d) Thevenin equivalent circuit; (e) Norton equivalent circuit.¹

findin the voltage across, current through, and power dissipated in a two-terminal nonlinear element (NLE). The method of analysis is a straightforward application of device $i-v$ characteristics. An interface is define at the terminals of the nonlinear element and the linear part of the circuit is reduced to the Thevenin equivalent in Fig. 27a. Treating the interface current i as the dependent variable, the $i-v$ relationship of the Thevenin equivalent is written in the form

$$i = \left(-\frac{1}{R_T}\right)v + \left(\frac{v_T}{R_T}\right)$$

This is the equation of a straight line in the $i-v$ plane shown in Fig. 27b. The line intersects the i axis ($v = 0$) at $i = i_{SC} = v_T/R_T$ and intersects the v axis ($i = 0$) at $v = v_{OC} = v_T$. This line is called the *load line*.

The nonlinear element has the $i-v$ characteristic shown in Fig. 27c. Mathematically this nonlinear characteristic has the form $i = f(v)$. Both the nonlinear equation and the load line equation must be solved simultaneously. This can be done by numerical methods when $f(v)$ is known explicitly, but often a graphical solution is adequate. By superimposing the load line on the $i-v$ characteristic curve of the nonlinear element in Fig. 27d, the point or points of intersection represent the values of i and v that satisfy the source constraints given in the form of the Thevenin equivalent above,

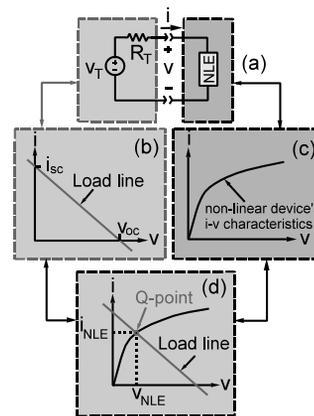

Fig. 27 Graphical analysis of nonlinear circuit: (a) given circuit; (b) load line; (c) nonlinear device $i-v$ characteristics; (d) Q point.¹

and nonlinear element constraints. In the terminology of electronics the point of intersection is called the operating point, or *Q point*, or the quiescent point.

2.5 Maximum Signal Transfer

Circuit interfacing involves interconnecting circuits in such a way that they are compatible. In this regard an

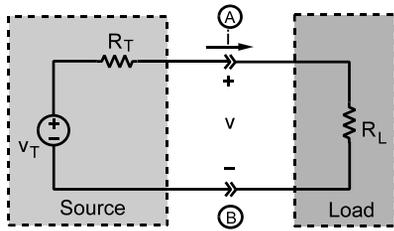

Fig. 28 Two-terminal interface for deriving maximum signal transfer conditions.¹

important consideration is the maximum signal levels that can be transferred across a given interface. This section defines the maximum voltage, current, and power available at an interface between a *fixed source* and an *adjustable load*.

The source can be represented by its Thevenin equivalent and the load by an equivalent resistance R_L , as shown in Fig. 28. For a fixed source the parameters v_T and R_T are given and the interface signal levels are functions of the load resistance R_L . By voltage division, the interface voltage is

$$v = \frac{R_L}{R_L + R_T} v_T$$

For a fixed source and a variable load, the voltage will be a maximum if R_L is made very large compared to R_T . Ideally R_L should be made infinite (an open circuit), in which case

$$v_{\text{MAX}} = v_T = v_{\text{OC}}$$

Therefore, the maximum voltage available at the interface is the source open-circuit voltage v_{OC} . The current delivered at the interface is

$$i = \frac{v_T}{R_L + R_T}$$

Again, for a fixed source and a variable load, the current will be a maximum if R_L is made very small

compared to R_T . Ideally R_L should be zero (a short circuit), in which case

$$i_{\text{MAX}} = \frac{v_T}{R_T} = i_N = i_{\text{SC}}$$

Therefore, the maximum current available at the interface is the source short-circuit current i_{SC} .

The power delivered at the interface is equal to the product vi . Using interface voltage, and interface current results found above, the power is

$$p = v \times i = \frac{R_L v_T^2}{(R_T + R_L)^2}$$

For a given source, the parameters v_T and R_T are fixed and the delivered power is a function of a single variable R_L . The conditions for obtaining maximum voltage ($R_L \rightarrow \infty$) or maximum current ($R_L = 0$) both produce zero power. The value of R_L that maximizes the power lies somewhere between these two extremes. The value can be found by differentiating the power expression with respect to R_L and solving for the value of R_L that makes $dp/dR_L = 0$. This occurs when $R_L = R_T$. Therefore, *maximum power transfer* occurs when the load resistance equals the Thevenin resistance of the source. When $R_L = R_T$ the source and load are said to be *matched*. Substituting the condition $R_L = R_T$ back into the power equation above shows the maximum power to be

$$p_{\text{MAX}} = \frac{v_T^2}{4R_T} = \frac{i_N^2 R_T}{4}$$

These results are consequences of what is known as the maximum power transfer theorem: *A fixed source with a Thevenin resistance R_T delivers maximum power to an adjustable load R_L when $R_L = R_T$.*

Figure 29 shows plots of the interface voltage, current, and power as functions of R_L/R_T . The plots of v/v_{OC} , i/i_{SC} , and p/p_{MAX} are normalized to the maximum available signal levels so the ordinates in Fig. 29 range from 0 to 1.

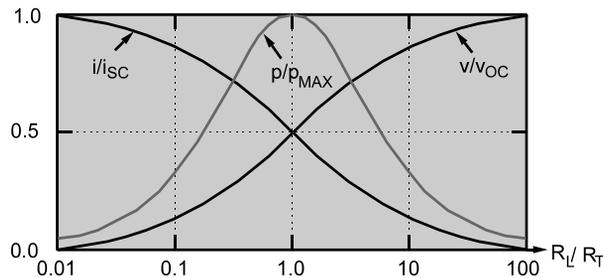

Fig. 29 Normalized plots of current, voltage, and power versus R_L/R_T .¹

The plot of the normalized power p/p_{MAX} in the neighborhood of the maximum is not a particularly strong function of R_L/R_T . Changing the ratio R_L/R_T by a factor of 2 in either direction from the maximum reduces p/p_{MAX} by less than 20%. The normalized voltage v/v_{OC} is within 20% of its maximum when $R_L/R_T = 4$. Similarly, the normalized current is within 20% of its maximum when $R_L/R_T = 3$. In other words, for engineering purposes maximum signal levels can be approached with load resistances that only approximate the theoretical requirements.

2.6 Interface Circuit Design

The maximum signal levels discussed in the previous section place bounds on what is achievable at an interface. However, those bounds are based on a fixed source and an adjustable load. In practice there are circumstances in which the source or the load or both can be adjusted to produce prescribed interface signal levels. Sometimes it is necessary to insert an interface circuit between the source and load. Figure 30 shows the general situations and some examples of resistive interface circuits. By its very nature the inserted circuit has two terminal pairs, or interfaces, at which voltage and current can be observed or specified. These terminal pairs are also called *ports*, and the interface circuit is referred to as a *two-port network*. The port connected to the source is called the input and the port connected to the load the output. The purpose of this two-port

network is to ensure that the source and load interact in a prescribed way.

Basic Circuit Design Concepts This section introduces a limited form of circuit design, as contrasted with circuit analysis. Although circuit analysis tools are essential in design, there are important differences. A linear circuit analysis problem generally has a unique solution. A circuit design problem may have many solutions or even no solution. The maximum available signal levels found above provide bounds that help test for the existence of a solution. Generally there will be several ways to meet the interface constraints, and it then becomes necessary to evaluate the alternatives using other factors such as cost, power consumption, or reliability. Currently only the resistor will be used to demonstrate interface design. In subsequent sections other useful devices such as op amps and capacitors and inductors will be used to design suitable interfaces. In a design situation the engineer must choose the resistance values in a proposed circuit. This decision is influenced by a host of practical considerations such as standard values, standard tolerances, manufacturing methods, power limitations, and parasitic elements.

Example 9. Select the load resistance in Fig. 31 so the interface signals are in the range defined by $v \geq 4 \text{ V}$ and $i \geq 30 \text{ mA}$.

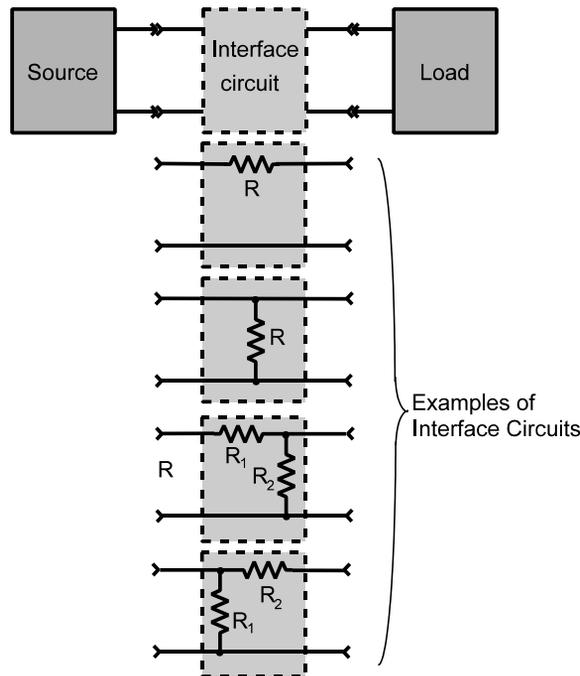

Fig. 30 General interface circuit and some examples.¹

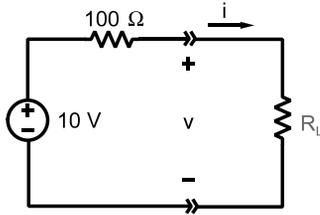

Fig. 31 (From Ref. 1.)

Solution. In this design problem the source circuit is given and a suitable load needs to be selected. For a fixed source the maximum signal levels available at the interface are

$$v_{MAX} = v_T = 10 \text{ V} \quad i_{MAX} = \frac{v_T}{R_T} = 100 \text{ mA}$$

The bounds given as design requirements are below the maximum available signal levels a suitable resistor can be found. Using voltage division, the interface voltage constraint requires

$$v = \frac{R_L}{100 + R_L} \times 10 \geq 4 \quad \text{or} \quad v = 10R_L \geq 4R_L + 400$$

This condition yields $R_L \geq 400/6 = 66.7 \Omega$. The interface current constraint can be written as

$$i = \frac{10}{100 + R_L} \geq 0.03 \quad \text{or} \quad i = 10 \geq 3 + 0.03R_L$$

which requires $R_L \leq 7/0.03 = 233 \Omega$. In principle any value of R_L between 66.7 and 233 Ω will work. However, to allow for circuit parameter variations, choose $R_L = 150 \Omega$ because it lies at the arithmetic midpoint of allowable range and is a standard value.

Example 10. Design the two-port interface circuit in Fig. 32 so that the 10-A source delivers 100 V to the 50- Ω load.

Solution. The problem requires that the current delivered to the load is $i = 100/50 = 2 \text{ A}$, which is well below the maximum available from the source. In fact, if the 10-A source is connected directly to the load, the source current divides equally between two 50- Ω resistors producing 5 A through the load. Therefore, an interface circuit is needed to reduce the load current to the specific 2-A level. Two possible design solutions are shown in Fig. 32. Applying current division to the parallel-resistor case yields the following constraint:

$$i = \frac{1/50}{1/50 + 1/50 + 1/R_{PAR}} \times 10$$

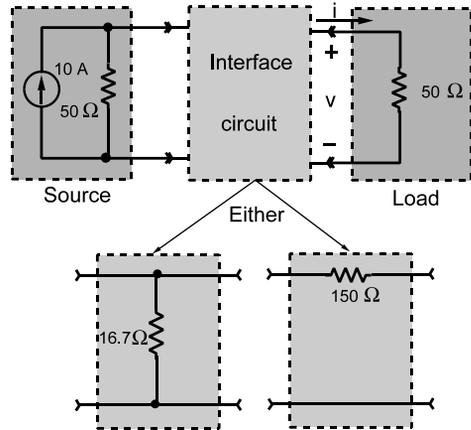

Fig. 32 (From Ref. 1.)

For the $i = 2\text{-A}$ design requirement this equation becomes

$$2 = \frac{10}{2 + 50/R_{PAR}}$$

Solving for R_{PAR} yields

$$R_{PAR} = \frac{50}{3} = 16.7 \Omega$$

Applying the two-path current division rule to the series-resistor case yields the following constraint:

$$i = \frac{50}{50 + (50 + R_{SER})} \times 10 = 2 \text{ A}$$

Solving for R_{SER} yields

$$R_{SER} = 150 \Omega$$

Both these two designs meet the basic $i = 2\text{-A}$ requirement. In practice, engineers evaluate alternative designs using additional criteria. One such consideration is the required power ratings of the resistors in each design. The voltage across the parallel resistor is $v = 100 \text{ V}$, so the power loss is

$$p_{PAR} = \frac{100^2}{50/3} = 600 \text{ W}$$

The current through the series-resistor interface is $i = 2 \text{ A}$ so the power loss is

$$p_{SER} = 2^2 \times 150 = 600 \text{ W}$$

In either design the resistors must have a power rating of at least 600 W. The series resistor is a standard

value whereas the parallel resistor is not. Other factors besides power rating and standard size could determine which design should be selected.

Example 11. Design the two-port interface circuit in Fig. 33 so the load is a match to $50\ \Omega$ between terminals C and D, while simultaneously the source matches to a load resistance of $300\ \Omega$ between A and B.

Solution. No single-resistor interface circuit could work. Hence try an interface circuit containing two resistors. Since the load must see a smaller resistance than the source, it should “look” into a parallel resistor. Since the source must see a larger resistance than the load, it should look into a series resistor. A configuration that meets these conditions is the L circuit shown in Figs. 33*b,c*.

The above discussion can be summarized mathematically. Using the L circuit, the design requirement at terminals C and D is

$$\frac{(R_1 + 300) R_2}{R_1 + 300 + R_2} = 50\ \Omega$$

At terminals A and B the requirement is

$$R_{11} + \frac{50R_2}{R_2 + 50} = 300\ \Omega$$

The design requirements yield two equations in two unknowns—what could be simpler? It turns out that

solving these nonlinear equations by hand analysis is a bit of a chore. They can easily be solved using a math solver such as MATLAB or MathCad. But a more heuristic approach might serve best.

Given the L circuits in Fig. 33*b*, such an approach goes as follows. Let $R_2 = 50\ \Omega$. Then the requirement at terminals C and D will be met, at least approximately. Similarly, if $R_1 + R_2 = 300\ \Omega$, the requirements at terminals A and B will be approximately satisfied. In other words, try $R_1 = 250\ \Omega$ and $R_2 = 50\ \Omega$ as a first cut. These values yield equivalent resistances of $R_{CD} = 50 || 550 = 45.8\ \Omega$ and $R_{AB} = 250 + 50 || 50 = 275\ \Omega$. These equivalent resistances are not the exact values specified but are within $\pm 10\%$. Since the tolerance on electrical components may be at least this high, a design using these values could be adequate. The exact values found by a math solver yields $R_1 = 273.861\ \Omega$ and $R_2 = 54.772\ \Omega$.

3 LINEAR ACTIVE CIRCUITS

This section treats the analysis and design of circuits containing active devices such as transistors or operational amplifier (op amps). An *active device* is a component that requires an external power supply to operate correctly. An *active circuit* is one that contains one or more active devices. An important property of active circuits is that they are capable of providing signal amplification one of the most important signal-processing functions in electrical engineering. Linear active circuits are governed by the proportionality property so their input–output relationships are of the form $y = Kx$. The term *signal amplification* means the proportionality factor $K > 1$ when the input x and output y have the same dimensions. Thus, active circuits can deliver more signal voltage, current, and power at their output than they receive from the input signal. The passive resistance circuits studied thus far cannot produce voltage, current, or power gains greater than unity.

3.1 Dependent Sources

When active devices operate in a linear mode, they can be modeled using resistors and one or more of the four dependent source elements shown in Fig. 34.

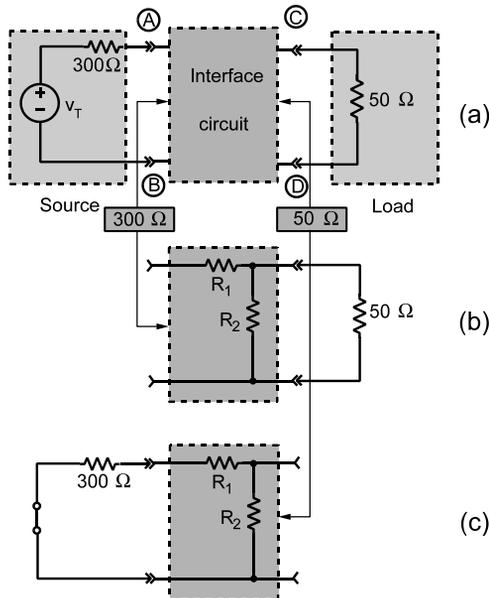

Fig. 33 (From Ref. 1.)

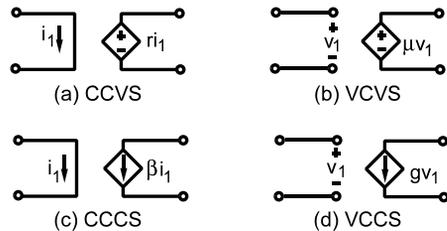

Fig. 34 Dependent source circuit symbols: (a) current-controlled voltage source; (b) voltage-controlled voltage source; (c) current-controlled current source; (d) voltage-controlled current source.¹

The dominant feature of a dependent source is that the strength or magnitude of the voltage source (VS) or current source (CS) is proportional to—that is, controlled by—a voltage (VC) or current (CC) appearing elsewhere in the circuit. For example, the dependent source model for a current-controlled current source (CCCS) is shown in Fig. 34c. The output current βi_1 is dependent on the input current i_1 and the dimensionless factor β . This dependency should be contrasted with the characteristics of the independent sources studied earlier. The voltage (current) delivered by an independent voltage (current) source does not depend on the circuit to which it is connected. Dependent sources are often but not always represented by the diamond symbol, in contrast to the circle symbol used for independent sources.

Each dependent source is characterized by a single parameter, μ , β , r , or g . These parameters are often called simply the *gain* of the controlled source. Strictly speaking, the parameters μ and β are dimensionless quantities called the *open-loop voltage gain* and *open-loop current gain*, respectively. The parameter r has the dimensions of ohms and is called the *transresistance*, a contraction of transfer resistance. The parameter g is then called *transconductance* and has the dimensions of siemens.

In every case the defining relationship for a dependent source has the form $y = Kx$, where x is the controlling variable, y is the controlled variable, and K is the element gain. It is this linear relationship between the controlling and controlled variables that make dependent sources linear elements.

Although dependent sources are elements used in circuit analysis, they are conceptually different from the other circuit elements. The linear resistor and ideal switch are models of actual devices called resistors and switches. But dependent sources are not listed in catalogs. For this reason dependent sources are more abstract, since they are not models of identifiable physical devices. Dependent sources are used in combination with other resistive elements to create models of active devices.

A voltage source acts like a short circuit when it is turned off. Likewise, a current source behaves like an open circuit when it is turned off. The same results apply to dependent sources, with one important difference. Dependent sources cannot be turned on and off individually because they depend on excitation supplied by independent sources. When applying the superposition principle or Thevenin's theorem to active circuits, the state of a dependent source depends on excitation supplied by independent sources. In particular, for active circuits the superposition principle states that the response due to all independent sources acting simultaneously is equal to the sum of the responses due to each independent source acting one at a time.

Analysis with Dependent Sources With certain modification the circuit analysis tools developed for

passive circuits apply to active circuits as well. Circuit reduction applies to active circuits, but the control variable for a dependent source must not be eliminated. Applying a source transformation to a dependent source is sometimes helpful. Methods like node and mesh analysis can be adapted to handle dependent sources as well. But the main difference is that the properties of active circuits can be significantly different from those of the passive circuits.

In the following example the objective is to determine the current, voltage, and power delivered to the 500- Ω output load in Fig. 35. The control current i_x is found using current division in the input circuit:

$$i_x = \left(\frac{50}{50 + 25} \right) i_s = \frac{2}{3} i_s$$

Similarly the output current i_o is found using current division in the output circuit:

$$i_o = \left(\frac{300}{300 + 500} \right) i_y = \frac{3}{8} i_y$$

But at node A KCL requires that $i_y = -48i_x$. Combining this result with the equations for i_x and i_o yields the output current:

$$i_o = \left(\frac{3}{8} \right) (-48) i_x = -18 \left(\frac{2}{3} i_s \right) = -12i_s \quad (22)$$

The output voltage v_o is found using Ohm's law:

$$v_o = i_o \times 500 = -6000i_s \quad (23)$$

The input-output relationships in Eqs. (22) and (23) are of the form $y = Kx$ with $K < 0$. The proportionality constants are negative because the reference direction for i_o in Fig. 35 is the opposite of the orientation of the dependent source reference mark. Active circuits often produce negative values of K . As a result the input and output signals have opposite signs, a result called *signal inversion*. In the analysis and design of active circuits it is important to keep track of signal inversions.

The delivered output power is

$$p_o = v_o i_o = (-6000i_s)(-12i_s) = 72,000i_s^2$$

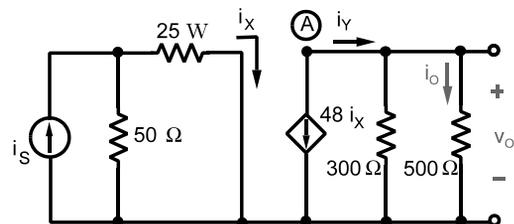

Fig. 35 Circuit with dependent source.¹

The input independent source delivers its power to the parallel combination of 50 and 25 Ω . Hence, the power supplied by the independent source is

$$p_S = (50||25) i_S^2 = \left(\frac{50}{3}\right) i_S^2$$

Given the input power and output power, we find the power gain in the circuit:

$$\text{Power gain} = \frac{p_O}{p_S} = \frac{72,000 i_S^2}{(50/3) i_S^2} = 432$$

A power gain greater than unity means that the circuit delivers more power at its output than it receives from the input source. At first glance, this appears to be a violation of energy conservation, but dependent sources are models of active devices that require an external power supply to operate. In general, circuit designers do not show the external power supply in circuit diagrams. Control source models assume that the external supply and the active device can handle whatever power is required by the circuit. With real devices this is not the case, and in circuit design engineers must ensure that the power limits of the device and external supply are not exceeded.

Node Voltage Analysis with Dependent Sources

Node voltage analysis of active circuits follows the same process as for passive circuits except that the additional constraints implied by the dependent sources must be accounted for. For example, the circuit in Fig. 36 has five nodes. With node E as the reference both independent voltage sources are connected to ground and force the condition $v_A = v_{S1}$ and $v_B = v_{S2}$.

Node analysis involves expressing element currents in terms of the node voltages and applying KCL at each unknown node. The sum of the currents *leaving* node C is

$$\frac{v_C - v_{S1}}{R_1} + \frac{v_C - v_{S2}}{R_2} + \frac{v_C}{R_B} + \frac{v_C - v_D}{R_P} = 0$$

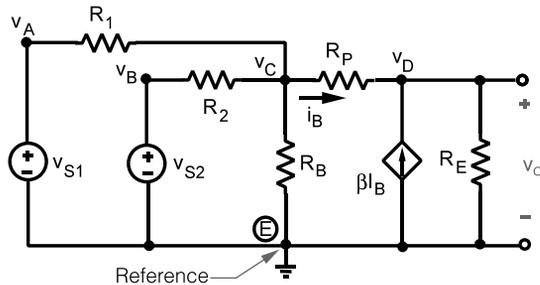

Fig. 36 Circuit used for node voltage analysis with dependent sources.¹

Similarly, the sum of currents leaving node D is

$$\frac{v_D - v_C}{R_P} + \frac{v_D}{R_E} - \beta i_B = 0$$

These two node equations can be rearranged into the forms

$$\begin{aligned} \text{Node C: } v_C \left(\frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_B} + \frac{1}{R_P} \right) - \frac{1}{R_P} v_D \\ = \frac{1}{R_1} v_{S1} + \frac{1}{R_2} v_{S2} \end{aligned}$$

$$\begin{aligned} \text{Node D: } -\frac{1}{R_P} v_C + \left(\frac{1}{R_P} + \frac{1}{R_E} \right) v_D \\ = \beta i_B \end{aligned}$$

Applying the fundamental property of node voltages and Ohm's law, the current i_B can be written in terms of the node voltages as

$$i_B = \frac{v_C - v_D}{R_P}$$

Substituting this expression for i_B into the above node equation and putting the results in standard form yield

$$\begin{aligned} \text{Node C: } \left(\frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_B} + \frac{1}{R_P} \right) v_C - \frac{1}{R_P} v_D \\ = \frac{1}{R_1} v_{S1} + \frac{1}{R_2} v_{S2} \end{aligned}$$

$$\begin{aligned} \text{Node D: } -(\beta + 1) \frac{1}{R_P} v_C \\ + \left[(\beta + 1) \frac{1}{R_P} + \frac{1}{R_E} \right] v_D = 0 \end{aligned}$$

The final result involves two equations in the two unknown node voltages and includes the effect of the dependent source.

This example illustrates a general approach to writing node voltage equations for circuits with dependent sources. Dependent sources are initially treated as if they are independent sources and node equations written for the resulting passive circuit. This step produces a set of symmetrical node equations with the independent and dependent source terms on the right side. Next the dependent source terms are expressed in terms of the unknown node voltages and moved to the left side with the other terms involving the unknowns. The last step destroys the coefficient symmetry but leads to a set of equations that can be solved for the active circuit response.

Mesh Current Analysis with Dependent Sources

Mesh current analysis of active circuits follows the same pattern noted for node voltage analysis. Treat the dependent sources initially as independent sources

and write the mesh equations of the resulting passive circuit. Then account for the dependent sources by expressing their constraints in terms of unknown mesh currents. The following example illustrates the method.

Example 12

- (a) Formulate mesh current equations for the circuit in Fig. 37.
- (b) Use the mesh equations to find v_O and R_{IN} when $R_1 = 50 \Omega$, $R_2 = 1 \text{ k}\Omega$, $R_3 = 100 \Omega$, $R_4 = 5 \text{ k}\Omega$, and $g = 100 \text{ mS}$.

Solution. (a) Applying source transformation to the parallel combination of R_3 and $g v_X$ in Fig. 37a produces the dependent voltage source $R_3 g v_X = \mu v_X$ in Fig. 37b. In the modified circuit we have identified two mesh currents. Initially treating the dependent source $(g R_3) v_X$ as an independent source leads to two symmetrical mesh equations:

Mesh A: $(R_1 + R_2 + R_3) i_A - R_3 i_B = v_S - (g R_3) v_X$
 Mesh B: $-R_3 i_A + (R_3 + R_4) i_B = (g R_3) v_X$

The control voltage v_X can be written in terms of mesh currents as

$$v_X = R_2 i_A$$

Substituting this equation for v_X into the mesh equations and putting the equations in standard form yield

$$(R_1 + R_2 + R_3 + g R_2 R_3) i_A - R_3 i_B = v_S$$

$$-(R_3 + g R_2 R_3) i_A + (R_3 + R_4) i_B = 0$$

The resulting mesh equations are not symmetrical because of the controlled source.

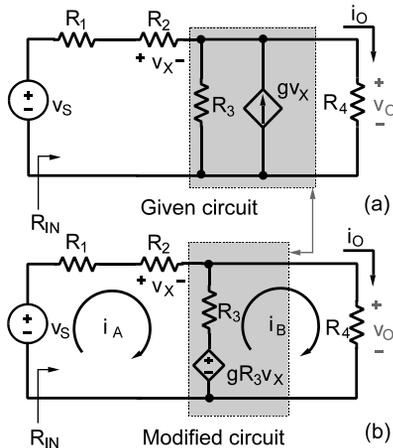

Fig. 37 (From Ref. 1.)

(b) Substituting the numerical values into the mesh equations gives

$$(1.115 \times 10^4) i_A - 10^2 i_B = v_S$$

$$-(1.01 \times 10^4) i_A + (5.1 \times 10^3) i_B = 0$$

Using Cramer's rule the mesh currents are found to be

$$i_A = (0.9131 \times 10^{-4}) v_S \quad \text{and}$$

$$i_B = (1.808 \times 10^{-4}) v_S$$

The output voltage and input resistance are found using Ohm's law:

$$v_O = R_4 i_B = 0.904 v_S \quad R_{IN} = \frac{v_S}{i_A} = 10.95 \text{ k}\Omega$$

Thevenin Equivalent Circuits with Dependent Sources

To find the Thevenin equivalent of an active circuit, the independent sources are left on or else one must supply excitation from an external test source. This means that the Thevenin resistance can not be found by the "look-back" method, which requires that all independent sources be turned off. Turning off the independent sources deactivates the dependent sources as well and can result in a profound change in input and output characteristics of an active circuit. Thus, Thevenin equivalents of active circuits can be found using the open-circuit voltage and short-circuit current at the interface.

Example 13. Find the Thevenin equivalent at the output interface of the circuit in Fig. 38.

Solution. In this circuit the controlled voltage v_X appears across an open circuit between nodes A and B. By the fundamental property of node voltages, $v_X = v_S - v_O$. With the load disconnected and the input source turned off, $v_X = 0$, the dependent voltage source μv_X acts like a short circuit, and the Thevenin resistance looking back into the output port is R_O . With the load connected and the input source turned on, the sum of currents leaving node B is

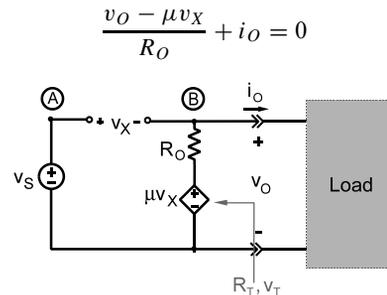

Fig. 38 (From Ref. 1.)

Using the relationship $v_X = v_S - v_O$ to eliminate v_X and then solving for v_O produce the output i - v relationship of the circuit as

$$v_O = \frac{\mu v_S}{\mu + 1} - i_O \left[\frac{R_O}{\mu + 1} \right]$$

The i - v relationship of a Thevenin circuit is $v = v_T - iR_T$. By direct comparison, the Thevenin parameters of the active circuit are found to be

$$v_T = \frac{\mu v_S}{\mu + 1} \quad \text{and} \quad R_T = \frac{R_O}{\mu + 1}$$

The circuit in Fig. 38 is a model of an op amp circuit called a voltage follower. The resistance R_O for a general-purpose op amp is on the order of 100Ω , while the gain μ is about 10^5 . Thus, the active Thevenin resistance of the voltage follower is not 100Ω , as the look-back method suggests, but around a milliohm!

3.2 Operational Amplifier

The operational amplifier is the premier linear active device made available by IC technology. John R. Ragazzini apparently first used the term operational amplifier in a 1947 paper and his colleagues who reported on work carried out for the National Defense Research Council during World War II. The paper described high-gain dc amplifier circuits that perform mathematical operations (addition, subtraction, multiplication, division, integration, etc.)—hence the name “operational” amplifier. For more than a decade the most important applications were general- and special-purpose analog computers using vacuum tube amplifiers. In the early 1960s general-purpose, discrete-transistor, op amp became readily available and by the mid-1960s the first commercial IC op amps entered the market. The transition from vacuum tubes to ICs resulted in a decrease in size, power consumption, and cost of op amps by over three orders of magnitude. By the early 1970s the IC version became the dominant

active device in analog circuits. The device itself is a complex array of transistors, resistors, diodes, and capacitors all fabricated and interconnected on a single silicon chip. In spite of its complexity, the op amp can be modeled by rather simple i - v characteristics.

Op Amp Notation Certain matters of notation and nomenclature must be discussed before developing a circuit model for the op amp. The op amp is a five-terminal device, as shown in Fig. 39a. The “+” and “−” symbols identify the input terminals and are a shorthand notation for the noninverting and inverting input terminals, respectively. These “+” and “−” symbols identify the two input terminals and have nothing to do with the polarity of the voltages applied. The other terminals are the output and the positive and negative supply voltage, usually labeled $+V_{CC}$ and $-V_{CC}$. While some op amps have more than five terminals, these five are always present. Figure 39b shows how these terminals are arranged in a common eight-pin IC package.

While the two power supply terminals in Fig. 39 are not usually shown in circuit diagrams, they are always there because the external power supplies connected to these terminals make the op amp an active device. The power required for signal amplification comes through these terminals from an external power source. The $+V_{CC}$ and $-V_{CC}$ voltages applied to these terminals also determine the upper and lower limits on the op amp output voltage.

Figure 40a shows a complete set of voltage and current variables for the op amp, while Fig. 40b shows the typical abbreviated set of signal variables. All voltages are defined with respect to a common reference node, usually ground. Voltage variables v_P , v_N , and v_O are defined by writing a voltage symbol beside the corresponding terminals. This notation means the “+” reference mark is at the terminal in question and the “−” reference mark is at the reference or ground terminal. The reference directions for the currents are directed in at input terminals and out at the output. A global KCL equation for the complete set of variables in Fig. 40a is $i_O = I_{C+} + I_{C-} + i_P + i_N$, NOT $i_O = i_N + i_P$, as might be inferred from Fig. 40b, since it does not

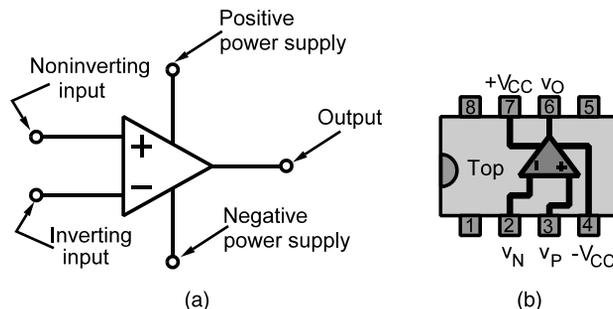

Fig. 39 Op amp: (a) circuit symbol; (b) pin out diagram for eight-pin package.¹

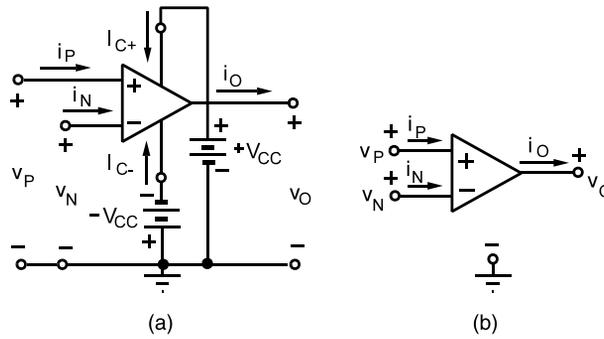

Fig. 40 Op amp voltage and current definitions: (a) complete set; (b) shorthand set.¹

include all of the currents. More importantly, it implies that the output current comes from the inputs. In fact, this is wrong. The input currents are very small, ideally zero. The output current comes from the supply voltages even though these terminals are not shown on the abbreviated circuit diagram.

Transfer Characteristics The dominant feature of the op amp is the transfer characteristic shown in Fig. 41. This characteristic provides the relationships between the *noninverting input* v_P , the *inverting input* v_N , and the *output voltage* v_O . The transfer characteristic is divided into three regions or modes called *+saturation*, *-saturation*, and *linear*. In the linear region the op amp is a *differential amplifier* because the output is proportional to the difference between the two inputs. The slope of the line in the linear region is called the *open-loop gain*, denoted as μ . In the linear region the input-output relation is $v_O = \mu(v_P - v_N)$. The open-loop gain of an op amp is very large, usually greater than 10^5 . As long as the net input $v_P - v_N$ is very small, the output will be proportional to the input. However, when $\mu|v_P - v_N| > V_{CC}$, the op amp is saturated and the output voltage is limited by the supply voltages (less some small internal losses).

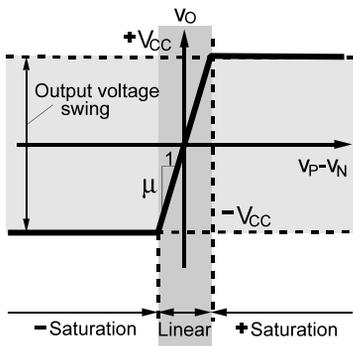

Fig. 41 Op amp transfer characteristics.¹

The op amp has three operating modes:

1. + Saturation mode when $\mu(v_P - v_N) > +V_{CC}$ and $v_O = +V_{CC}$.
2. - Saturation mode when $\mu(v_P - v_N) < -V_{CC}$ and $v_O = -V_{CC}$.
3. Linear mode when $\mu|v_P - v_N| < V_{CC}$ and $v_O = \mu(v_P - v_N)$.

Usually op amp circuits are analyzed and designed using the linear mode model.

Ideal Op Amp Model A controlled source model of an op amp operating in its linear range is shown in Fig. 42. This model includes an input resistance (R_I), an output resistance (R_O), and a voltage-controlled voltage source whose gain is the open-loop gain μ . Some typical ranges for these op amp parameters are given in Table 3, along with the values for the ideal op amp. The high input and low output resistances and high open-loop gain are the key attributes of an op amp. The ideal model carries these traits to the extreme limiting values.

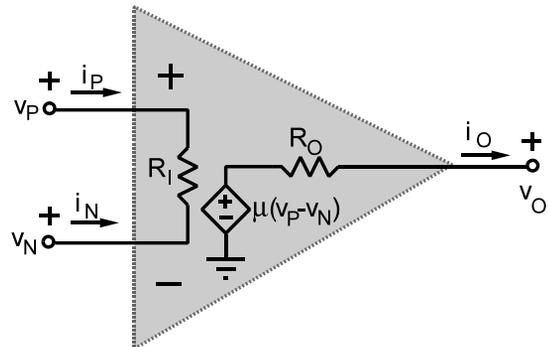

Fig. 42 Dependent source model of op amp operating in linear mode.¹

Table 3 Typical Op Amp Parameters

Name	Parameter	Range	Ideal Values
Open-loop gain	μ	10^5 – 10^8	∞
Input resistance	R_I	10^6 – $10^{13} \Omega$	$\infty \Omega$
Output resistance	R_O	10 – 100Ω	0Ω
Supply voltages	V_{CC}	± 5 to ± 40 V	

The controlled source model can be used to develop the i – v relationships of the ideal model. This discussion is restricted to the linear region of operation. This means the output voltage is bounded as

$$-V_{CC} \leq v_o \leq +V_{CC} \quad -\frac{V_{CC}}{\mu} \leq (v_P - v_N) \leq +\frac{V_{CC}}{\mu}$$

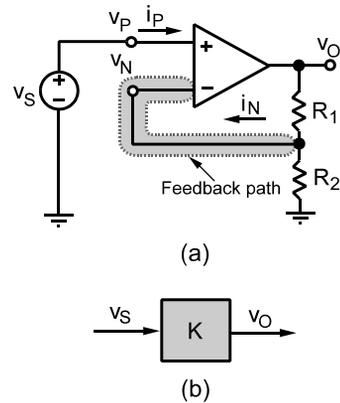

The supply voltages V_{CC} are most commonly ± 15 V although other supply voltages are available, while μ is a very large number, usually 10^5 or greater. Consequently, linear operation requires that $v_P \cdot v_N$. For the ideal op amp the open-loop gain is infinite ($\mu \rightarrow \infty$), in which case linear operation requires $v_P = v_N$. The input resistance R_I of the ideal op amp is assumed to be infinite so the currents at both input terminals are zero. In summary, the i – v relationships of the *ideal model* of the op amp are

$$v_P = v_N \quad i_P = i_N = 0 \quad (24)$$

At first glance the element constraints of the ideal op amp appear to be fairly useless. They actually look more like connection constraints and are totally silent about the output quantities (v_O and i_O), which are usually the signals of interest. In fact, they seem to say that the op amp input terminals are simultaneously a short circuit ($v_P = v_N$) and an open circuit ($i_P = i_N = 0$). The ideal model of the op amp is useful because in linear applications feedback is always present. That is, in order for the op amp to operate in a linear mode, it is necessary that there be feedback paths from the output to one or both of the inputs. These feedback paths ensure that $v_P = v_N$ and allow for analysis of op amp circuits using the ideal op amp element constraints.

Op Amp Circuit Analysis This section introduces op amp circuit analysis using circuits that are building blocks for analog signal-processing systems. The key to using the *building block* approach is to recognize the feedback pattern and to isolate the basic circuit as a building block.

Noninverting Op Amp To illustrate the effects of feedback, consider the circuit in Fig. 43. This circuit has a feedback path from the output to the inverting input via a voltage divider. Since the ideal op amp draws no current at either input ($i_P = i_N = 0$),

**Fig. 43** Noninverting amplifier circuit.¹

voltage division determines the voltage at the inverting input as

$$v_N = \frac{R_2}{R_1 + R_2} v_O$$

The input source connection at the noninverting input requires the condition $v_P = v_S$. But the ideal op amp element constraints demand that $v_P = v_N$; therefore, the input–output relationship of the overall circuit is

$$v_O = \frac{R_1 + R_2}{R_2} v_S \quad (25)$$

The circuit in Fig. 43a is called a *noninverting amplifier*. The input–output relationship is of the form $v_O = K v_S$, a linear relationship. Figure 43b shows the functional building block for this circuit, where the proportionality constant K is

$$K = \frac{R_1 + R_2}{R_2} \quad (26)$$

The constant K is called the *closed-loop gain*, since it includes the effect of the feedback path. When discussing op amp circuits, it is necessary to distinguish between two types of gains. The first is the open-loop gain μ provided by the op amp device. The gain μ is a large number with a large uncertainty tolerance. The second type is the closed-loop gain K of the op amp circuit with a feedback path. The gain K must be smaller than μ , typically no more than $1/100$ of μ , and its value is determined by the resistance elements in the feedback path.

For example, the closed-loop gain in Eq. (26) is really the voltage division rule upside down. The uncertainty tolerance assigned to K is determined by the quality of the resistors in the feedback path, and not the uncertainty in the actual value of the closed-loop gain. In effect, feedback converts a very large but

imprecisely known open-loop gain into a much smaller but precisely controllable closed-loop gain.

Example 14. Design an amplifier with a closed-loop gain $K = 10$.

Solution. Using a noninverting op amp circuit, the design problem is to select the values of the resistors in the feedback path. From Eq. (26) the design constraint is

$$10 = \frac{R_1 + R_2}{R_2}$$

This yields one constraint with two unknowns. Arbitrarily selecting $R_2 = 10 \text{ k}\Omega$ makes $R_1 = 90 \text{ k}\Omega$. These resistors would normally have high precision ($\pm 1\%$ or less) to produce a precisely controlled closed-loop gain.

Comment: The problem of choosing resistance values in op amp circuit design problems deserves some discussion. Although resistances from a few ohms to several hundred megohms are commercially available, generally designers limit themselves to the range from about $1 \text{ k}\Omega$ to perhaps $2.2 \text{ M}\Omega$. The lower limit of $1 \text{ k}\Omega$ exists in part because of power dissipation in the resistors and to minimize the effects of loading (discussed later). Typically resistors with 3 W power ratings or less are used. The maximum voltages in op amp circuits are often around $\pm 15 \text{ V}$ although other values exist, including single-sided op amps, with a $0\text{--}5 \text{ V}$ V_{CC} for use in digital applications. The smallest 3-W resistance we can use is $R_{\text{MIN}} > (15)^2/0.25 = 900 \Omega$, or about $1 \text{ k}\Omega$. The upper bound of $2.2 \text{ M}\Omega$ exists because it is difficult to maintain precision in a high-value resistor because of surface leakage caused by humidity. High-value resistors are also noisy, which leads to problems when they are in the feedback path. The range $1 \text{ k}\Omega$ to $2.2 \text{ M}\Omega$ should be used as a guideline and not an inviolate design rule. Actual design choices are influenced by system-specific factors and changes in technology.

Voltage Follower The op amp in Fig. 44a is connected as *voltage follower* or *buffer*. In this case the feedback path is a direct connection from the output to the inverting input. The feedback connection forces the condition $v_N = v_O$. The input current $i_P = 0$ so there is no voltage across the source resistance R_S . Applying KVL results in $v_P = v_S$. The ideal op amp model requires $v_P = v_N$, so that $v_O = v_S$. By inspection the closed-loop gain is $K = 1$. The output exactly equals the input, that is, the output follows the input, and hence the name voltage follower.

The voltage follower is used in interface circuits because it isolates the source and load—hence its other name, *buffer*. Note that the input–output relationship $v_O = v_S$ does not depend on the source or load resistance. When the source is connected directly to the load as in Fig. 44b, the voltage delivered to the load depends on R_S and R_L . The source and load interaction limits the signals that can transfer across the interface.

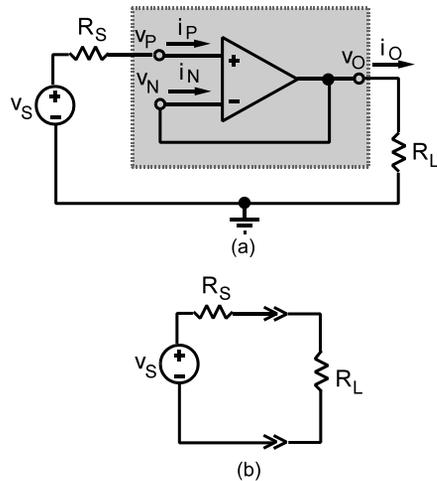

Fig. 44 (a) Source–load interface with voltage follower; (b) interface without voltage follower.¹

When the voltage follower is inserted between the source and load, the signal levels are limited by the capability of the op amp.

Inverting Amplifier The circuit in Fig. 45 is called an *inverting amplifier*. The key feature of this circuit is that the input signal and the feedback are both applied at the inverting input. Note that the noninverting input is grounded, making $v_P = 0$. Using the fundamental property of node voltages and KCL, the sum of currents entering node A can be written as

$$\frac{v_S - v_N}{R_1} + \frac{v_O - v_N}{R_2} - i_N = 0$$

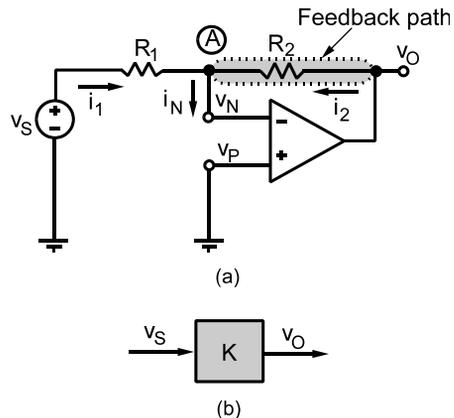

Fig. 45 Inverting amplifier circuit.¹

The element constraints for the op amp are $v_P = v_N$ and $i_P = i_N = 0$. Since $v_P = 0$, it follows that $v_N = 0$. Substituting the op amp constraints and solving for the input–output relationship yield

$$v_O = - \left(\frac{R_2}{R_1} \right) v_S \quad (27)$$

This result is of the form $v_O = K v_S$, where K is the closed-loop gain. However, in this case the closed-loop gain $K = -R_2/R_1$ is negative, indicating a signal inversion—hence the name inverting amplifier. The block diagram symbol shown in Fig. 45b is used to indicate either the inverting or noninverting op amp configuration since both circuits provide a gain of K .

The op amp constraints mean that the input current i_1 in Fig. 43a is

$$i_1 = \frac{v_S - v_N}{R_1} = \frac{v_S}{R_1}$$

This in turn means that the input resistance seen by the source v_S is

$$R_{IN} = \frac{v_S}{i_1} = R_1 \quad (28)$$

In other words, the inverting amplifier has a finite input resistance determined by the external resistor R_1 . This finite input resistance must be taken into account when analyzing circuits with op amps in the inverting amplifier configuration

Summing Amplifier The *summing amplifier* or *adder* circuit is shown in Fig. 46a. This circuit has two inputs connected at node A, which is called the *summing point*. Since the noninverting input is

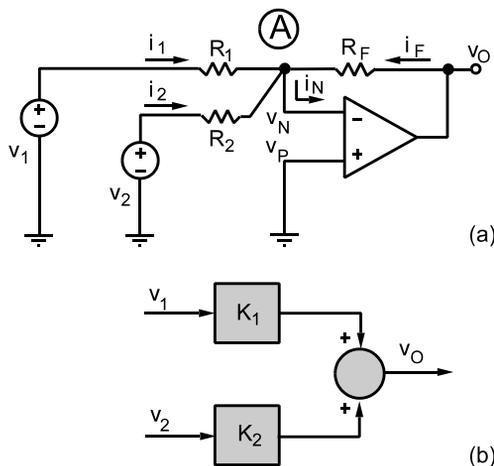

Fig. 46 Inverting summer.¹

grounded, $v_P = 0$. This configuration is similar to the inverting amplifier hence a similar analysis yields the circuit input–output relationship

$$v_O = \begin{cases} \left(-\frac{R_F}{R_1} \right) v_1 + \left(-\frac{R_F}{R_2} \right) v_2 \\ (K_1)v_1 + (K_2)v_2 \end{cases} \quad (29)$$

The output is a weighted sum of the two inputs. The scale factors, or gains as they are called, are determined by the ratio of the feedback resistor R_F to the input resistor for each input: that is, $K_1 = -R_F/R_1$ and $K_2 = -R_F/R_2$. In the special case $R_1 = R_2 = R$, Eq. (29) reduces to

$$v_O = K (v_1 + v_2)$$

where $K = -R_F/R$. In this special case the output is proportional to the negative sum of the two inputs—hence the name inverting summing amplifier or simply adder. A block diagram representation of this circuit is shown in Fig. 46b.

Example 15. Design an inverting summer that implements the input–output relationship $v_O = -(5v_1 + 13v_2)$.

Solution. The design problem involves selecting the input and feedback resistors so that

$$\frac{R_F}{R_1} = 5 \quad \text{and} \quad \frac{R_F}{R_2} = 13$$

One solution is to arbitrarily select $R_F = 65 \text{ k}\Omega$, which yields $R_1 = 13 \text{ k}\Omega$ and $R_2 = 5 \text{ k}\Omega$. The resulting circuit is shown in Fig. 47a. The design can be modified to use standard resistance values for resistors with $\pm 5\%$ tolerance. Selecting the standard

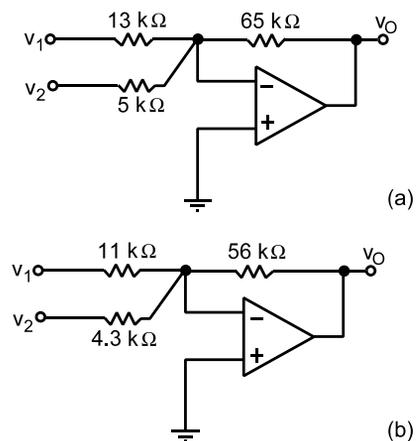

Fig. 47 (From Ref. 1.)

value $R_F = 56 \text{ k}\Omega$ requires $R_1 = 11.2 \text{ k}\Omega$ and $R_2 = 4.31 \text{ k}\Omega$. The nearest standard values are 11 and $4.3 \text{ k}\Omega$. The resulting circuit shown in Fig. 47b uses only standard value resistors and produces gains of $K_1 = 56/11 = 5.09$ and $K_2 = 56/4.3 = 13.02$. These nominal gains are within 2% of the values in the specific input-output relationship.

Differential Amplifier The circuit in Fig. 48a is called a *differential amplifier* or *subtractor*. Like the summer, this circuit has two inputs, but unlike the summer, one is applied at the inverting input and one at the noninverting input of the op amp. The input-output relationship can be obtained using the superposition principle.

With source v_2 off there is no excitation at the noninverting input and $v_P = 0$. In effect, the noninverting input is grounded and the circuit acts like an inverting amplifier with the result that

$$v_{O1} = -\frac{R_2}{R_1}v_1$$

Now turning v_2 back on and turning v_1 off, the circuit looks like a noninverting amplifier with a voltage divider connected at its input. Thus

$$v_{O2} = \left[\frac{R_4}{R_3 + R_4} \right] \left[\frac{R_1 + R_2}{R_1} \right] v_2$$

Using superposition the two outputs are added to obtain the output with both sources on:

$$v_O = \begin{cases} v_{O1} + v_{O2} \\ -\left[\frac{R_2}{R_1} \right] v_1 + \left[\frac{R_4}{R_3 + R_4} \right] \left[\frac{R_1 + R_2}{R_1} \right] v_2 \\ -[K_1]v_1 + [K_2]v_2 \end{cases} \quad (30)$$

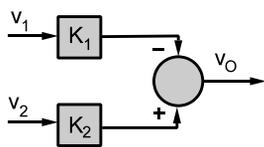

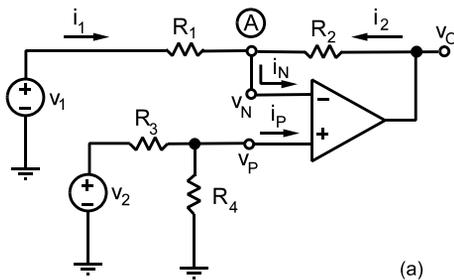

Fig. 48 Differential amplifier.¹

where K_1 and K_2 are the inverting and noninverting gains. Figure 48b shows how the differential amplifier is represented in a block diagram. In the special case of $R_1 = R_2 = R_3 = R_4$, Eq. (30) reduces to $v_O = v_2 - v_1$. In this case the output is equal to the difference between the two inputs—hence the name differential amplifier or subtractor.

Noninverting Summer The circuit in Fig. 49 is an example of a *noninverting summer*. The input-output relationship for a general noninverting summer is

$$v_O = K \left[\left(\frac{R_{EQ}}{R_1} \right) v_1 + \left(\frac{R_{EQ}}{R_2} \right) v_2 + \dots + \left(\frac{R_{EQ}}{R_n} \right) v_n \right] \quad (31)$$

where R_{EQ} is the Thevenin resistance looking to the left at point P with all sources turned off (i.e., $R_{EQ} = R_1 \parallel R_2 \parallel R_3 \dots \parallel R_n$) and K is the gain of the noninverting amplifier circuit to the right of point P. Comparing this equation with the general inverting summer result in Eq. (29), we see several similarities. In both cases the weight assigned to an input voltage is proportional to a resistance ratio in which the denominator is its input resistance. In the inverting summer the numerator of the ratio is the feedback resistor R_F and in the noninverting case the numerator is the equivalent of all input resistors R_{EQ} .

Design with Op Amp Building Blocks The block diagram representation of the basic op amp circuit configuration were developed in the preceding section. The noninverting and inverting amplifier are represented as gain blocks. The summing amplifier and differential amplifier require both gain blocks and the summing symbol. One should exercise care when translating from a block diagram to a circuit, or vice versa, since some gain blocks may involve negative gains. For example, the gain of the inverting amplifier is negative, as are the gains of the common inverting summing amplifier and the K_1 gain of the differential amplifier. The minus sign is sometimes moved to the summing symbol and the gain within the block changed to a positive number. Since there is

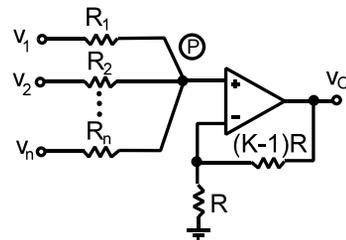

Fig. 49 Noninverting summer.²

no standard convention for doing this, it is important to keep track of the signs associated with gain blocks and summing point symbol.

Operational amplifier circuit design generally requires that a given equation or block diagram representation of a signal-processing function be created to implement that the function. Circuit design can often be accomplished by interconnecting the op amp, summer, and subtractor building blocks. The design process is greatly simplified by the near one-to-one correspondence between the op amp circuits and the elements in a block diagram. However, the design process is not unique since often there are several ways to use basic op amp circuits to meet the design objective. Some solutions are better than others are. The following example illustrates the design process.

Example 16. Design an op amp circuit that implements the block diagram in Fig. 50.

Solution. The input–output relationship represented by the block diagram is $v_o = 5v_1 + 10v_2 + 20v_3$. An op amp adder can implement the summation required in this relationship. A three-input adder implements

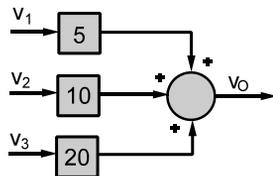

Fig. 50 (From Ref. 2.)

the relationship

$$v_o = - \left[\frac{R_F}{R_1} v_1 + \frac{R_F}{R_2} v_2 + \frac{R_F}{R_3} v_3 \right]$$

The required scale factors are realized by first selecting $R_F = 100 \text{ k}\Omega$ and then choosing $R_1 = 20 \text{ k}\Omega$, $R_2 = 10 \text{ k}\Omega$, and $R_3 = 5 \text{ k}\Omega$. However, the adder involves a signal inversion. To correctly implement the block diagram, we must add an inverting amplifier ($K = -R_2/R_1$) with $R_1 = R_2 = 100 \text{ k}\Omega$. The final implementation is shown in Fig. 51a. An alternate solution avoiding the second inverting op amp by using a non-inverting summer is shown in Fig. 51b.

Digital-to-Analog Converters Operational amplifier play an important role in the interface between digital systems and analog systems. The parallel 4-bit output in Fig. 52 is a digital representation of a signal. Each bit can only have two values: (a) a high or 1 (typically +5 V) and (b) a low or 0 (typically 0 V).

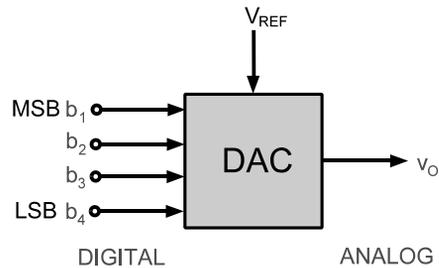

Fig. 52 A DAC.¹

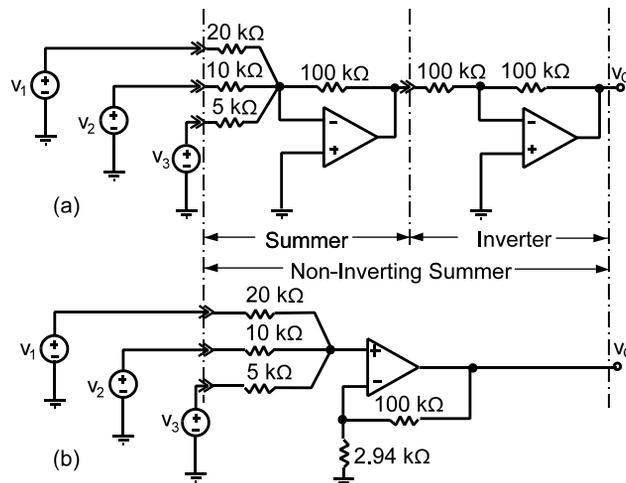

Fig. 51 (From Ref. 2.)

The bits have binary weights so that v_1 is worth $2^3 = 8$ times as much as v_4 , v_2 is worth $2^2 = 4$ times as much as v_4 , v_3 is worth $2^1 = 2$ times as much as v_4 , and v_4 is equal to $2^0 = 1$ times itself. In a 4-bit DAC v_4 is the least significant bit (LSB) and v_1 the most significant bit (MSB). To convert the digital representation of the signal to analog form, each bit must be weighted so that the analog output v_o is

$$v_o = \pm K(8v_1 + 4v_2 + 2v_3 + 1v_4) \quad (32)$$

where K is a scale factor or gain applied to the analog signal. Equation (32) is the input-output relationship of a 4-bit digital-to-analog converter (DAC).

One way to implement Eq. (32) is to use an inverting summer with binary-weighted input resistors. Figure 53 shows the op amp circuit and a block diagram of the circuit input-output relationship. In either form, the output is seen to be a binary-weighted sum of the digital input scaled by $-R_F/R$. That is, the output voltage is

$$v_o = \frac{-R_F}{R}(8v_1 + 4v_2 + 2v_3 + v_4)$$

The $R-2R$ ladder in Fig. 54a also implements a 4-bit DAC. The resistance seen looking back into the $R-2R$ ladder at point A with all sources turned off is seen to be $R_T = R$. A Thevenin equivalent circuit of the $R-2R$ network is shown in Fig. 54b, where

$$v_T = \frac{1}{2}v_1 + \frac{1}{4}v_2 + \frac{1}{8}v_3 + \frac{1}{16}v_4$$

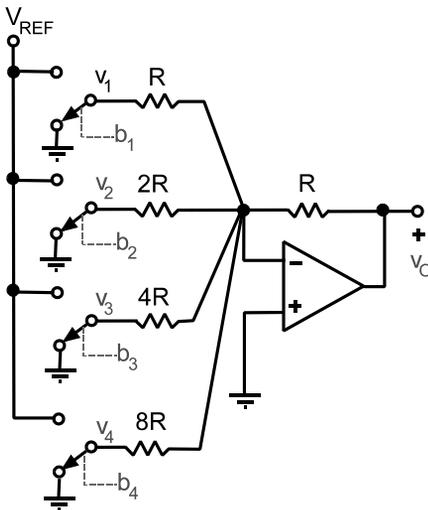

Fig. 53 Binary-weighted summer DAC.¹

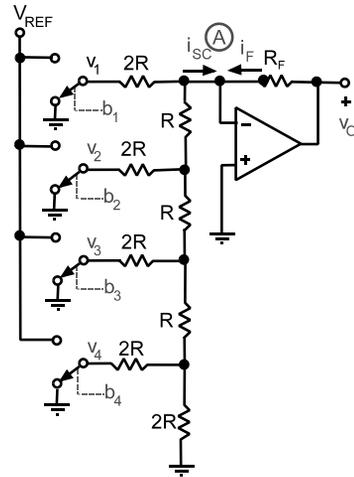

Fig. 54 An $R-2R$ ladder DAC.¹

The output voltage is found using the inverting amplifier gain relationship:

$$v_o = \frac{-R_F}{R}v_T = \frac{-R_F}{R}\left(\frac{v_1}{2} + \frac{v_2}{4} + \frac{v_3}{8} + \frac{v_4}{16}\right)$$

Using $R_F = 16R$ yields

$$v_o = -(8v_1 + 4v_2 + 2v_3 + v_4)$$

which shows the binary weights assigned to the digital inputs.

In theory the circuits in Figs. 53 and 54 perform the same signal-processing function—4-bit digital-to-analog conversion. However, there are important practical differences between the two circuits. The inverting summer in Fig. 53 requires precision resistors with four different values spanning an 8 : 1 range. A more common 8-bit converter would require eight precision resistors spanning a 256 : 1 range. Moreover, the digital voltage sources in Fig. 53 see input resistances that span an 8 : 1 range; therefore, the source-load interface is not the same for each bit. On the other hand, the resistances in the $R-2R$ ladder in Fig. 54 span only a 2 : 1 range regardless of the number of digital bits. The $R-2R$ ladder also presents the same input resistance to each binary input. The $R-2R$ ladder converters are readily made on integrated or thin-film circuits and are the preferred DAC type.

Instrumentation Systems One of the most interesting and useful applications of op amp circuits is in instrumentation systems that collect and process data about physical phenomena. In such a system an *input transducer* (a device that converts some physical quantity, such as temperature, strain, light intensity,

acceleration, wavelength, rotation, velocity, pressure, or whatever, into an electrical signal) generates an electrical signal that describes some ongoing physical process. In a simple system the transducer signal is processed by op amp circuits and displayed on an *output transducer* such as a meter or an oscilloscope or more commonly sent into a DAC for further processing or analysis by a microprocessor or digital computer. The output signal can also be used in a feedback control system to monitor and regulate the physical process itself or to control a robotic device.

The block diagram in Fig. 55 shows an instrumentation system in its simplest form. The objective of the system is to deliver an output signal that is directly proportional to the physical quantity measured by the input transducer. The input transducer converts a physical variable x into an electrical voltage v_{TR} . For many transducers this voltage is of the form $v_{TR} = mx + b$, where m is a calibration constant and b is a constant

offset or bias. The transducer voltage is often quite small and must be amplified by the gain K , as indicated in Fig. 55. The amplified signal includes both a signal component $K(mx)$ and a bias component $K(b)$. The amplified bias $K(b)$ is then removed by subtracting a constant electrical signal. The resulting output voltage $K(mx)$ is directly proportional to the quantity measured and goes to an output transducer for display. The required gain K can be found from the relation

$$K = \frac{\text{desired output range}}{\text{available input range}} \quad (33)$$

Example 17. Design a light intensity detector to detect 5–20 lm of incident light using a photocell serving as the input transducer. The system output is to be displayed on a 0–10-V voltmeter. The photocell characteristics are shown in Fig. 56a. The design

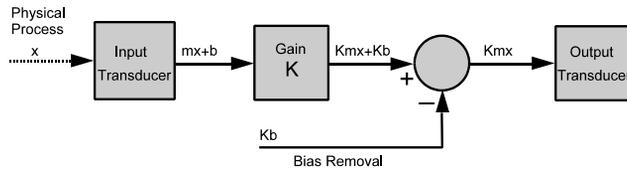

Fig. 55 Block diagram of instrumentation system.²

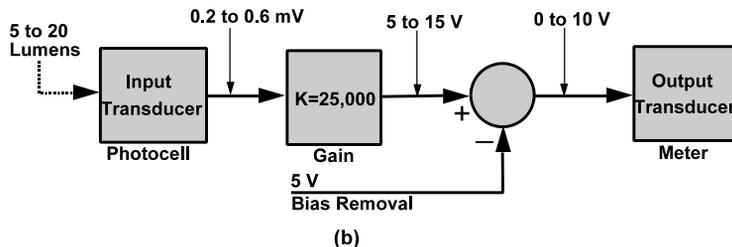

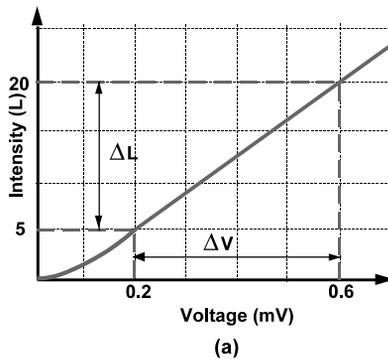

Fig. 56 (From Ref. 2.)

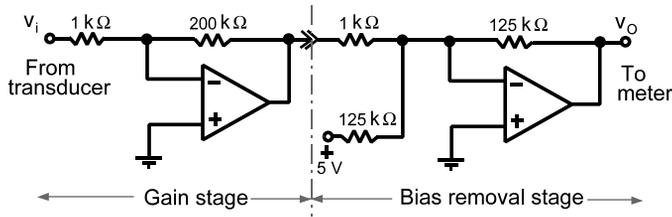

Fig. 57 (From Ref. 2.)

requirements are that 5 lm indicates 0 V and 20 lm indicates 10 V on the voltmeter.

Solution. From the transducer's characteristics the light intensity range $\Delta L = 20 - 5 = 15$ lm will produce an available range of $\Delta v = (0.6 \text{ m} - 0.2 \text{ m}) = 0.4 \text{ mV}$ at the system input. This 0.4-mV change must be translated into a 0–10-V range at the system output. To accomplish this, the transducer voltage must be amplified by a gain of

$$K = \frac{\text{desired output range}}{\text{available input range}} = \frac{10 - 0}{0.6 \times 10^{-3} - 0.2 \times 10^{-3}} = 2.5 \times 10^4$$

When the transducer's output voltage range (0.2–0.6 mV) is multiplied by the gain K found above, we obtain a voltage range of 5–15 V. This range is shifted to the required 0–10-V range by subtracting the 5-V bias from the amplified signal. A block diagram of the required signal-processing functions is shown in Fig. 56b.

A cascade connection of op amp circuits is used to realize the signal-processing functions in the block diagram. Figure 57 shows one possible design using an inverting amplifier and an inverting adder. This design includes two inverting circuits in cascade so the signal inversions cancel in the output signal. Part of the overall gain of $K = 2.5 \times 10^4$ is realized in the inverting amplifier ($K_1 = -200$) and the remainder by the inverting summer ($K_2 = -125$). Dividing the overall gain between the two stages avoids trying to produce too large of a gain in a single stage. A single-stage gain of $K = 25,000$ is not practical since the closed-loop gain is not small compared to the open-loop gain μ of most op amps. The high gain would also require a very low input resistance that could load the input and an uncommonly large feedback resistance, for example, 100 Ω and 2.5 M Ω .

Example 18. A strain gauge is a resistive device that measures the elongation (strain) of a solid material caused by applied forces (stress). A typical strain gauge consists of a thin film of conducting material deposited on an insulating substrate. When bonded to

a member under stress, the resistance of the gauge changes by an amount

$$\Delta R = 2R_G \frac{\Delta L}{L}$$

where R_G is the resistance of the gage with no applied stress and $\Delta L/L$ is the elongation of the material expressed as a fraction of the unstressed length L . The change in resistance ΔR is only a few tenths of a milliohm, far too little to be measured with an ohmmeter. To detect such a small change, the strain gage is placed in a Wheatstone bridge circuit like the one shown in Fig. 58. The bridge contains fixed resistors R_A and R_B , two matched strain gages R_{G1} and R_{G2} , and a precisely controlled reference voltage v_{REF} . The values of R_A and R_B are chosen so that the bridge is balanced ($v_1 = v_2$) when no stress is applied. When stress is applied, the resistance of the stressed gage changes to $R_{G2} + \Delta R$ and the bridge is unbalanced ($v_1 \neq v_2$). The differential signal ($v_2 - v_1$) indicates the strain resulting from the applied stress.

Design an op amp circuit to translate strains on the range $0 < \Delta L/L < 0.02\%$ into an output voltage on the range $0 < v_O < 4$ for $R_G = 120 \Omega$ and $v_{REF} = 25 \text{ V}$.

Solution. With external stress applied, the resistance R_{G2} changes to $R_{G2} + \Delta R$. Applying voltage division to each leg of the bridge yields

$$v_2 = \frac{R_{G2} + \Delta R}{R_{G1} + R_{G2}} V_{REF} \quad v_1 = \frac{R_B}{R_A + R_B} V_{REF}$$

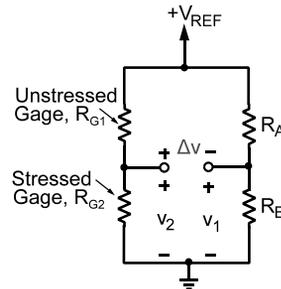

Fig. 58 (From Ref. 2.)

The differential voltage ($\Delta v = v_2 - v_1$) can be written as

$$\Delta v = v_2 - v_1 = V_{\text{REF}} \left[\frac{R_{G1} + \Delta R}{R_{G1} + R_{G2}} - \frac{R_A}{R_A + R_B} \right]$$

By selecting $R_{G1} = R_{G2} = R_A = R_B = R_G$, a balanced bridge is achieved in the unstressed state, in which case the differential voltage reduces to

$$\Delta v = v_2 - v_1 = V_{\text{REF}} \left[\frac{\Delta R}{2R_G} \right] = V_{\text{REF}} \left[\frac{\Delta L}{L} \right]$$

Thus, the differential voltage Δv is directly proportional to the strain $\Delta L/L$. However, for $V_{\text{REF}} = 25$ V and $\Delta L/L = 0.02\%$ the differential voltage is only $(V_{\text{REF}})(\Delta L/L) = 25 \times 0.0002 = 5$ mV. To obtain the required 4-V output, a voltage gain of $K = 4/0.005 = 800$ is required.

The op amp subtractor is specifically designed to amplify differential signals. Selecting $R_1 = R_3 = 10$ k Ω and $R_2 = R_4 = 8$ M Ω produces an input-output relationship for the subtractor circuit of

$$v_O = 800(v_2 - v_1)$$

Figure 59 shows the selected design.

The input resistance of the subtractor circuit must be large to avoid loading the bridge circuit. The Thevenin resistance look-back into the bridge circuit is

$$\begin{aligned} R_T &= R_{G1} \parallel R_{G2} + R_A \parallel R_B \\ &= R_G \parallel R_G + R_G \parallel R_G \\ &= R_G = 120 \Omega \end{aligned}$$

which is small compared to 10-k Ω input resistance of the subtractor's inverting input.

Comment. The transducer in this example is the resistor R_{G2} . In the unstressed state the voltage across

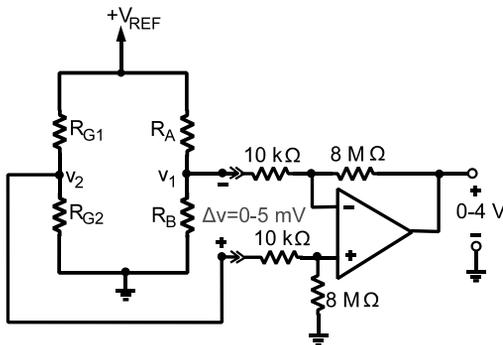

Fig. 59 (From Ref. 2.)

this resistor is $v_2 = 12.5$ V. In the stressed state the voltage is $v_2 = 12.5$ V plus a 5-mV signal. In other words, the transducer's 5-mV signal component is accompanied by a very large bias. It is important to amplify the 12.5-V bias component by $K = 800$ before subtracting it out. The bias is eliminated at the input by using a bridge circuit in which $v_1 = 12.5$ V and then processing the differential signal $v_2 - v_1$. The situation illustrated in this example is actually quite common. Consequently, the first amplification stage in most instrumentation systems is a differential amplifier

4 AC CIRCUITS

4.1 Signals

Electrical engineers normally think of a signal as an electrical current $i(t)$, voltage $v(t)$, or power $p(t)$. In any case, the time variation of the signal is called a waveform. More formally, a *waveform* is an equation or graph that define the signal as a function of time.

Waveforms that are constant for all time are called *dc signals*. The abbreviation dc stands for direct current, but it applies to either voltage or current. Mathematical expressions for a dc voltage $v(t)$ or current $i(t)$ take the form

$$v(t) = V_0 \quad i(t) = I_0 \quad \text{for } -\infty < t < \infty$$

Although no physical signal can remain constant forever, it is still a useful model, however, because it approximates the signals produced by physical devices such as batteries. In a circuit diagram signal variables are normally accompanied by reference marks (+, -, \rightarrow or \leftarrow). It is important to remember that these reference marks *do not* indicate the polarity of a voltage or the direction of current. The marks provide a baseline for determining the sign of the numerical value of the actual waveform. When the actual voltage polarity or current direction coincides with the reference directions, the signal has a positive value. When the opposite occurs, the value is negative.

Since there are infinitely many different signals, it may seem that the study of signals involves the uninviting task of compiling a lengthy catalog of waveforms. Most of the waveforms of interest can be addressed using just three basic signal models: the step, exponential, and sinusoidal functions.

Step Waveform The first basic signal in our catalog is the step waveform. The general step function is based on the *unit step function* defined as

$$u(t) \equiv \begin{cases} 0 & \text{for } t < 0 \\ 1 & \text{for } t \geq 0 \end{cases}$$

Mathematically, the function $u(t)$ has a jump discontinuity at $t = 0$. While it is impossible to generate a true step function since signal variables like current and voltage cannot transition from one value to

another in zero time, it is possible to generate very good approximations to the step function. What is required is that the transition time be short compared with other response times in the circuit. The step waveform is a versatile signal used to construct a wide range of useful waveforms. It often is necessary to turn things on at a time other than zero and with an amplitude different from unity. Replacing t by $t - T_S$ produces a waveform $V_A u(t - T_S)$ which takes on the values

$$V_A u(t - T_S) = \begin{cases} 0 & \text{for } t < T_S \\ V_A & \text{for } t \geq T_S \end{cases} \quad (34)$$

The *amplitude* V_A scales the size of the step discontinuity and the *time shift* parameter T_S advances or delays the time at which the step occurs.

Amplitude and time shift parameters are required to define the general step function. The amplitude V_A carries the units of volts. The amplitude of the step function in an electric current is I_A and carries the units of amperes. The constant T_S carries the units of time, usually seconds. The parameters V_A (or I_A) and T_S can be positive, negative, or zero, as shown in Fig. 60.

Example 19. Express the waveform in Fig. 61a in terms of step functions.

Solution. The amplitude of the pulse jumps to a value of 3 V at $t = 1$ s; therefore, $3u(t - 1)$ is part of the equation for the waveform. The pulse returns to zero at $t = 3$ sec, so an equal and opposite step must

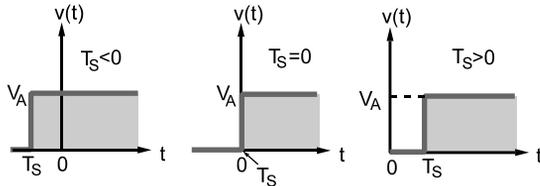

Fig. 60 Effect time shifting on step function waveform.¹

occur at $t = 3$ sec. Putting these observations together, we express the rectangular pulse as

$$v(t) = 3u(t - 1) - 3u(t - 3)$$

Figure 61b shows how the two step functions combine to produce the given rectangular pulse.

Impulse Function The generalization of Example 19 is the waveform

$$v(t) = V_A [u(t - T_1) - u(t - T_2)] \quad (35)$$

This waveform is a rectangular pulse of amplitude V_A that turns on at $t = T_1$ and off at $t = T_2$. Pulses that turn on at some time T_1 and off at some later time T_2 are sometimes called *gating functions* because they are used in conjunction with electronic switches to enable or inhibit the passage of another signal.

A rectangular pulse centered on $t = 0$ is written in terms of step functions as

$$v_1(t) = \frac{1}{T} \left[u\left(t + \frac{T}{2}\right) - u\left(t - \frac{T}{2}\right) \right] \quad (36)$$

The pulse in Eq. (36) is zero everywhere except in the range $-T/2 \leq t \leq T/2$, where its amplitude is $1/T$. The area under the pulse is 1 because its amplitude is inversely proportional to its duration. As shown in Fig. 62a, the pulse becomes narrower and higher as T decreases but maintains its unit area. In the limit as $T \rightarrow 0$ the amplitude approaches infinity but the area remains unity. The function obtained in the limit is called a *unit impulse*, symbolized as $\delta(t)$. The graphical representation of $\delta(t)$ is shown in Fig. 62b. The impulse is an idealized model of a large-amplitude, short-duration pulse.

A formal definition of the unit impulse is

$$\delta(t) = 0 \quad \text{for } t \neq 0 \quad \text{and} \quad \int_{-\infty}^t \delta(x) dx = u(t) \quad (37)$$

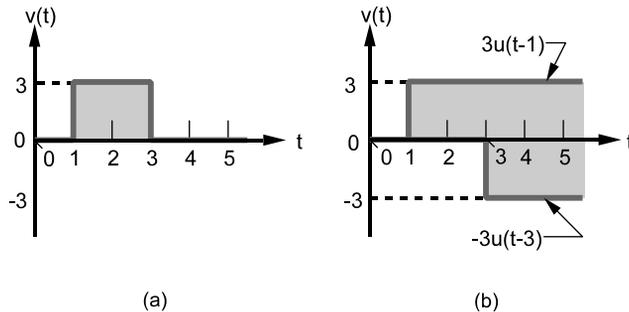

Fig. 61 (From Ref. 1.)

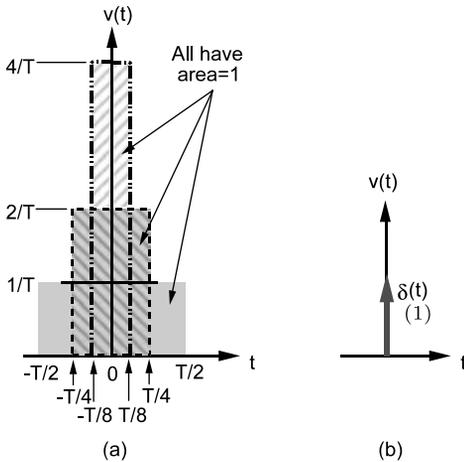

Fig. 62 Rectangular pulse waveforms and impulse.¹

The first condition says the impulse is zero everywhere except at $t = 0$. The second condition implies that the impulse is the derivative of a step function although it cannot be justified using elementary mathematics since the function $u(t)$ has a discontinuity at $t = 0$ and its derivative at that point does not exist in the usual sense. However, the concept can be justified using limiting conditions on continuous functions as discussed in texts on signals and systems.

The strength of an impulse is defined by its area since amplitude is infinite. An impulse of strength K is denoted $K\delta(t)$, where K is the area under the impulse. In the graphical representation of the impulse the value of K is written in parentheses beside the arrow, as shown in Fig. 62b.

Ramp Function The unit ramp is defined as the integral of a step function:

$$r(t) = \int_{-\infty}^t u(x) dx = tu(t) \quad (38)$$

The unit-ramp waveform $r(t)$ is zero for $t \leq 0$ and is equal to t for $t > 0$. The slope of $r(t)$ is unity. The general ramp waveform is written $Kr(t - T_S)$. The general ramp is zero for $t \leq T_S$ and equal to $K(t - T_S)$ for $t > 0$. The scale factor K defines the slope of the ramp for $t > 0$. By adding a series of ramps the triangular and sawtooth waveforms can be created.

Singularity Functions The impulse, step, and ramp form a triad of related signals that are referred to as *singularity functions*. They are related by integration or by differentiation as

$$\delta(t) = \int_{-\infty}^t \delta'(x) dx \quad \delta'(t) = \frac{d\delta(t)}{dt}$$

$$u(t) = \int_{-\infty}^t \delta(x) dx \quad \delta(t) = \frac{du(t)}{dt} \quad (39)$$

$$r(t) = \int_{-\infty}^t u(x) dx \quad u(t) = \frac{dr(t)}{dt}$$

These signals are used to generate other waveforms and as test inputs to linear systems to characterize their responses. When applying the singularity functions in circuit analysis, it is important to remember that $u(t)$ is a dimensionless function. But $\delta(t)$ carries the units of reciprocal seconds and $r(t)$ carries units of seconds. Here, $\delta'(t)$ is called a doublet and is included for completeness. It is the derivative of an impulse function and carries the units of reciprocal seconds squared.

Exponential Waveform The exponential signal is a step function whose amplitude gradually decays to zero. The equation for this waveform is

$$v(t) = [V_A e^{-t/T_C}] u(t) \quad (40)$$

A graph of $v(t)$ versus t/T_C is shown in Fig. 63. The exponential starts out like a step function. It is zero for $t < 0$ and jumps to a maximum amplitude of V_A at $t = 0$. Thereafter it monotonically decays toward zero versus time. The two parameters that define the waveform are the amplitude V_A (in volts) and the time constant T_C (in seconds). The amplitude of a current exponential would be written I_A and carry the units of amperes.

The time constant is of special interest, since it determines the rate at which the waveform decays to zero. An exponential decays to about 37% of its initial amplitude $v(0) = V_A$ in one time constant because, at $t = T_C$, $v(T_C) = V_A e^{-1}$ or approximately $0.368 V_A$. At $t = 5T_C$, the value of the waveform is $V_A e^{-5}$.

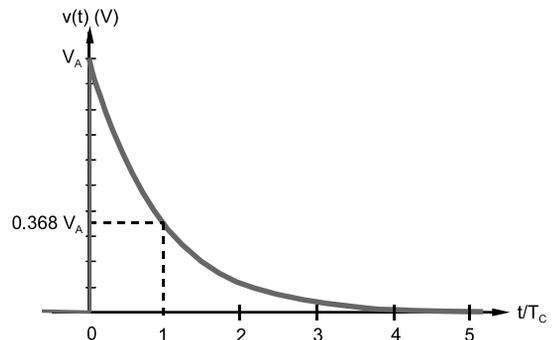

Fig. 63 Exponential waveform.

or approximately $0.00674V_A$. An exponential signal decays to less than 1% of its initial amplitude in a time span of five time constants. In theory an exponential endures forever, but practically speaking after about $5T_C$ the waveform amplitude becomes negligibly small. For this reason we define the *duration* of an exponential waveform to be $5T_C$.

Decrement Property of Exponential Waveforms

The *decrement property* describes the decay rate of an exponential signal. For $t > 0$ the exponential waveform is given by $v(t) = V_A e^{-t/T_C}$. At time $t + \Delta t$ the amplitude is

$$v(t + \Delta t) = V_A e^{-(t+\Delta t)/T_C} = V_A e^{-t/T_C} e^{-\Delta t/T_C}$$

The ratio of these two amplitudes is

$$\frac{v(t + \Delta t)}{v(t)} = \frac{V_A e^{-t/T_C} e^{-\Delta t/T_C}}{V_A e^{-t/T_C}} = e^{-\Delta t/T_C} \quad (41)$$

The decrement ratio is independent of amplitude and time. In any fixed time period Δt , the fractional decrease depends only on the time constant. The decrement property states that the same percentage decay occurs in equal time intervals.

Slope Property of Exponential Waveforms The slope of the exponential waveform (for $t > 0$) is found by differentiating Eq. (40) with respect to time:

$$\frac{dv(t)}{dt} = -\frac{V_A}{T_C} e^{-t/T_C} = -\frac{v(t)}{T_C} \quad (42)$$

The *slope property* states that the time rate of change of the exponential waveform is inversely proportional to the time constant. Small time constants lead to large slopes or rapid decays, while large time constants produce shallow slopes and long decay times.

Sinusoidal Waveform The cosine and sine functions are important in all branches of science and engineering. The corresponding time-varying waveform in Fig. 64 plays an especially prominent role in electrical engineering.

In contrast with the step and exponential waveforms studied earlier, the sinusoid extends indefinitely in time in both the positive and negative directions. The sinusoid in Fig. 64 is an endless repetition of identical oscillations between positive and negative peaks. The *amplitude* V_A define the maximum and minimum values of the oscillations. The *period* T_0 is the time required to complete one cycle of the oscillation. Using these two parameters, a voltage sinusoid can be expressed as

$$v(t) = V_A \cos\left(\frac{2\pi t}{T_0}\right) \quad \text{V} \quad (43)$$

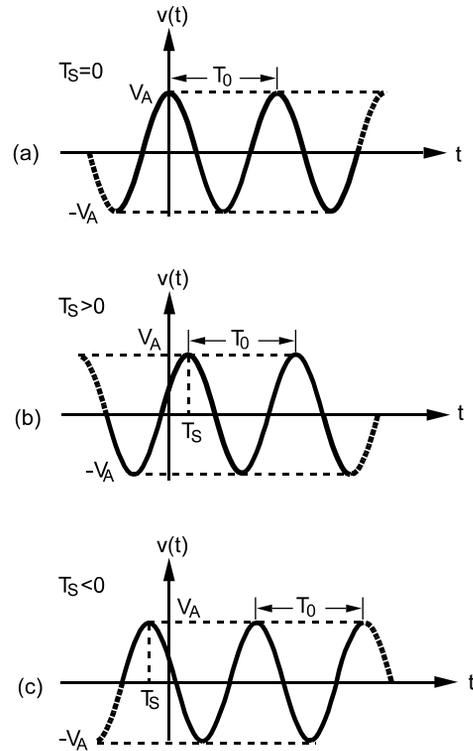

Fig. 64 Effect of time shifting on sinusoidal waveform.¹

The waveform $v(t)$ carries the units of V_A (volts in this case) and the period T_0 carries the units of time t (usually seconds). Equation (43) produces the waveform in Fig. 64 which has a positive peak at $t = 0$ since $v(0) = V_A$.

As in the case of the step and exponential functions, the general sinusoid is obtained by replacing t by $t - T_S$. Inserting this change in Eq. (43) yields a general expression for the sinusoid as

$$v(t) = V_A \cos\left[\frac{2\pi(t - T_S)}{T_0}\right] \quad (44)$$

where the constant T_S is the time shift parameter. The sinusoid shifts to the right when $T_S > 0$ and to the left when $T_S < 0$. In effect, time shifting causes the positive peak nearest the origin to occur at $t = T_S$.

The time-shifting parameter can also be represented by an angle:

$$v(t) = V_A \cos\left[\frac{2\pi t}{T_0} + \phi\right] \quad (45)$$

The parameter ϕ is called the *phase angle*. The term phase angle is based on the circular interpretation of the cosine function where the period is divided into

2π radians or 350° . In this sense the phase angle is the angle between $t = 0$ and the nearest positive peak. The relation between T_S and ϕ is

$$\phi = -2\pi \frac{T_S}{T_0} \quad (46)$$

An alternative form of the general sinusoid is obtained by expanding Eq. (45) using the identity $\cos(x + y) = \cos(x)\cos(y) - \sin(x)\sin(y)$. This results in the general sinusoid being written as

$$v(t) = a \cos\left(\frac{2\pi t}{T_0}\right) + b \sin\left(\frac{2\pi t}{T_0}\right) \quad (47)$$

The two amplitude-like parameters a and b have the same units as the waveform (volts in this case) and are called Fourier coefficients. By definition the Fourier coefficients are related to the amplitude and phase parameters by the equations

$$\begin{aligned} a &= V_A \cos \phi & V_A &= \sqrt{a^2 + b^2} \\ b &= -V_A \sin \phi & \phi &= \tan^{-1} \frac{-b}{a} \end{aligned} \quad (48)$$

It is customary to describe the time variation of the sinusoid in terms of a frequency parameter. *Cyclic frequency* f_0 is defined as the number of periods per unit time. By definition the period T_0 is the number of seconds per cycle; consequently the number of cycles per second is

$$f_0 = \frac{1}{T_0} \quad (49)$$

where f_0 is the cyclic frequency or simply the frequency. The unit of frequency (cycles per second) is the *hertz* (Hz). Because there are 2π radians per cycle, the *angular frequency* ω_0 in radians per second is related to cyclic frequency by the relationship

$$\omega_0 = 2\pi f_0 = \frac{2\pi}{T_0} \quad (50)$$

In summary, there are several equivalent ways to describe the general sinusoid:

$$v(t) = \begin{cases} V_A \cos\left[\frac{2\pi(t - T_S)}{T_0}\right] = V_A \cos\left(\frac{2\pi t}{T_0} + \phi\right) \\ = a \cos\left(\frac{2\pi t}{T_0}\right) + b \sin\left(\frac{2\pi t}{T_0}\right) \\ V_A \cos[2\pi f_0(t - T_S)] = V_A \cos(2\pi f_0 t + \phi) \\ = a \cos(2\pi f_0 t + \phi) + b \sin(2\pi f_0 t + \phi) \\ V_A \cos[\omega_0(t - T_S)] = V_A \cos(\omega_0 t + \phi) \\ = a \cos(\omega_0 t) + b \sin(\omega_0 t) \end{cases} \quad (51)$$

Additive Property of Sinusoids The *additive property* of sinusoids states that summing two or more sinusoids with the same frequency yields a sinusoid with different amplitude and phase parameters but the same frequency.

Derivative and Integral Property of Sinusoids

The *derivative* and *integral* properties of the sinusoid state that a sinusoid maintains its wave shape when differentiated or integrated. These operations change the amplitude and phase angle but do not change the basic sinusoidal wave shape or frequency. The fact that the wave shape is unchanged by differentiation and integration is a key property of the sinusoid. No other periodic waveform has this shape-preserving property.

Waveform Partial Descriptors

An equation or graph define a waveform for all time. The value of a waveform $v(t)$, $i(t)$, or $p(t)$ at time t is called the *instantaneous value* of the waveform. Engineers often use numerical values or terminology that characterizes a waveform but do not give a complete description. These waveform *partial descriptors* fall into two categories: (a) those that describe temporal features and (b) those that describe amplitude features.

Temporal Descriptors

Temporal descriptors identify waveform attributes relative to the time axis. A signal $v(t)$ is *periodic* if $v(t + T_0) = v(t)$ for all t , where the period T_0 is the smallest value that meets this condition. Signals that are not periodic are called *aperiodic*. The fact that a waveform is periodic provides important information about the signal but does not specify all of its characteristics. The period and periodicity of a waveform are partial descriptors. A sine wave, square wave, and triangular wave are all periodic. Examples of aperiodic waveforms are the step function, exponential, and damped sine.

Waveforms that are identically zero prior to some specific time are said to be *causal*. A signal $v(t)$ is *causal* if $v(t) = 0$ for $t < T$; otherwise it is *non-causal*. It is usually assumed that a causal signal is zero for $t < 0$, since time shifting can always place the starting point of a waveform at $t = 0$. Examples of causal waveforms are the step function, exponential, and damped sine. An infinitely repeating periodic waveform is noncausal.

Causal waveforms play a central role in circuit analysis. When the input driving force $x(t)$ is causal, the circuit response $y(t)$ must also be causal. That is, a physically realizable circuit cannot anticipate and respond to an input before it is applied. Causality is an important temporal feature but only a partial description of the waveform.

Amplitude Descriptors Amplitude descriptors are generally positive scalars that identify size features of the waveform. Generally a waveform's amplitude varies between two extreme values denoted as V_{MAX}

and V_{MIN} . The *peak-to-peak* value (V_{pp}) describes the total excursion of $v(t)$ and is define as

$$V_{\text{pp}} = V_{\text{MAX}} - V_{\text{MIN}} \quad (52)$$

Under this definitio V_{pp} is always positive even if V_{MAX} and V_{MIN} are both negative. The *peak value* (v_p) is the maximum of the absolute value of the waveform. That is,

$$V_p = \max \{|V_{\text{MAX}}|, |V_{\text{MIN}}|\} \quad (53)$$

The peak value is a positive number that indicates the maximum absolute excursion of the waveform from zero. Figure 65 shows examples of these two amplitude descriptors.

The *average value* (v_{avg}) smoothes things out to reveal the underlying waveform baseline. Average value is the area under the waveform over some period of time T divided by that time period:

$$V_{\text{avg}} = \frac{1}{T} \int_{t_0}^{t_0+T} v(x) dx \quad (54)$$

For periodic signals the averaging interval T equals the period T_0 . The average value measures the waveform's baseline with respect to the $v = 0$ axis. In other words, it indicates whether the waveform contains a constant, non-time-varying component. The average value is also called the *dc component* of the waveform because dc signals are constant for all t .

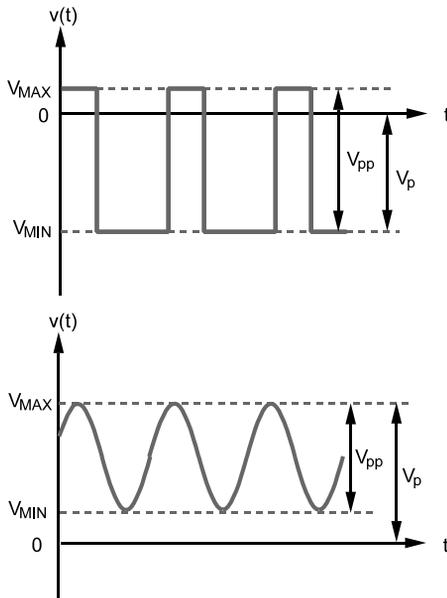

Fig. 65 Peak value (V_p) and peak-to-peak value (V_{pp}).¹

Root-Mean-Square Value The *root-mean-square value* (v_{rms}) of a waveform is a measure of the average power carried by the signal. The instantaneous power delivered to a resistor R by a voltage $v(t)$ is

$$p(t) = \frac{1}{R} [v(t)]^2$$

The average power delivered to the resistor in time span T is define as

$$P_{\text{avg}} = \frac{1}{T} \int_{t_0}^{t_0+T} p(t) dt$$

Combining the above equations yields

$$P_{\text{avg}} = \frac{1}{R} \left[\frac{1}{T} \int_{t_0}^{t_0+T} [v(t)]^2 dt \right]$$

The quantity inside the large brackets is the average value of the square of the waveform. The units of the bracketed term are volts squared. The square root of this term define the amplitude descriptor v_{rms} :

$$V_{\text{rms}} = \sqrt{\frac{1}{T} \int_{t_0}^{t_0+T} [v(t)]^2 dt} \quad (55)$$

For periodic signals the averaging interval is one cycle since such a waveform repeats itself every T_0 seconds. The average power delivered to a resistor in terms of v_{rms} is

$$P_{\text{avg}} = \frac{1}{R} V_{\text{rms}}^2 \quad (56)$$

The equation for average power in terms of v_{rms} has the same form as the instantaneous power. For this reason the rms value is also called the *effective value*, since it determines the average power delivered to a resistor in the same way that a dc waveform $v(t) = v_{\text{dc}}$ determines the instantaneous power. If the waveform amplitude is doubled, its rms value is doubled, and the average power is quadrupled. Commercial electrical power systems use transmission voltages in the range of several hundred kilovolts (rms) to transfer large blocks of electrical power.

4.2 Energy Storage Devices

Capacitor A capacitor is a dynamic element involving the time variation of an electric field produced by a voltage. Figure 66a shows the parallel-plate capacitor, which is the simplest physical form of a capacitive device, and two common circuit symbols for the capacitor are shown in Fig. 66b.

Electrostatics shows that a uniform electric field $\mathcal{E}(t)$ exists between the metal plates when a voltage exists across the capacitor. The electric field produces

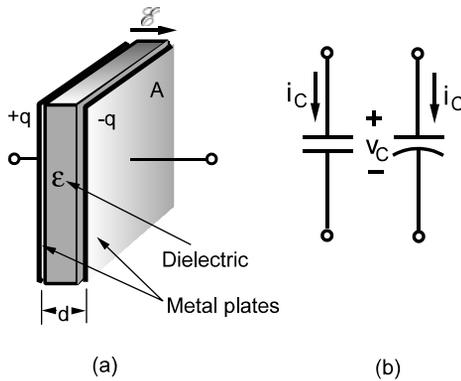

Fig. 66 Capacitor: (a) parallel-plate device; (b) circuit symbol.¹

charge separation with equal and opposite charges appearing on the capacitor plates. When the separation d is small compared with the dimension of the plates, the electric field between the plates is

$$\mathcal{E}(t) = \frac{q(t)}{\varepsilon A}$$

where ε is the permittivity of the dielectric, A is the area of the plates, and $q(t)$ is the magnitude of the electric charge on each plate. The relationship between the electric field and the voltage across the capacitor $v_C(t)$ is given by

$$\mathcal{E}(t) = \frac{v_C(t)}{d}$$

Setting both equations equal and solving for the charge $q(t)$ yields

$$q(t) = \left[\frac{\varepsilon A}{d} \right] v_C(t) = C v_C(t) \quad (57)$$

The proportionality constant inside the bracket in this equation is the *capacitance* C . The unit of capacitance is the farad (F), a term that honors the British physicist Michael Faraday. Values of capacitance range from picofarads (10^{-12} F) in semiconductor devices to tens of millifarads (10^{-3} F) in industrial capacitor banks. Differentiating Eq. (57) with respect to time t and realizing that $i_C(t)$ is the time derivative of $q(t)$ result in the capacitor i - v relationship

$$i_C(t) = \frac{dq(t)}{dt} = \frac{d[Cv_C(t)]}{dt} = C \frac{dv_C(t)}{dt} \quad (58)$$

The time derivative in Eq. (58) means the current is zero when the voltage across the capacitor is constant, and vice versa. In other words, the capacitor acts like an open circuit ($i_C = 0$) when dc excitations are

applied. The capacitor is a dynamic element because the current is zero unless the voltage is changing. However, a discontinuous change in voltage requires an infinite current, which is physically impossible. Therefore, the capacitor voltage must be a continuous function of time.

Equation (59a) is the integral form of the capacitor i - v relationship where x is a dummy integration variable:

$$v_C(t) = v_C(0) + \frac{1}{C} \int_0^t i_C(x) dx \quad (59a)$$

With the passive-sign convention the power associated with the capacitor is

$$p_C(t) = i_C(t) \times v_C(t) \quad (59b)$$

This equation shows that the power can be either positive or negative because the capacitor voltage and its time rate of change can have opposite signs. The ability to deliver power implies that the capacitor can store energy. Assuming that zero energy is stored at $t = 0$, the capacitor energy is expressed as

$$w_C(t) = \frac{1}{2} C v_C^2(t) \quad (60)$$

The stored energy is never negative, since it is proportional to the square of the voltage. The capacitor absorbs power from the circuit when storing energy and returns previously stored energy when delivering power to the circuit.

Inductor The inductor is a dynamic circuit element involving the time variation of the magnetic field produced by a current. Magnetostatics shows that a magnetic flux ϕ surrounds a wire carrying an electric current. When the wire is wound into a coil the lines of flux concentrate along the axis of the coil as shown in Fig. 67a. In a linear magnetic medium the flux is proportional to both the current and the number of turns in the coil. Therefore, the total flux is

$$\phi(t) = k_1 N i_L(t)$$

where k_1 is a constant of proportionality involving the permeability of the physical surroundings and dimensions of the wire.

The magnetic flux intercepts or links the turns of the coil. The flux linkages in a coil is represented by the symbol λ , with units of webers (Wb), named after the German scientist Wilhelm Weber (1804–1891). The number of flux linkages is proportional to the number of turns in the coil and to the total magnetic flux so λ is given as

$$\lambda(t) = N \phi(t)$$

Substituting for $\phi(t)$ gives

$$\lambda(t) = [k_1 N^2] i_L(t) = L i_L(t) \quad (61)$$

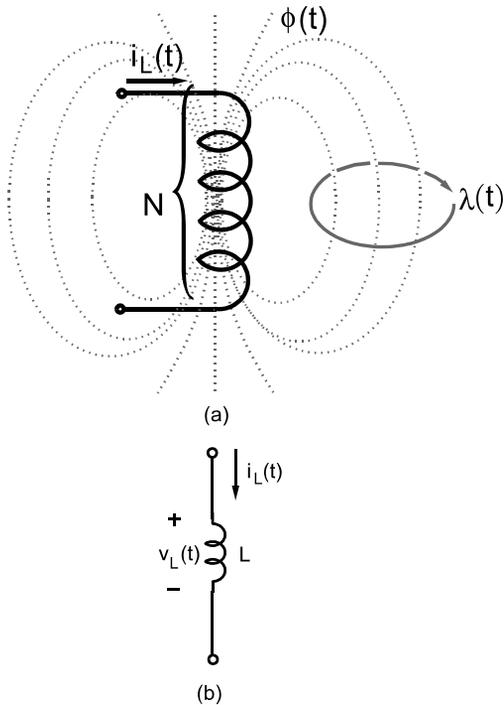

Fig. 67 (a) Magnetic flux surrounding current-carrying coil. (b) Circuit symbol for inductor.¹

The $k_1 N^2$ inside the brackets in this equation is called the *inductance* L of the coil. The unit of inductance is the henry (H) (plural henrys), a name that honors American scientist Joseph Henry. Figure 67b shows the circuit symbol for an inductor.

Equation (61) is the inductor element constraint in terms of current and flux linkages. Differentiating Eq. (61) with respect to time t and realizing that according to Faraday's law $v_L(t)$ is the time derivative of $\lambda(t)$ result in the inductor i - v relationship

$$v_L(t) = \frac{d[\lambda(t)]}{dt} = \frac{d[Li_L(t)]}{dt} = L \frac{di_L(t)}{dt} \quad (62)$$

The time derivative in Eq. (62) means that the voltage across the inductor is zero unless the current is time varying. Under dc excitation the current is constant and $v_L = 0$ so the inductor acts like a short circuit. The inductor is a dynamic element because only a changing current produces a nonzero voltage. However, a discontinuous change in current produces an infinite voltage, which is physically impossible. Therefore, the current $i_L(t)$ must be a continuous function of time t .

Equation (63) is the integral form of the inductor i - v relationship where x is a dummy integration

variable:

$$i_L(t) = i_L(0) + \frac{1}{L} \int_0^t v_L(x) dx \quad (63)$$

With the passive-sign convention the inductor power is

$$p_L(t) = i_L(t) \times v_L(t) \quad (64)$$

This expression shows that power can be positive or negative because the inductor current and its time derivative can have opposite signs. The ability to deliver power indicates that the inductor can store energy. Assuming that zero energy is stored at $t = 0$, the inductor energy is expressed as

$$w_L(t) = \frac{1}{2} Li_L^2(t) \quad (65)$$

The energy stored in an inductor is never negative because it is proportional to the square of the current. The inductor stores energy when absorbing power and returns previously stored energy when delivering power.

Equivalent Capacitance and Inductance Resistors connected in series or parallel can be replaced by equivalent resistances. The same principle applies to connections of capacitors and inductors. N capacitors connected in parallel can be replaced by a single capacitor equal to the sum of the capacitance of the parallel capacitors, that is,

$$C_{EQ} = C_1 + C_2 + \cdots + C_N \quad (\text{parallel connection}) \quad (66)$$

The initial voltage, if any, on the equivalent capacitance is $v(0)$, the common voltage across all of the original N capacitors at $t = 0$. Likewise, N capacitors connected in series can be replaced by a single capacitor equal to

$$C_{EQ} = \frac{1}{1/C_1 + 1/C_2 + \cdots + 1/C_N} \quad (\text{series connection}) \quad (67)$$

The equivalent capacitance of a parallel connection is the sum of the individual capacitances. The reciprocal of the equivalent capacitance of a series connection is the sum of the reciprocals of the individual capacitances. Since the capacitor and inductor are dual elements, the corresponding results for inductors are found by interchanging the series and parallel equivalence rules for the capacitor. That is, in a series connection the equivalent inductance is the sum of the individual inductances:

$$L_{EQ} = L_1 + L_2 + \cdots + L_N \quad (\text{series connection}) \quad (68)$$

For the parallel connection the reciprocals add to produce the reciprocal of the equivalent inductance:

$$L_{EQ} = \frac{1}{1/L_1 + 1/L_2 + \dots + 1/L_N}$$

(parallel connection) (69)

Example 20. Find the equivalent capacitance and inductance of the circuit in Fig. 68a.

Solution. The circuit contains both inductors and capacitors. The inductors and the capacitors are combined separately. The 5-pF capacitor in parallel with the 0.1-μF capacitor yields an equivalent capacitance of 0.100005 μF. For all practical purposes the 5-pF capacitor can be ignored, leaving two 0.1-μF capacitors in series with equivalent capacitance of 0.05 μF. Combining this equivalent capacitance in parallel with the remaining 0.05-μF capacitor yields an overall equivalent capacitance of 0.1 μF. The parallel 700- and 300-μH inductors yield an equivalent inductance of $1/(1/700 + 1/300) = 210 \mu\text{H}$. This equivalent inductance is effectively in series with the 1-mH inductor at the bottom, yielding $1000 + 210 = 1210 \mu\text{H}$ as the overall equivalent inductance. Figure 68b shows the simplified equivalent circuit.

Mutual Inductance The $i-v$ characteristics of the inductor result from the magnetic field produced by current in a coil of wire. The magnetic flux spreads out around the coil forming closed loops that cut or link with the turns in the coil. If the current is changing, then Faraday's law states that voltage across the coil is equal to the time rate of change of the total flux linkages.

Now suppose that a second coil is brought close to the first coil. The flux from the first coil will link with the turns of the second coil. If the current in the first

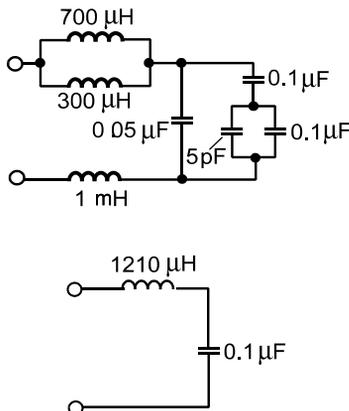

Fig. 68 (From Ref. 1.)

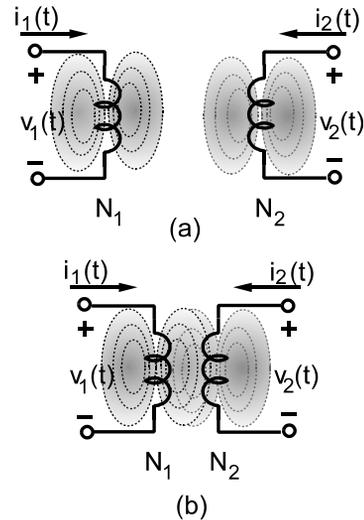

Fig. 69 (a) Inductors separated, only self-inductance present. (b) Inductors coupled, both self- and mutual inductance present.¹

coil is changing, then these flux linkages will generate a voltage in the second coil. The coupling between a changing current in one coil and a voltage across a second coil results in *mutual inductance*.

If there is coupling between the two coils in Fig. 69, there are two distinct effects occurring in the coils. First there is the self-inductance due to the current flowing in each individual coil and the voltage induced by that current in that coil. Second, there are the voltages occurring in the second coil caused by current flowing through the first coil and vice versa. A double-subscript notation is used because it clearly identifies the various cause-and-effect relationships. The first subscript indicates the coil in which the effect takes place and the second identifies the coil in which the cause occurs. For example, $v_{11}(t)$ is the voltage across coil 1 due to causes occurring in coil 1 itself, while $v_{12}(t)$ is the voltage across coil 1 due to causes occurring in coil 2. The self-inductance is

$$\begin{aligned} \text{Coil 1: } v_{11}(t) &= \frac{d\lambda_{11}(t)}{dt} = N_1 \frac{d\phi_1(t)}{dt} \\ &= [k_1 N_1^2] \frac{di_1(t)}{dt} \\ \text{Coil 2: } v_{22}(t) &= \frac{d\lambda_{22}(t)}{dt} = N_2 \frac{d\phi_2(t)}{dt} \\ &= [k_2 N_2^2] \frac{di_2(t)}{dt} \end{aligned} \tag{70}$$

Equations (70) provide the $i-v$ relationships for the coils when there is no mutual coupling. The mutual

inductance is

$$\begin{aligned}
 \text{Coil 1: } v_{12}(t) &= \frac{d\lambda_{12}(t)}{dt} = N_1 \frac{d\phi_{12}(t)}{dt} \\
 &= [k_{12}N_1N_2] \frac{di_2(t)}{dt} \\
 \text{Coil 2: } v_{21}(t) &= \frac{d\lambda_{21}(t)}{dt} = N_2 \frac{d\phi_{21}(t)}{dt} \\
 &= [k_{21}N_1N_2] \frac{di_1(t)}{dt} \quad (71)
 \end{aligned}$$

The quantity $\phi_{12}(t)$ is the flux intercepting coil 1 due to the current in coil 2 and $\phi_{21}(t)$ is the flux intercepting coil 2 due to the current in coil 1. The expressions in Eq. (71) are the $i-v$ relationships describing the cross coupling between coils when there is mutual coupling.

When the magnetic medium supporting the flux is linear, the superposition principle applies, and the total voltage across the coils is the sum of the results in Eqs. (70) and (71):

$$\begin{aligned}
 \text{Coil 1: } v_1(t) &= v_{11}(t) + v_{12}(t) \\
 \text{Coil 2: } v_2(t) &= v_{21}(t) + v_{22}(t)
 \end{aligned}$$

There are four inductance parameters in these equations. Two *self-inductance* parameters $L_1 = k_1N_1^2$ and $L_2 = k_2N_2^2$ and two *mutual inductances* $M_{12} = k_{12}N_1N_2$ and $M_{21} = k_{21}N_2N_1$. In a linear magnetic medium $k_{12} = k_{21} = k_M$, there is a single mutual inductance parameter M define as $M = M_{12} = M_{21} = k_MN_1N_2$. Putting these all together yields

$$\begin{aligned}
 \text{Coil 1: } v_1(t) &= L_1 \frac{di_1(t)}{dt} \pm M \frac{di_2(t)}{dt} \\
 \text{Coil 2: } v_2(t) &= \pm M \frac{di_1(t)}{dt} + L_2 \frac{di_2(t)}{dt} \quad (72)
 \end{aligned}$$

The coupling across coils can be additive or subtractive. This gives rise to the \pm sign in front of the mutual inductance M . Additive (+) coupling means that a positive rate of change of current in coil 2 induces a positive voltage in coil 1, and vice versa for subtractive coupling (-).

When applying these element equations, it is necessary to know when to use a plus sign and when to use a minus sign. Since the additive or subtractive nature of a coupled-coil set is predetermined by the manufacturer of the windings, a dot convention is used. The dots shown near one terminal of each coil are special reference marks indicating the relative orientation of the coils. Figure 70 shows the dot convention.

The correct sign for the mutual inductance term hinges on how the reference marks for currents and voltages are assigned relative to the coil dots: *Mutual*

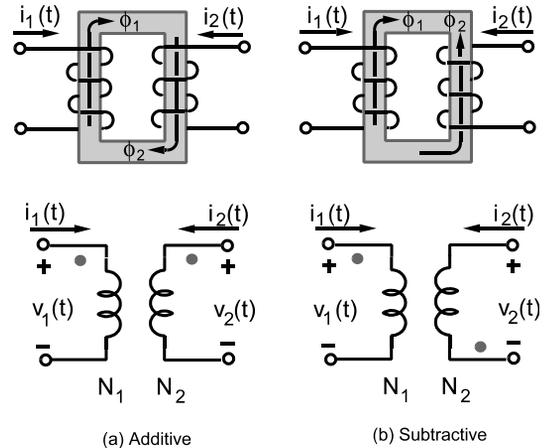

Fig. 70 Winding orientations and corresponding reference dots: (a) additive; (b) subtractive.

inductance is additive when both current reference directions point toward or both point away from dotted terminals; otherwise, it is subtractive.

Ideal Transformer A transformer is an electrical device that utilizes mutual inductance coupling between two coils. Transformers find application in virtually every type of electrical system, especially in power supplies and commercial power grids.

In Fig. 71 the transformer is shown as an interface device between a source and a load. The coil connected to the source is called the *primary winding* and the coil connected to the load the *secondary winding*. In most applications the transformer is a coupling device that transfers signals (especially power) from the source to the load. The basic purpose of the device is to change voltage and current levels so the signal conditions at the source and load are compatible.

Transformer design involves two primary goals: (a) to maximize the magnetic coupling between the two windings and (b) to minimize the power loss in the windings. The first goal produces near-perfect coupling ($k \cong 1$) so that almost all of the flux in one winding

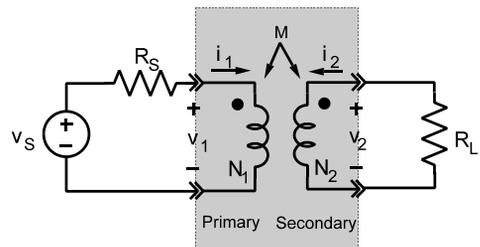

Fig. 71 Transformer connected at source-load interface.¹

links the other. The second goal produces nearly zero power loss so that almost all of the power delivered to the primary winding transfers to the load. The *ideal transformer* is a circuit element in which coupled coils are assumed to have perfect coupling and zero power loss.

Perfect coupling assumes that all the coupling coefficients are equal to each other, that is, $k_{11} = k_{22} = k_{12} = k_{21} = k_M \cong 1$. Dividing the two equations in Eq. (72) and using the concept of perfect coupling result in the equation

$$\frac{v_2(t)}{v_1(t)} = \pm \frac{N_2}{N_1} = \pm n \quad (73)$$

where n is the *turns ratio*. With perfect coupling the secondary voltage is proportional to the primary voltage so they have the same wave shape. For example, when the primary voltage is $v_1(t) = V_A \sin \omega t$, the secondary voltage is $v_2(t) = \pm n V_A \sin \omega t$. When the turns ratio $n > 1$, the secondary-voltage amplitude is larger than the primary and the device is called a *step-up transformer*. Conversely, when $n < 1$, the secondary voltage is smaller than the primary and the device is called a *step-down transformer*. The ability to increase or decrease ac voltage levels is a basic feature of transformers. Commercial power systems use transmission voltages of several hundred kilovolts. For residential applications the transmission voltage is reduced to safer levels (typically 220/110 V_{rms}) using step-down transformers.

The \pm sign in Eq. (73) depends on the reference marks given the primary and secondary currents relative to the dots indicating the relative coil orientations. The rule for the ideal transformer is a corollary of the rule for selecting the sign of the mutual inductance term in coupled-coil element equations.

The ideal transformer model also assumes that there is no power loss in the transformer. With the passive-sign convention, the power in the primary winding and secondary windings is $v_1(t)i_1(t)$ and $v_2(t)i_2(t)$, respectively. Zero power loss requires

$$v_1(t)i_1(t) + v_2(t)i_2(t) = 0$$

which can be rearranged in the form

$$\frac{i_2(t)}{i_1(t)} = -\frac{v_1(t)}{v_2(t)}$$

But under the perfect-coupling assumption $v_2(t)/v_1(t) = \pm n$. With zero power loss and perfect coupling the primary and secondary currents are related as

$$\frac{i_2(t)}{i_1(t)} = \mp \frac{1}{n} \quad (74)$$

The correct sign in this equation depends on the orientation of the current reference directions relative to the dots describing the transformer structure.

With both perfect coupling and zero power loss, the secondary current is inversely proportional to the turns ratio. A step-up transformer ($n > 1$) increases the voltage and decreases the current, which improves transmission line efficiency because the i^2R losses in the conductors are smaller.

Using the ideal transformer model requires some caution. The relationships in Eqs. (73) and (74) state that the secondary signals are proportional to the primary signals. These element equations appear to apply to dc signals. This is of course wrong. The element equations are an idealization of mutual inductance, and mutual inductance requires time-varying signals to provide the coupling between two coils.

Equivalent Input Resistance Because a transformer changes the voltage and current levels, it effectively changes the load resistance seen by a source in the primary circuit. Consider the circuit shown in Fig. 72. The device equations are

$$\begin{aligned} \text{Resistor:} \quad v_2(t) &= R_L i_L(t) \\ \text{Transformer:} \quad v_2(t) &= n v_1(t) \\ i_2(t) &= -\frac{1}{n} i_1(t) \end{aligned}$$

Dividing the first transformer equation by the second and inserting the load resistance constraint yield

$$\frac{v_2(t)}{i_2(t)} = \frac{i_L(t)R_L}{i_2(t)} = -n^2 \frac{v_1(t)}{i_1(t)}$$

Applying KCL at the output interface tells us $i_L(t) = -i_2(t)$. Therefore, the equivalent resistance seen on the primary side is

$$R_{EQ} = \frac{v_1(t)}{i_1(t)} = \frac{1}{n^2} R_L \quad (75)$$

The equivalent load resistance seen on the primary side depends on the turns ratio and the load resistance.

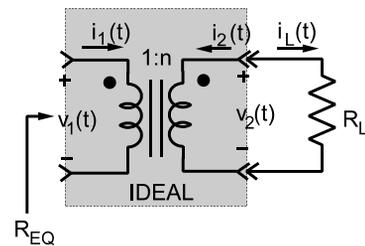

Fig. 72 Equivalent resistance seen in primary winding.¹

Adjusting the turns ratio can make R_{EQ} equal to the source resistance. Transformer coupling can produce the resistance match condition for maximum power transfer when the source and load resistances are not equal.

4.3 Phasor Analysis of Alternating Current Circuits

Those ac circuits that are excited by a single frequency, for example, power systems, can be easily and effectively analyzed using sinusoidal steady-state techniques. Such a technique was first proposed by Charles Steinmetz (1865–1923) using a vector representation of sinusoids called *phasors*.

Sinusoids and Phasors The phasor concept is the foundation for the analysis of linear circuits in the sinusoidal steady state. Simply put, a *phasor* is a complex number representing the amplitude and phase angle of a sinusoidal voltage or current. The connection between sine waves and complex numbers is provided by Euler's relationship:

$$e^{j\theta} = \cos \theta + j \sin \theta$$

To develop the phasor concept, it is necessary to adopt the point of view that the cosine and sine functions can be written in the form

$$\cos \theta = \operatorname{Re}\{e^{j\theta}\} \quad \text{and} \quad \sin \theta = \operatorname{Im}\{e^{j\theta}\}$$

where Re stands for the "real part of" and Im for the "imaginary part of." Development of the phasor concept begins with reference of phasors to the cosine function as

$$\begin{aligned} v(t) &= V_A \cos(\omega t + \phi) = V_A \operatorname{Re}\{e^{j(\omega t + \phi)}\} \\ &= V_A \operatorname{Re}\{e^{j\omega t} e^{j\phi}\} = \operatorname{Re}\{(V_A e^{j\phi}) e^{j\omega t}\} \quad (76) \end{aligned}$$

Moving the amplitude V_A inside the real-part operation does not change the final result because it is real constant. By definition the quantity $V_A e^{j\phi}$ in Eq. (76) is the *phasor representation* of the sinusoid $v(t)$. The phasor \mathbf{V} —a boldface V —or sometimes written with a tilde above the variable, \tilde{V} , can be represented in polar or rectangular form as

$$\mathbf{V} = \underbrace{V_A e^{j\phi}}_{\text{polar form}} = \underbrace{V_A (\cos \phi + j \sin \phi)}_{\text{rectangular form}} \quad (77)$$

Note that \mathbf{V} is a complex number determined by the amplitude and phase angle of the sinusoid. Figure 73 shows a graphical representation commonly called a phasor diagram. An alternative way to write the polar form of a phasor is to replace the exponential $e^{j\phi}$ by the shorthand notation $\angle \phi$, that is, $\mathbf{V} = V_A \angle \phi$,

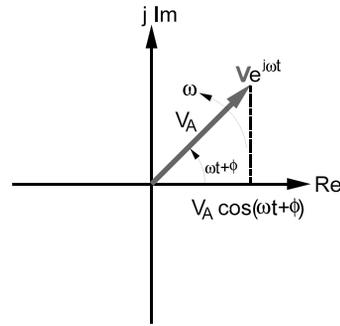

Fig. 73 Complex exponential $\mathbf{V} e^{j\omega t}$.

which is equivalent to the polar form in Eq. (77). It is important to realize that a phasor is determined by its amplitude and phase angle and does not contain any information about the frequency of the sinusoid.

The first feature points out that signals can be described in different ways. Although the phasor \mathbf{V} and waveform $v(t)$ are related concepts, they have quite different physical interpretations and one must clearly distinguish between them. The absence of frequency information in the phasors results from the fact that in the sinusoidal steady state all currents and voltages are sinusoids with the same frequency. Carrying frequency information in the phasor would be redundant, since it is the same for all phasors in any given steady-state circuit problem.

In summary, given a sinusoidal waveform $v(t) = V_A \cos(\omega t + \phi)$, the corresponding phasor representation is $\mathbf{V} = V_A e^{j\phi}$. Conversely, given the phasor $\mathbf{V} = V_A e^{j\phi}$, the corresponding sinusoid waveform is found by multiplying the phasor by $e^{j\omega t}$ and reversing the steps in Eq. (76) as follows:

$$\begin{aligned} v(t) &= \operatorname{Re}\{\mathbf{V} e^{j\omega t}\} = \operatorname{Re}\{(V_A e^{j\phi}) e^{j\omega t}\} \\ &= V_A \operatorname{Re}\{e^{j(\omega t + \phi)}\} = V_A \cos(\omega t + \phi) \end{aligned}$$

The frequency ω in the complex exponential $\mathbf{V} e^{j\omega t}$ in Eq. (76) must be expressed or implied in a problem statement, since by definition it is not contained in the phasor. Figure 73 shows a geometric interpretation of the complex exponential $\mathbf{V} e^{j\omega t}$ as a vector in the complex plane of length V_A , which rotates counterclockwise with a constant angular velocity ω . The real-part operation projects the rotating vector onto the horizontal (real) axis and thereby generates $v(t) = V_A \cos(\omega t + \phi)$. The complex exponential is sometimes called a *rotating phasor*, and the phasor \mathbf{V} is viewed as a snapshot of the situation at $t = 0$.

Properties of Phasors Phasors have two properties. The *additive property* states that the phasor representing a sum of sinusoids of the same frequency is

obtained by adding the phasor representations of the component sinusoids. To establish this property, we write the expression

$$v(t) = v_1(t) + v_2(t) + \cdots + v_N(t)$$

$$v(t) = \operatorname{Re}\{\mathbf{V}_1 e^{j\omega t}\} + \operatorname{Re}\{\mathbf{V}_2 e^{j\omega t}\} + \cdots + \operatorname{Re}\{\mathbf{V}_N e^{j\omega t}\} \quad (78)$$

where $v_1(t)$, $v_2(t)$, \dots , $v_N(t)$ are sinusoids of the same frequency whose phasor representations are \mathbf{V}_1 , \mathbf{V}_2 , \dots , \mathbf{V}_N . The real-part operation is additive, so the sum of real parts equals the real part of the sum. Consequently, Eq. (78) can be written in the form

$$v(t) = \operatorname{Re}\{\mathbf{V}_1 e^{j\omega t} + \mathbf{V}_2 e^{j\omega t} + \cdots + \mathbf{V}_N e^{j\omega t}\}$$

$$= \operatorname{Re}\{(\mathbf{V}_1 + \mathbf{V}_2 + \cdots + \mathbf{V}_N) e^{j\omega t}\} \quad (79)$$

Hence the phasor \mathbf{V} representing $v(t)$ is

$$\mathbf{V} = \mathbf{V}_1 + \mathbf{V}_2 + \cdots + \mathbf{V}_N \quad (80)$$

The result in Eq. (80) applies only if the component sinusoids all have the same frequency so that $e^{j\omega t}$ can be factored out as shown in the last line in Eq. (79).

The *derivative property* of phasors allows us to easily relate the phasor representing a sinusoid to the phasor representing its derivative. Differentiating Eq. (76) with respect to time t yields

$$\frac{dv(t)}{dt} = \frac{d}{dt} \operatorname{Re}\{\mathbf{V} e^{j\omega t}\} = \operatorname{Re}\left\{\mathbf{V} \frac{d}{dt} e^{j\omega t}\right\}$$

$$= \operatorname{Re}\{j\omega \mathbf{V} e^{j\omega t}\} \quad (81)$$

From the definition of a phasor we see that the quantity $j\omega \mathbf{V}$ on the right side of this equation is the phasor representation of the time derivative of the sinusoidal waveform.

In summary, the *additive property* states that adding phasors is equivalent to adding sinusoidal waveforms of the same frequency. The *derivative property* states that multiplying a phasor by $j\omega$ is equivalent to differentiating the corresponding sinusoidal waveform.

Phasor Circuit Analysis Phasor circuit analysis is a method of finding sinusoidal steady-state responses directly from the circuit without using differential equations.

Connection Constraints in Phasor Form Kirchhoff's laws in phasor form are as follows:

KVL: The algebraic sum of phasor voltages around a loop is zero.

KCL: The algebraic sum of phasor currents at a node is zero.

Device Constraints in Phasor Form The device constraints of the three passive elements are

$$\text{Resistor: } v_R(t) = Ri_R(t)$$

$$\text{Inductor: } v_L(t) = L \frac{di_L(t)}{dt} \quad (82)$$

$$\text{Capacitor: } i_C(t) = C \frac{dv_C(t)}{dt}$$

Now in the sinusoidal steady state all of these currents and voltages are sinusoids. In the sinusoidal steady state the voltage and current of the resistor can be written in terms of phasors as $v_R(t) = \operatorname{Re}\{\mathbf{V}_R e^{j\omega t}\}$ and $i_R(t) = \operatorname{Re}\{\mathbf{I}_R e^{j\omega t}\}$. Consequently, the resistor i - v relationship in Eq. (82) can be expressed in terms of phasors as follows:

$$\operatorname{Re}\{\mathbf{V}_R e^{j\omega t}\} = R \times \operatorname{Re}\{\mathbf{I}_R e^{j\omega t}\}$$

Moving R inside the real-part operation on the right side of this equation does not change things because R is a real constant:

$$\operatorname{Re}\{\mathbf{V}_R e^{j\omega t}\} = \operatorname{Re}\{R \mathbf{I}_R e^{j\omega t}\}$$

This relationship holds only if the phasor voltage and current for a resistor are related as

$$\mathbf{V}_R = R \mathbf{I}_R \quad (83a)$$

If the current through a resistor is $i_R(t) = I_A \cos(\omega t + \varphi)$. Then the phasor current is $\mathbf{I}_R = I_A e^{j\varphi}$ and, according to Eq. (83a), the phasor voltage across the resistor is

$$\mathbf{V}_R = R I_A e^{j\varphi} \quad (83b)$$

This result shows that the voltage has the same phase angle (φ) as the current. Phasors with the same phase angle are said to be *in phase*; otherwise they are said to be *out of phase*.

In the sinusoidal steady state the voltage and phasor current for the inductor can be written in terms of phasors as $v_L(t) = \operatorname{Re}\{\mathbf{V}_L e^{j\omega t}\}$ and $i_L(t) = \operatorname{Re}\{\mathbf{I}_L e^{j\omega t}\}$. Using the derivative property of phasors, the inductor i - v relationship can be expressed as

$$\operatorname{Re}\{\mathbf{V}_L e^{j\omega t}\} = L \times \operatorname{Re}\{j\omega \mathbf{I}_L e^{j\omega t}\}$$

$$= \operatorname{Re}\{j\omega L \mathbf{I}_L e^{j\omega t}\} \quad (84)$$

Moving the real constant L inside the real-part operation does not change things, leading to the conclusion that phasor voltage and current for an inductor are related as

$$\mathbf{V}_L = j\omega L \mathbf{I}_L \quad (85)$$

When the current is $i_L(t) = i_A \cos(\omega t + \phi)$, the corresponding phasor is $\mathbf{I}_L = I_A e^{j\phi}$ and the $i-v$ constraint in Eq. (85) yields

$$\begin{aligned} \mathbf{V}_L &= j\omega L \mathbf{I}_L = (\omega L e^{j90^\circ})(I_A e^{j\phi}) \\ &= \omega L I_A e^{j(\phi+90^\circ)} \end{aligned}$$

The resulting phasor diagram in Fig. 74 shows that the inductor voltage and current are 90° out of phase. The voltage phasor is advanced by 90° counterclockwise, which is in the direction of rotation of the complex exponential $e^{j\omega t}$. When the voltage phasor is advanced counterclockwise, that is, ahead of the rotating current phasor, the voltage phasor *leads* the current phasor by 90° or equivalently the current *lags* the voltage by 90° .

Finally, the capacitor voltage and current in the sinusoidal steady state can be written in terms of phasors as $v_C(t) = \text{Re}\{\mathbf{V}_C e^{j\omega t}\}$ and $i_C(t) = \text{Re}\{\mathbf{I}_C e^{j\omega t}\}$. Using the derivative property of phasors, the $i-v$ relationship of the capacitor becomes

$$\begin{aligned} \text{Re}\{\mathbf{I}_C e^{j\omega t}\} &= C \times \text{Re}\{j\omega \mathbf{V}_C e^{j\omega t}\} \\ &= \text{Re}\{j\omega C \mathbf{V}_C e^{j\omega t}\} \end{aligned} \quad (86)$$

Moving the real constant C inside the real-part operation does not change the final results, so we conclude that the phasor voltage and current for a capacitor are related as

$$\mathbf{I}_C = j\omega C \mathbf{V}_C \quad \text{or} \quad \mathbf{V}_C = \frac{1}{j\omega C} \mathbf{I}_C \quad (87)$$

When $i_C(t) = I_A \cos(\omega t + \phi)$, then Eq. (87) the phasor voltage across the capacitor is

$$\begin{aligned} \mathbf{V}_C &= \frac{1}{j\omega C} \mathbf{I}_C = \left(\frac{1}{\omega C} e^{-j90^\circ}\right)(I_A e^{j\phi}) \\ &= \frac{I_A}{\omega C} e^{j(\phi-90^\circ)} \end{aligned}$$

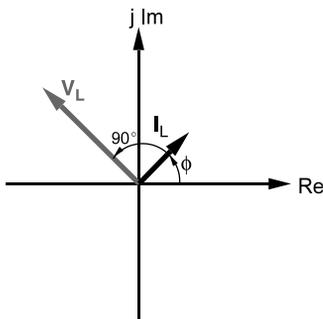

Fig. 74 Phasor $i-v$ characteristics of inductor.¹

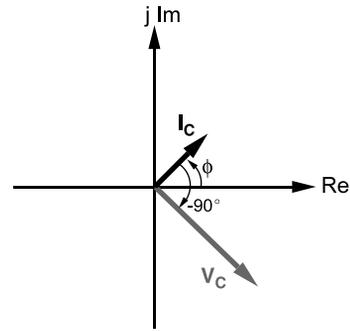

Fig. 75 Phasor $i-v$ characteristics of capacitor.¹

The resulting phasor diagram in Fig. 75 shows that voltage and current are 90° out of phase. In this case the voltage phasor is retarded by 90° clockwise, which is in a direction opposite to the rotation of the complex exponential $e^{j\omega t}$. When the voltage is retarded clockwise, that is, behind the rotating current phasor, we say the voltage phasor *lags* the current phasor by 90° or equivalently the current *leads* the voltage by 90° .

Impedance Concept The $\mathbf{I}-\mathbf{V}$ constraints in Eqs. (83a), (85), and (87) are all of the form

$$\mathbf{V} = \mathbf{Z} \mathbf{I} \quad (88)$$

where Z is called the impedance of the element. Equation (88) is analogous to Ohm's law in resistive circuits. *Impedance* is the proportionality constant relating phasor voltage and phasor current in linear, two-terminal elements. The impedances of the three passive elements are

$$\begin{aligned} \text{Resistor:} \quad Z_R &= R \\ \text{Inductor:} \quad Z_L &= j\omega L \\ \text{Capacitor:} \quad Z_C &= \frac{1}{j\omega C} = -\frac{j}{\omega C} \end{aligned} \quad (89)$$

Since impedance relates phasor voltage to phasor current, it is a complex quantity whose units are ohms. Although impedance can be a complex number, it is not a phasor. Phasors represent sinusoidal signals while impedances characterize circuit elements in the sinusoidal steady state.

Basic Circuit Analysis in Phasor Domain The phasor constraints have the same format as the constraints for resistance circuits; therefore, familiar tools such as series and parallel equivalence, voltage and current division, proportionality and superposition, and Thevenin and Norton equivalent circuits are applicable to phasor circuit analysis. The major difference is that the circuit responses are complex numbers (phasors) and not waveforms.

Series Equivalence and Voltage Division Consider a simple series circuit with several impedances connected to a phasor voltage. The same phasor responses \mathbf{V} and \mathbf{I} exist when the series-connected elements are replaced by equivalent impedance Z_{EQ} :

$$Z_{EQ} = \frac{\mathbf{V}}{\mathbf{I}} = Z_1 + Z_2 + \cdots + Z_N$$

In general, the equivalent impedance Z_{EQ} is a complex quantity of the form

$$Z_{EQ} = R + jX$$

where R is the real part and X is the imaginary part. The real part of Z is called *resistance* and the imaginary part (X , not jX) is called *reactance*. Both resistance and reactance are expressed in ohms. For passive circuits resistance is always positive while reactance X can be either positive or negative. A positive X is called an *inductive* reactance because the reactance of an inductor is ωL , which is always positive. A negative X is called a *capacitive* reactance because the reactance of a capacitor is $-1/\omega C$, which is always negative.

The phasor voltage across the k th element in the series connection is

$$\mathbf{V}_k = Z_k \mathbf{I}_k = \frac{Z_k}{Z_{EQ}} \mathbf{V} \quad (90)$$

Equation (90) is the phasor version of the voltage division principle. The phasor voltage across any element in a series connection equals the ratio of its impedance to the equivalent impedance of the connection times the total phasor voltage across the connection.

Example 21. The circuit in Fig. 76a is operating in the sinusoidal steady state with $v_S(t) = 35 \cos 1000t$ volts.

- Transform the circuit into the phasor domain.
- Solve for the phasor current \mathbf{I} .

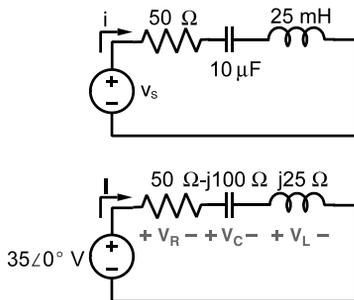

Fig. 76 (From Ref. 1.)

- Solve for the phasor voltage across each element.
- Find the waveforms corresponding to the phasors found in (b) and (c).

Solution

- The phasor representing the input source voltage is $\mathbf{V}_S = 35\angle 0^\circ$. The impedances of the three passive elements are

$$Z_R = R = 50 \Omega$$

$$Z_L = j\omega L = j1000 \times 25 \times 10^{-3} = j25 \Omega$$

$$Z_C = \frac{1}{j\omega C} = \frac{1}{j1000 \times 10^{-5}} = -j100 \Omega$$

Using these, results we obtain the phasor domain circuit in Fig. 76b.

- The equivalent impedance of the series connection is

$$\begin{aligned} Z_{EQ} &= 50 + j25 - j100 = 50 - j75 \\ &= 90.1\angle -56.3^\circ \Omega \end{aligned}$$

The current in the series circuit is

$$\mathbf{I} = \frac{\mathbf{V}_S}{Z_{EQ}} = \frac{35\angle 0^\circ}{90.1\angle -56.3^\circ} = 0.388\angle 56.3^\circ \text{ A}$$

- The current \mathbf{I} exists in all three series elements so the voltage across each passive element is

$$\begin{aligned} \mathbf{V}_R &= Z_R \mathbf{I} = 50 \times 0.388\angle 56.3^\circ \\ &= 19.4\angle 56.3^\circ \text{ V} \end{aligned}$$

$$\begin{aligned} \mathbf{V}_L &= Z_L \mathbf{I} = j25 \times 0.388\angle 56.3^\circ \\ &= 9.70\angle 146.3^\circ \text{ V} \end{aligned}$$

$$\begin{aligned} \mathbf{V}_C &= Z_C \mathbf{I} = -j100 \times 0.388\angle 56.3^\circ \\ &= 38.8\angle -33.7^\circ \text{ V} \end{aligned}$$

- The sinusoidal steady-state waveforms corresponding to the phasors in (b) and (c) are

$$\begin{aligned} i(t) &= \text{Re}\{0.388e^{j56.3^\circ} e^{j1000t}\} \\ &= 0.388 \cos(1000t + 56.3^\circ) \text{ A} \end{aligned}$$

$$\begin{aligned} v_R(t) &= \text{Re}\{19.4e^{j56.3^\circ} e^{j1000t}\} \\ &= 19.4 \cos(1000t + 56.3^\circ) \text{ V} \end{aligned}$$

$$\begin{aligned} v_L(t) &= \text{Re}\{9.70e^{j146.3^\circ} e^{j1000t}\} \\ &= 9.70 \cos(1000t + 146.3^\circ) \text{ V} \end{aligned}$$

$$v_C(t) = \operatorname{Re}\{38.8e^{j-33.7^\circ} e^{j1000t}\}$$

$$= 38.8 \cos(1000t - 33.7^\circ) \text{ V}$$

Parallel Equivalence and Current Division Consider a number of impedances connected in parallel so the same phasor voltage \mathbf{V} appears across them. The same phasor responses \mathbf{V} and \mathbf{I} exist when the parallel-connected elements are replaced by equivalent impedance Z_{EQ} :

$$\frac{1}{Z_{\text{EQ}}} = \frac{\mathbf{I}}{\mathbf{V}} = \frac{1}{Z_1} + \frac{1}{Z_2} + \cdots + \frac{1}{Z_N}$$

These results can also be written in terms of admittance Y , which is defined as the reciprocal of impedance:

$$Y = \frac{1}{Z} = G + jB$$

The real part of Y is called *conductance* and the imaginary part B is called *susceptance*, both of which are expressed in units of siemens.

The phasor current through the k th element of the parallel connection is

$$\mathbf{I}_k = Y_k \mathbf{V}_k = \frac{Y_k}{Y_{\text{EQ}}} \mathbf{I} \quad (91)$$

Equation (91) is the phasor version of the current division principle. The phasor current through any element in a parallel connection equals the ratio of its admittance to the equivalent admittance of the connection times the total phasor current entering the connection.

Example 22. For the circuit in Fig. 77 solve for the phasor voltage \mathbf{V} and for the phasor current through each branch.

Solution

(a) The admittances of the two parallel branches are

$$Y_1 = \frac{1}{-j500} = j2 \times 10^{-3} \text{ S}$$

$$Y_2 = \frac{1}{500 + j1000} = 4 \times 10^{-4} - j8 \times 10^{-4} \text{ S}$$

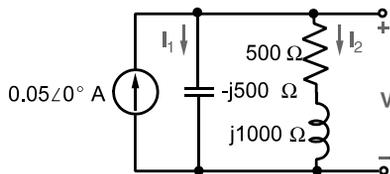

Fig. 77 (From Ref. 1.)

The equivalent admittance of the parallel connection is

$$Y_{\text{EQ}} = Y_1 + Y_2 = 4 \times 10^{-4} + j12 \times 10^{-4}$$

$$= 12.6 \times 10^{-4} \angle 71.6^\circ \text{ S}$$

and the voltage across the parallel circuit is

$$\mathbf{V} = \frac{\mathbf{I}_S}{Y_{\text{EQ}}} = \frac{0.05 \angle 0^\circ}{12.6 \times 10^{-4} \angle 71.6^\circ}$$

$$= 39.7 \angle -71.6^\circ \text{ V}$$

(b) The current through each parallel branch is

$$\mathbf{I}_1 = Y_1 \mathbf{V} = j2 \times 10^{-3} \times 39.7 \angle -71.6^\circ$$

$$= 79.4 \angle 18.4^\circ \text{ mA}$$

$$\mathbf{I}_2 = Y_2 \mathbf{V} = (4 \times 10^{-4} - j8 \times 10^{-4})$$

$$\times 39.7 \angle -71.6^\circ = 35.5 \angle -135^\circ \text{ mA}$$

Y-Δ Transformations In section 1.2 in the discussion of equivalent circuits the equivalence of Δ- and Y-connected resistors to simplify resistance circuits with no series- or parallel-connected branches was covered. The same basic concept applies to the Δ- and Y-connected impedances (see Fig. 78).

The equations for the Δ-Y transformation are

$$Z_1 = \frac{Z_B Z_C}{Z_A + Z_B + Z_C} \quad Z_2 = \frac{Z_C Z_A}{Z_A + Z_B + Z_C}$$

$$Z_3 = \frac{Z_A Z_B}{Z_A + Z_B + Z_C} \quad (92)$$

The equations for a Y-Δ transformation are

$$Z_A = \frac{Z_1 Z_2 + Z_2 Z_3 + Z_1 Z_3}{Z_1}$$

$$Z_B = \frac{Z_1 Z_2 + Z_2 Z_3 + Z_1 Z_3}{Z_2}$$

$$Z_C = \frac{Z_1 Z_2 + Z_2 Z_3 + Z_1 Z_3}{Z_3} \quad (93)$$

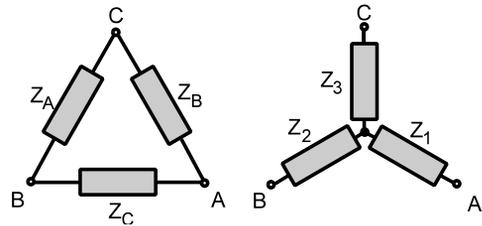

Fig. 78 Y-Δ impedance transformation.²

The equations have the same form except that here they involve impedances rather than resistances.

Example 23. Find the phasor current \mathbf{I}_{IN} in Fig. 79a.

Solution. One cannot use basic reduction tools on the circuit because no elements are connected in series or parallel. However, by replacing either the upper Δ (A, B, C) or lower Δ (A, B, D) by an equivalent Y subcircuit, series and parallel reduction methods can be applied. Choosing the upper Δ because it has two equal resistors simplifies the transformation equations. The sum of the impedance in the upper Δ is $100 + j200\Omega$. This sum is the denominator in the expression in Δ - Y transformation equations. The three Y impedances are found to be

$$Z_1 = \frac{(50)(j200)}{100 + j200} = 40 + j20 \Omega$$

$$Z_2 = \frac{(50)(j200)}{100 + j200} = 40 + j20 \Omega$$

$$Z_3 = \frac{(50)(50)}{100 + j200} = 5 - j10 \Omega$$

Figure 79b shows the revised circuit with the equivalent Y inserted in place of the upper Δ . Note that the transformation introduces a new node labeled N . The revised circuit can be reduced by series and parallel equivalence. The total impedance of the path NAD is $40 - j100\Omega$. The total impedance of the path NBD is $100 + j20\Omega$. These paths are connected in parallel so

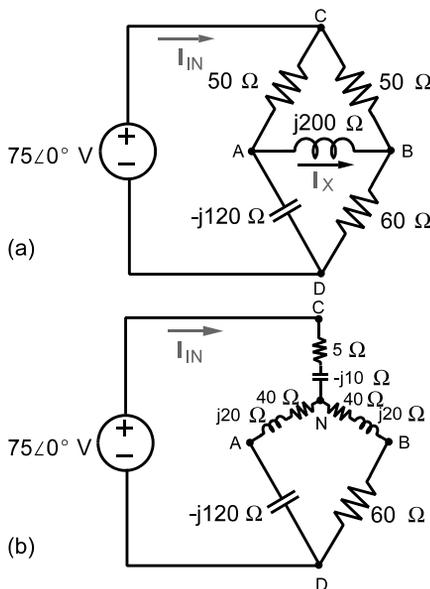

Fig. 79 (From Ref. 2.)

the equivalent impedance between nodes N and D is

$$\begin{aligned} Z_{ND} &= \frac{1}{1/(40 - j100) + 1/(100 + j20)} \\ &= 60.6 - j31.1 \Omega \end{aligned}$$

The impedance Z_{ND} is connected in series with the remaining leg of the equivalent Y , so the equivalent impedance seen by the voltage source is

$$Z_{EQ} = 5 - j10 + Z_{ND} = 65.6 - j41.1 \Omega$$

The input current then is

$$\begin{aligned} \mathbf{I}_{IN} &= \frac{\mathbf{V}_S}{Z_{EQ}} = \frac{75\angle 0^\circ}{65.6 - j41.1} = 0.891 + j0.514 \\ &= 968\angle 32.0^\circ \text{ mA} \end{aligned}$$

Circuit Theorems in Phasor Domain Phasor analysis does not alter the linearity properties of circuits. Hence all of the theorems that are applied to resistive circuits can be applied to phasor analysis. These include proportionality, superposition, and Thevenin and Norton equivalence.

Proportionality The *proportionality* property states that phasor output responses are proportional to the input phasor. Mathematically proportionality means that $\mathbf{Y} = K\mathbf{X}$, where \mathbf{X} is the input phasor, \mathbf{Y} the output phasor, and K the proportionality constant. In phasor circuit analysis the proportionality constant is generally a complex number.

Superposition Care needs to be taken when applying superposition to phasor circuits. If the sources all have the same frequency, then one can transform the circuit into the phasor domain (impedances and phasors) and proceed as in dc circuits with the superposition theorem. If the sources have different frequencies, then superposition can still be used but its application is different. With different frequency sources each source must be treated in a separate steady-state analysis because the element impedances change with frequency. The phasor response for each source must be changed into waveforms and then superposition applied in the time domain. In other words, the superposition principle always applies in the time domain. It also applies in the phasor domain when all independent sources have the same frequency. The following example illustrates the latter case.

Example 24. Use superposition to find the steady-state current $i(t)$ in Fig. 80 for $R = 10 \text{ k}\Omega$, $L = 200 \text{ mH}$, $v_{S1} = 24 \cos 20,000t \text{ V}$, and $v_{S2} = 8 \cos(60,000t + 30^\circ) \text{ V}$.

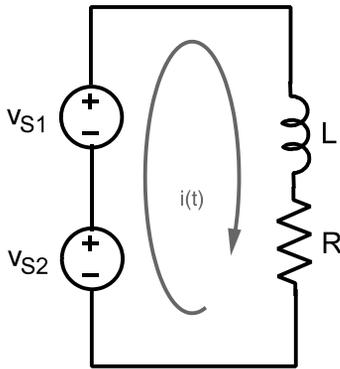

Fig. 80 (From Ref. 1.)

Solution. In this example the two sources operate at different frequencies. With source 2 off, the input phasor is $\mathbf{V}_{S1} = 24\angle 0^\circ$ V at a frequency $\omega = 20$ krad/sec. At this frequency the equivalent impedance of the inductor and resistor is

$$Z_{EQ1} = R + j\omega L = (10 + j4) \text{ k}\Omega$$

The phasor current due to source 1 is

$$\mathbf{I}_1 = \frac{\mathbf{V}_{S1}}{Z_{EQ1}} = \frac{24\angle 0^\circ}{10,000 + j4000} = 2.23\angle -21.8^\circ \text{ mA}$$

With source 1 off and source 2 on, the input phasor $\mathbf{V}_{S2} = 8\angle 30^\circ$ V at a frequency $\omega = 60$ krad/sec. At this frequency the equivalent impedance of the inductor and resistor is

$$Z_{EQ2} = R + j\omega L = (10 + j12) \text{ k}\Omega$$

The phasor current due to source 2 is

$$\begin{aligned} \mathbf{I}_2 &= \frac{\mathbf{V}_{S2}}{Z_{EQ2}} = \frac{8\angle 30^\circ}{10,000 + j12,000} \\ &= 0.512\angle -20.2^\circ \text{ mA} \end{aligned}$$

The two input sources operate at different frequencies so the phasors responses \mathbf{I}_1 and \mathbf{I}_2 cannot be added to obtain the overall response. In this case the overall response is obtained by adding the corresponding time domain waveforms:

$$\begin{aligned} i(t) &= \text{Re}\{\mathbf{I}_1 e^{j20,000t}\} + \text{Re}\{\mathbf{I}_2 e^{j60,000t}\} \\ i(t) &= 2.23 \cos(20,000t - 21.8^\circ) \\ &\quad + 0.512 \cos(60,000t - 20.2^\circ) \text{ mA} \end{aligned}$$

Thevenin and Norton Equivalent Circuits In the phasor domain a two-terminal circuit containing linear

elements and sources can be replaced by Thevenin or Norton equivalent circuits. The general concept of Thevenin's and Norton's theorems and their restrictions are the same as in the resistive circuit studied earlier. The important difference here is that the signals \mathbf{V}_T , \mathbf{I}_N , \mathbf{V} , and \mathbf{I} are phasors and $Z_T = 1/Y_N$ and Z_L are complex numbers representing the source and load impedances.

Thevenin equivalent circuits are useful to address the maximum power transfer problem. Consider the source-load interface as shown in Fig. 81. The source circuit is represented by a Thevenin equivalent circuit with source voltage \mathbf{V}_T and source impedance $Z_T = R_T + jX_T$. The load circuit is represented by an equivalent impedance $Z_L = R_L + jX_L$. In the maximum-power-transfer problem the source parameters \mathbf{V}_T , R_T , and X_T are given, and the objective is to adjust the load impedance R_L and X_L so that average power to the load is a maximum.

The average power to the load is expressed in terms of the phasor current and load resistance:

$$P = \frac{1}{2} R_L |\mathbf{I}|^2$$

Then, using series equivalence, the magnitude of the interface current is

$$\begin{aligned} |\mathbf{I}| &= \left| \frac{\mathbf{V}_T}{Z_T + Z_L} \right| = \frac{|\mathbf{V}_T|}{|(R_T + R_L) + j(X_T + X_L)|} \\ &= \frac{|\mathbf{V}_T|}{\sqrt{(R_T + R_L)^2 + (X_T + X_L)^2}} \end{aligned}$$

Combining the last two equations yields the average power delivered across the interface:

$$P = \frac{1}{2} \frac{R_L |\mathbf{V}_T|^2}{(R_T + R_L)^2 + (X_T + X_L)^2}$$

Since the quantities $|\mathbf{V}_T|$, R_T , and X_T are fixed, P will be maximized when $X_L = -X_T$. This choice of X_L always is possible because a reactance can be positive or negative. When the source Thevenin equivalent has an inductive reactance ($X_T > 0$), the load is selected

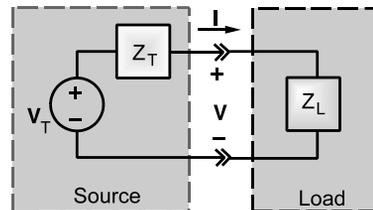

Fig. 81 Source-load interface in the sinusoidal steady state.¹

to have a capacitive reactance of the same magnitude and vice versa. This step reduces the net reactance of the series connection to zero, creating a condition in which the net impedance seen by the Thevenin voltage source is purely resistive. In summary, to obtain maximum power transfer in the sinusoidal steady state, we select the load resistance and reactance so that $R_L = R_T$ and $X_L = -X_T$. The condition for maximum power transfer is called a *conjugate match*, since the load impedance is the conjugate of the source impedance $Z_L = Z_T^*$. Under conjugate-match conditions the maximum average power available from the source circuit is

$$P_{\text{MAX}} = \frac{|V_T|^2}{8R_T}$$

where $|V_T|$ is the peak amplitude of the Thevenin equivalent voltage.

It is important to remember that conjugate matching applies when the source is fixed and the load is adjustable. These conditions arise frequently in power-limited communication systems. However, conjugate matching does not apply to electrical power systems because the power transfer constraints are different.

Node Voltage and Mesh Current Analysis in Phasor Domain The previous sections discuss basic analysis methods based on equivalence, reduction, and circuit theorems. These methods are valuable because they work directly with element impedances and thereby allow insight into steady-state circuit behavior. However, node and mesh analysis allows for solution of more complicated circuits than the basic methods can easily handle. These general methods use node voltage or mesh current variables to reduce the number of equations that must be solved simultaneously. These solution approaches are identical to those in resistive circuits except that phasors are used for signals and impedances in lieu of only resistors. The following are examples of node voltage and mesh current problems.

Example 25. Use node analysis to find the node voltages V_A and V_B in Fig. 82a.

Solution. The voltage source is connected in series with an impedance consisting of a resistor and inductor connected in parallel. The equivalent impedance of this parallel combination is

$$Z_{\text{EQ}} = \frac{1}{1/50 + 1/(j100)} = 40 + j20 \Omega$$

Applying a source transformation produces an equivalent current source of

$$I_{\text{EQ}} = \frac{10\angle -90^\circ}{40 + j20} = -0.1 - j0.2 \text{ A}$$

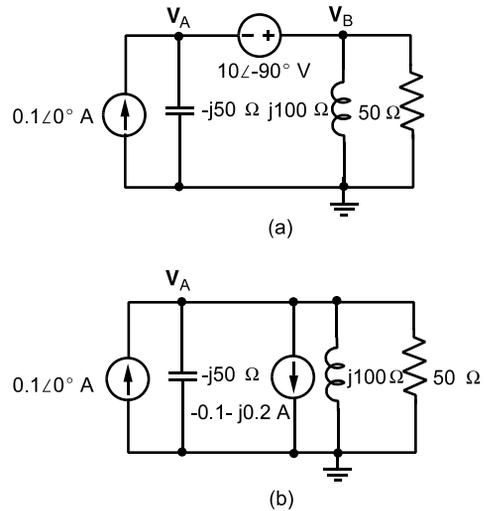

Fig. 82 (From Ref. 1.)

Figure 82b shows the circuit produced by the source transformation. The node voltage equation at the remaining nonreference node in Fig. 82b is

$$\left(\frac{1}{-j50} + \frac{1}{j100} + \frac{1}{50} \right) V_A = 0.1\angle 0^\circ - (-0.1 - j0.2)$$

Solving for V_A yields

$$V_A = \frac{0.2 + j0.2}{0.02 + j0.01} = 12 + j4 = 12.6\angle 18.4^\circ \text{ V}$$

Referring to Fig. 82a, KVL requires $V_B = V_A + 10\angle -90^\circ$. Therefore, V_B is found to be

$$\begin{aligned} V_B &= (12 + j4) + 10\angle -90^\circ = 12 - j6 \\ &= 13.4\angle -26.6^\circ \text{ V} \end{aligned}$$

Example 26. The circuit in Fig. 83 is an equivalent circuit of an ac induction motor. The current I_S is called the stator current, I_R the rotor current, and I_M the magnetizing current. Use the mesh current method to solve for the branch currents I_S , I_R , and I_M .

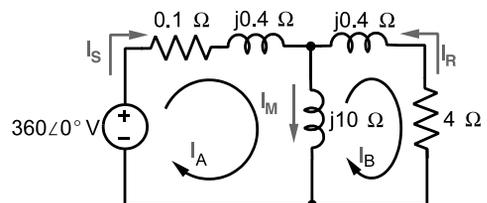

Fig. 83 (From Ref. 1.)

Solution. Applying KVL to the sum of voltages around each mesh yields

$$\begin{aligned}\text{Mesh A: } & -360\angle 0^\circ + [0.1 + j0.4]\mathbf{I}_A \\ & + j10[\mathbf{I}_A - \mathbf{I}_B] = 0 \\ \text{Mesh B: } & j10[\mathbf{I}_B - \mathbf{I}_A] \\ & + [4 + j0.4]\mathbf{I}_B = 0\end{aligned}$$

Solving these equations for \mathbf{I}_A and \mathbf{I}_B produces

$$\mathbf{I}_A = 79.0 - j48.2 \text{ A} \quad \mathbf{I}_B = 81.7 - j14.9 \text{ A}$$

The required stator, rotor, and magnetizing currents are related to these mesh currents as follows:

$$\begin{aligned}\mathbf{I}_S &= \mathbf{I}_A = 92.5\angle 31.4^\circ \text{ A} \\ \mathbf{I}_R &= -\mathbf{I}_B = -81.8 + j14.9 = 83.0\angle 170^\circ \text{ A} \\ \mathbf{I}_M &= \mathbf{I}_A - \mathbf{I}_B = -2.68 - j33.3 = 33.4\angle -94.6^\circ \text{ A}\end{aligned}$$

4.4 Power in Sinusoidal Steady State

Average and Reactive Power In power applications it is normal to think of one circuit as the source and the other as the load. It is important to describe the flow of power across the interface between source and load when the circuit is operating in the sinusoidal steady state. The interface voltage and current in the time domain are sinusoids of the form

$$v(t) = V_A \cos(\omega t + \theta) \quad i(t) = I_A \cos \omega t$$

where v_A and i_A are real, positive numbers representing the peak amplitudes of the voltage and current, respectively. The forms of $v(t)$ and $i(t)$ above are completely general. The positive maximum of the current $i(t)$ occurs at $t = 0$ whereas $v(t)$ contains a phase angle θ to account for the fact that the voltage maximum may not occur at the same time as the current's. In the phasor domain the angle $\theta = \varphi_V - \varphi_I$ is the angle between the phasors $\mathbf{V} = V_A \angle \varphi_V$ and $\mathbf{I} = I_A \angle \varphi_I$. In effect, choosing $t = 0$ at the current maximum shifts the phase reference by an amount $-\varphi_I$ so that the voltage and current phasors become $\mathbf{V} = V_A \angle \theta$ and $\mathbf{I} = I_A \angle 0^\circ$.

The instantaneous power in the time domain is

$$p(t) = v(t) \times i(t) = V_A I_A \cos(\omega t + \theta) \cos \omega t$$

This expression for instantaneous power contains both dc and ac components. Using the identities $\cos^2 x = \frac{1}{2}(1 + \cos 2x)$ and $\cos x \sin x = \frac{1}{2} \sin 2x$, $p(t)$ can be written as

$$\begin{aligned}p(t) &= \underbrace{\left[\frac{1}{2} V_A I_A \cos \theta \right]}_{\text{dc component}} \\ &+ \underbrace{\left[\frac{1}{2} V_A I_A \cos \theta \right] \cos 2\omega t - \left[\frac{1}{2} V_A I_A \sin \theta \right] \sin 2\omega t}_{\text{ac component}}\end{aligned}\quad (94)$$

The instantaneous power is the sum of a dc component and a double-frequency ac component. That is, the instantaneous power is the sum of a constant plus a sinusoid whose frequency is 2ω , which is twice the angular frequency of the voltage and current. The instantaneous power in Eq. (94) is periodic and its average value is

$$P = \frac{1}{T} \int_0^T p(t) dt$$

where $T = 2\pi/2\omega$ is the period of $p(t)$. Since the average value of a sinusoid is zero, the *average value* of $p(t)$, denoted P , is equal to the constant or dc term in Eq. (94):

$$P = \frac{1}{2} V_A I_A \cos \theta \quad (95)$$

The amplitude of the $\sin 2\omega t$ term in Eq. (94) has a form much like the average power in Eq. (95), except it involves $\sin \theta$ rather than $\cos \theta$. This amplitude factor is called the *reactive power* of $p(t)$, where reactive power Q is defined as

$$Q = \frac{1}{2} V_A I_A \sin \theta \quad (96)$$

The instantaneous power in terms of the average power and reactive power is

$$p(t) = \underbrace{P(1 + \cos 2\omega t)}_{\text{unipolar}} - \underbrace{Q \sin 2\omega t}_{\text{bipolar}} \quad (97)$$

The first term in Eq. (97) is said to be unipolar because the factor $1 + \cos 2\omega t$ never changes sign. As a result, the first term is either always positive or always negative depending on the sign of P . The second term is said to be bipolar because the factor $\sin 2\omega t$ alternates signs every half cycle.

The energy transferred across the interface during one cycle $T = 2\pi/2\omega$ of $p(t)$ is

$$\begin{aligned}W &= \int_0^T p(t) dt \\ W &= P \underbrace{\int_0^T (1 + \cos 2\omega t) dt}_{\text{net energy}} - Q \underbrace{\int_0^T \sin 2\omega t dt}_{\text{no net energy}} \quad (98) \\ W &= P \times T \quad - \quad 0\end{aligned}$$

Only the unipolar term in Eq. (97) provides any net energy transfer and that energy is proportional to the average power P . With the passive-sign convention the energy flows from source to load when $W > 0$. Equation (98) shows that the net energy will be positive if the average power $P > 0$. Equation (95) points out that the average power P is positive when $\cos \theta > 0$, which in turn means $|\theta| < 90^\circ$.

The bipolar term in Eq. (97) is a power oscillation which transfers no net energy across the interface. In the sinusoidal steady state the load borrows energy from the source circuit during part of a cycle and temporarily stores it in the load's reactance, namely its inductance or capacitance. In another part of the cycle the borrowed energy is returned to the source unscathed. The amplitude of the power oscillation is called reactive power because it involves periodic energy storage and retrieval from the reactive elements of the load. The reactive power can be either positive or negative depending on the sign of $\sin \theta$. However, the sign of Q says nothing about the net energy transfer, which is controlled by the sign of P .

Consumers are interested in average power since this component carries net energy from source to load. For most power system customers the basic cost of electrical service is proportional to the net energy delivered to the load. Large industrial users may also pay a service charge for their reactive power as well. This may seem unfair, since reactive power transfers no net energy. However, the electric energy borrowed and returned by the load is generated within a power system that has losses. From a power company's viewpoint the reactive power is not free because there are losses in the system connecting the generators in the power plant to the source-load interface at which the lossless interchange of energy occurs.

In ac power circuit analysis, it is necessary to keep track of both the average power and reactive power. These two components of power have the same dimensions, but because they represent quite different effects, they traditionally are given different units. The average power is expressed in watts while reactive power is expressed in volt-amperes reactive (VARs).

Complex Power It is important to relate average and reactive power to phasor quantities because ac circuit analysis is conveniently carried out using phasors. The magnitude of a phasor represents the peak amplitude of a sinusoid. However, in power circuit analysis it is convenient to express phasor magnitudes in rms values. In this chapter phasor voltages and currents are expressed as

$$\mathbf{V} = V_{\text{rms}} e^{j\phi_V} \quad \text{and} \quad \mathbf{I} = I_{\text{rms}} e^{j\phi_I}$$

Equations (95) and (96) express average and reactive power in terms of peak amplitudes v_A and i_A . The peak and rms values of a sinusoid are related by $V_{\text{rms}} = V_A/\sqrt{2}$. The expression for average power can

be easily converted to rms amplitudes, Eq. (95), as

$$P = \frac{V_A I_A}{2} \cos \theta = \frac{V_A}{\sqrt{2}} \frac{I_A}{\sqrt{2}} \cos \theta \quad (99)$$

$$P = V_{\text{rms}} I_{\text{rms}} \cos \theta$$

where $\theta = \phi_V - \phi_I$ is the angle between the voltage and current phasors. By similar reasoning, Eq. (96) becomes

$$Q = V_{\text{rms}} I_{\text{rms}} \sin \theta \quad (100)$$

Using rms phasors, we define the *complex power* (S) at a two-terminal interface as

$$S = \mathbf{V}\mathbf{I}^* = V_{\text{rms}} e^{j\phi_V} I_{\text{rms}} e^{-j\phi_I} = [V_{\text{rms}} I_{\text{rms}}] e^{j(\phi_V - \phi_I)} \quad (101)$$

That is, the complex power at an interface is the product of the voltage phasor times the conjugate of the current phasor. Using Euler's relationship and the fact that the angle $\theta = \phi_V - \phi_I$, complex power can be written as

$$S = [V_{\text{rms}} I_{\text{rms}}] e^{j\theta} = [V_{\text{rms}} I_{\text{rms}}] \cos \theta + j[V_{\text{rms}} I_{\text{rms}}] \sin \theta = P + jQ \quad (102)$$

The real part of the complex power S is the average power while the imaginary part is the reactive power. Although S is a complex number, it is not a phasor. However, it is a convenient variable for keeping track of the two components of power when voltage and current are expressed as phasors.

The power triangles in Fig. 84 provide a convenient way to remember complex power relationships and terminology. Considering those cases in which net energy is transferred from source to load, $P > 0$ and the power triangles fall in the first or fourth quadrant.

The magnitude $|S| = v_{\text{rms}} i_{\text{rms}}$ is called *apparent power* and is expressed using the unit volt-ampere (VA). The ratio of the average power to the apparent power is called the *power factor* (pf):

$$\text{pf} = \frac{P}{|S|} = \frac{V_{\text{rms}} I_{\text{rms}} \cos \theta}{V_{\text{rms}} I_{\text{rms}}} = \cos \theta$$

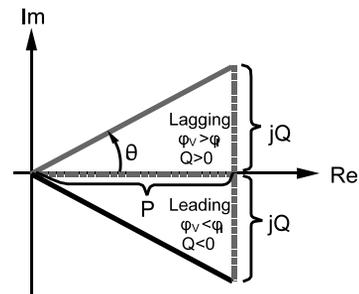

Fig. 84 Power triangles.¹

Since $\text{pf} = \cos \theta$, the angle θ is called the *power factor angle*.

When the power factor is unity, the phasors \mathbf{V} and \mathbf{I} are in phase ($\theta = 0^\circ$) and the reactive power is zero since $\sin \theta = 0$. When the power factor is less than unity, the reactive power is not zero and its sign is indicated by the modifier *lagging* or *leading*. The term *lagging power factor* means the current phasor lags the voltage phasor so that $\theta = \phi_V - \phi_I > 0$. For a lagging power factor S falls in the first quadrant in Fig. 84 and the reactive power is positive since $\sin \theta > 0$. The term *leading power factor* means the current phasor leads the voltage phasor so that $\theta = \phi_V - \phi_I < 0$. In this case S falls in the fourth quadrant in Fig. 84 and the reactive power is negative since $\sin \theta < 0$. Most industrial and residential loads have lagging power factors.

The apparent power rating of electrical power equipment is an important design parameter. The ratings of generators, transformers, and transmission lines are normally stated in kilovolt-amperes. The rating of most loads is stated in kilowatts and power factor. The wiring must be large enough to carry the required current and insulated well enough to withstand the rated voltage. However, only the average power is potentially available as useful output, since the reactive power represents a lossless interchange between the source and device. Because reactive power increases the apparent power rating without increasing the available output, it is desirable for electrical devices to operate as close as possible to unity power factor (zero reactive power).

In many cases power circuit loads are described in terms of their power ratings at a specific voltage or current level. In order to find voltages and current elsewhere in the circuit, it is necessary to know the load impedance. In general, the load produces the element constraint $\mathbf{V} = \mathbf{Z}\mathbf{I}$. Using this constraint in Eq. (101), we write the complex power of the load as

$$S = \mathbf{V} \times \mathbf{I} = \mathbf{Z}\mathbf{I} \times \mathbf{I}^* = Z|\mathbf{I}|^2 \\ = (R + jX)I_{\text{rms}}^2$$

where R and X are the resistance and reactance of the load, respectively. Since $S = P + jQ$, we conclude that

$$R = \frac{P}{I_{\text{rms}}^2} \quad \text{and} \quad X = \frac{Q}{I_{\text{rms}}^2} \quad (103)$$

The load resistance and reactance are proportional to the average and reactive power of the load, respectively.

The first condition in Eq. (103) demonstrates that resistance cannot be negative, since P cannot be negative for a passive circuit. The second condition points out that when the reactive power is positive the load is inductive, since $X_L = \omega L$ is positive. Conversely, when the reactive power is negative the load

is capacitive, since $X_C = -1/\omega C$ is negative. The terms inductive load, lagging power factor, and positive reactive power are synonymous, as are the terms capacitive load, leading power factor, and negative reactive power.

Example 27. At 440 V (rms) a two-terminal load draws 3 kVA of apparent power at a lagging power factor of 0.9. Find i_{rms} , P , Q , and the load impedance.

Solution

$$I_{\text{rms}} = \frac{|S|}{V_{\text{rms}}} = \frac{3000}{440} = 6.82 \text{ A (rms)}$$

$$P = V_{\text{rms}} I_{\text{rms}} \cos \theta = 3000 \times 0.9 = 2.7 \text{ kW.}$$

For $\cos \theta = 0.9$ lagging, $\sin \theta = 0.436$ and $Q = v_{\text{rms}} I_{\text{rms}} \sin \theta = 1.31 \text{ kVAR.}$

$$Z = \frac{P + jQ}{(I_{\text{rms}})^2} = \frac{2700 + j1310}{46.5} = 58.0 + j28.2 \ \Omega$$

Three-Phase Circuits The three-phase system shown in Fig. 85 is the predominant method of generating and distributing ac electrical power. The system uses four lines (A , B , C , N) to transmit power from the source to the loads. The symbols stand for the three phases A , B , and C and a neutral line labeled N . The three-phase generator in Fig. 85 is modeled as three independent sources, although the physical hardware is a single unit with three separate windings. Similarly, the loads are modeled as three separate impedances, although the actual equipment may be housed within a single container.

The terminology Y connected and Δ connected refers to the two ways the source and loads can be electrically connected. In a Y connection the three elements are connected from line to neutral, while in the Δ connection they are connected from line to line.

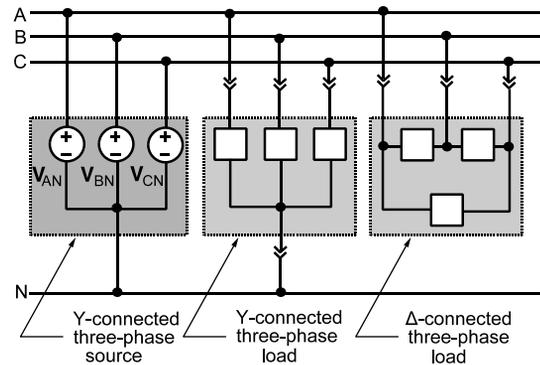

Fig. 85 Three-phase source connected to three-phase Y connection and to three-phase Δ connection.²

In most systems the source is Y connected while the loads can be either Y or Δ, although the latter is more common.

Three-phase sources usually are Y connected because the Δ connection involves a loop of voltage sources. Large currents may circulate in this loop if the three voltages do not exactly sum to zero. In analysis situations, a Δ connection of ideal voltage sources is awkward because it is impossible to uniquely determine the current in each source.

A double-subscript notation is used to identify voltages in the system. The reason is that there are at least six voltages to deal with: three line-to-line voltages and three line-to-neutral voltages. The two subscripts are used to define the points across which a voltage is defined. For example, V_{AB} means the voltage between points A and B with an implied plus reference mark at the first subscript (A) and an implied minus at the second subscript (B).

The three line-to-neutral voltages are called the *phase voltages* and are written in double-subscript notation as V_{AN} , V_{BN} , and V_{CN} . Similarly, the three line-to-line voltages, called simply the *line voltages*, are identified as V_{AB} , V_{BC} , and V_{CA} . From the definition of the double-subscript notation it follows that $V_{XY} = -V_{YX}$. Using this result and KVL we derive the relationships between the line voltages and phase voltages:

$$\begin{aligned} V_{AB} &= V_{AN} + V_{NB} = V_{AN} - V_{BN} \\ V_{BC} &= V_{BN} + V_{NC} = V_{BN} - V_{CN} \\ V_{CA} &= V_{CN} + V_{NA} = V_{CN} - V_{AN} \end{aligned} \quad (104)$$

A balanced three-phase source produces phase voltages that obey the following two constraints:

$$\begin{aligned} |V_{AN}| &= |V_{BN}| = |V_{CN}| = V_P \\ V_{AN} + V_{BN} + V_{CN} &= 0 + j0 \end{aligned}$$

That is, the phase voltages have equal amplitudes (v_P) and sum to zero. There are two ways to satisfy these constraints:

Positive Phase Sequence	Negative Phase Sequence
$V_{AN} = V_P \angle 0^\circ$	$V_{AN} = V_P \angle 0^\circ$
$V_{BN} = V_P \angle -120^\circ$	$V_{BN} = V_P \angle -240^\circ$
$V_{CN} = V_P \angle -240^\circ$	$V_{CN} = V_P \angle -120^\circ$

(105)

Figure 86 shows the phasor diagrams for the positive and negative phase sequences. It is apparent that both sequences involve three equal-length phasors that are separated by an angle of 120° . As a result, the sum of any two phasors cancels the third. In the positive sequence the phase B voltage lags the phase A voltage by 120° . In the negative sequence phase B lags by 240° . It also is apparent that one phase sequence can be converted into the other by simply interchanging the labels on lines B and C. From a circuit analysis viewpoint there is no conceptual difference between the two sequences.

However, the reader is cautioned that “no conceptual difference” does not mean phase sequence is unimportant. It turns out that three-phase motors run in one direction when the positive sequence is applied and in the opposite direction for the negative sequence. In practice, it is essential that there be no confusion about which line A, B, and C is and whether the source phase sequence is positive or negative.

A simple relationship between the line and phase voltages is obtained by substituting the positive-phase-sequence voltages from Eq. (105) into the phasor sums in Eq. (104):

$$\begin{aligned} V_{AB} &= V_{AN} - V_{BN} = \sqrt{3}V_P \angle 30^\circ \\ V_{BC} &= \sqrt{3}V_P \angle -90^\circ \\ V_{CA} &= \sqrt{3}V_P \angle -210^\circ \end{aligned}$$

Figure 87 shows the phasor diagram of these results. The line voltage phasors have the same amplitude and are displaced from each other by 120° . Hence, they obey equal-amplitude and zero-sum constraints like the phase voltages.

If the amplitude of the line voltages is v_L , then $V_L = \sqrt{3}V_P$. In a balanced three-phase system the

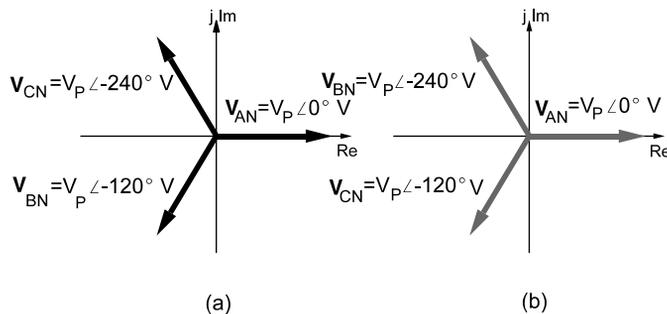

Fig. 86 Two possible phase sequences: (a) positive; (b) negative.¹

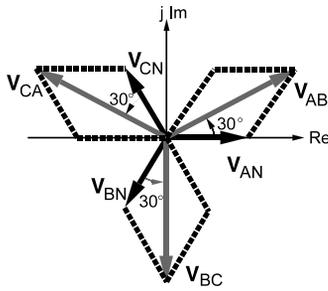

Fig. 87 Phasor diagram showing phase and line voltages for positive phase sequence.¹

line voltage amplitude is $\sqrt{3}$ times the phase voltage amplitude. This ratio appears in equipment descriptions such as 277/480 V three-phase, where 277 is the phase voltage and 480 the line voltage. It is necessary to choose one of the phasors as the zero-phase reference when defining three-phase voltages and currents. Usually the reference is the line A phase voltage (i.e., $V_{AN} = V_P \angle 0^\circ$), as illustrated in Figs. 86 and 87.

5 TRANSIENT RESPONSE OF CIRCUITS

5.1 First-Order Circuits

First-order *RC* and *RL* circuits contain linear resistors and a single capacitor or a single inductor. Figure 88 shows *RC* and *RL* circuits divided into two parts: (a) the dynamic element and (b) the rest of the circuit containing only linear resistors and sources.

Dealing first with the *RC* circuit in Fig. 88a, a KVL equation is

$$R_T i(t) + v(t) = v_T(t)$$

The capacitor *i-v* constraint is

$$i(t) = C \frac{dv(t)}{dt}$$

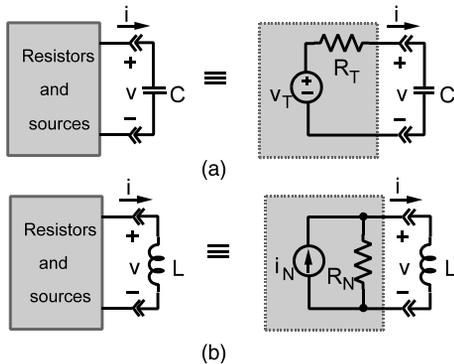

Fig. 88 First-order circuits: (a) *RC* circuit; (b) *RL* circuit.¹

Substituting the *i-v* constraint into the source constraint produces the equation governing the *RC* series circuit:

$$R_T C \frac{dv(t)}{dt} + v(t) = v_T(t) \tag{106}$$

The unknown in Eq. (106) is the capacitor voltage *v(t)*, which is called the *state variable* because it determines the amount or state of energy stored in the capacitive element.

Writing a KCL equation for the *RL* circuit in Fig. 88b yields

$$\frac{1}{R_N} v(t) + i(t) = i_N(t)$$

The element constraint for the inductor is

$$v(t) = L \frac{di(t)}{dt}$$

Combining the element and source constraints produces the differential equation for the *RL* circuit:

$$\frac{L}{R_N} \frac{di(t)}{dt} + i(t) = i_N(t) \tag{107}$$

The unknown in Eq. (107) is the inductor current, also called the state variable because it determines the amount or state of energy stored in the inductive element.

Note that Eqs. (106) and (107) have the same form. In fact, interchanging the following quantities converts one equation into the other:

$$G \leftrightarrow R \quad L \leftrightarrow C \quad i \leftrightarrow v \quad i_N \leftrightarrow v_T$$

This interchange is an example of the principle of duality. Because of duality there is no need to study the *RC* and *RL* circuits as independent problems. Everything learned solving the *RC* circuit can be applied to the *RL* circuit as well.

Step Response of *RL* and *RC* Circuits For the *RC* circuit the response *v(t)* must satisfy the differential equation (106) and the initial condition *v(0)*. The initial energy can cause the circuit to have a nonzero response even when the input $v_T(t) = 0$ for $t \geq 0$.

When the input to the *RC* circuit in Fig. 88 is a step function, the source can be written as $v_T(t) = v_A u(t)$. The circuit differential equation (106) then becomes

$$R_T C \frac{dv(t)}{dt} + v(t) = V_A u(t)$$

The step response of this circuit is a function *v(t)* that satisfies this differential equation for $t \geq 0$ and

meets the initial condition $v(0)$. Since $u(t) = 1$ for $t \geq 0$

$$R_T C \frac{dv(t)}{dt} + v(t) = V_A \quad \text{for } t \geq 0 \quad (108)$$

The solution $v(t)$ can be divided into two components:

$$v(t) = v_N(t) + v_F(t)$$

The first component $v_N(t)$ is the *natural response* and is the general solution equation (108) when the input is set to zero. The natural response has its origin in the physical characteristic of the circuit and does not depend on the form of the input. The component $v_F(t)$ is the *forced response* and is a particular solution of Eq. (108) when the input is the step function.

Finding the natural response requires the general solution of Eq. (108) with the input set to zero:

$$R_T C \frac{dv_N(t)}{dt} + v_N(t) = 0 \quad \text{for } t \geq 0$$

But this is the homogeneous equation that produces the zero-input response. Therefore, the form of the natural response is

$$v_N(t) = K e^{-t/(R_T C)} \quad t \geq 0$$

This is a general solution of the homogeneous equation because it contains an arbitrary constant K . To evaluate K from the initial condition the total response is needed since the initial condition applies to the total response (natural plus forced).

Turning now to the forced response, a particular solution of the equation needs to be found:

$$R_T C \frac{dv_F(t)}{dt} + v_F(t) = V_A \quad \text{for } t \geq 0 \quad (109)$$

The equation requires that a linear combination of $v_F(t)$ and its derivative equal a constant v_A for $t \geq 0$. Setting $v_F(t) = K_F$ meets this condition since $dv_F/dt = dV_A/dt = 0$. Substituting $v_F = K_F$ into Eq. (109) results in $K_F = v_A$.

Now combining the forced and natural responses yields

$$v(t) = v_N(t) + v_F(t)$$

$$v(t) = K e^{-t/(R_T C)} + V_A \quad t \geq 0$$

This equation is the general solution for the step response because it satisfies Eq. (106) and contains an arbitrary constant K . This constant can now be evaluated using the initial condition, $v(0) = V_0 = K e^0 + V_A = K + V_A$. The initial condition requires that $K = V_0 - V_A$. Substituting this conclusion into the

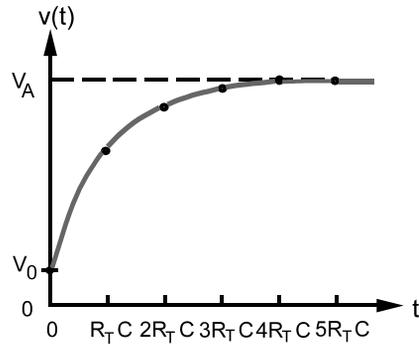

Fig. 89 Step response of first-order RC circuit.¹

general solution yields the step response of the RC circuit:

$$v(t) = (V_0 - V_A)e^{-t/(R_T C)} + V_A \quad t \geq 0 \quad (110)$$

A typical plot of the waveform of $v(t)$ is shown in Fig. 89. The RL circuit in Fig. 88 is the dual of the RC circuit, so the development of its step response is similar. The result is

$$i(t) = (I_0 - I_A)e^{-R_N t/L} + I_A \quad t \geq 0 \quad (111)$$

The RL circuit step response has the same form as the RC circuit step response in Eq. (110). At $t = 0$ the starting value of the response is $i(0) = I_0$ as required by the initial condition. The final value is the forced response $i(\infty) = I_F = I_A$, since the natural response decays to zero as time increases.

Initial and Final Conditions The state variable responses can be written in the form

$$v_c(t), i_L(t) = [\text{IC} - \text{FC}]e^{-t/T_C} + \text{FC} \quad t \geq 0 \quad (112)$$

where IC stands for the initial condition ($t = 0$) and FC for the final condition ($t = \infty$). To determine the step response of any first-order circuit, only three quantities, IC, FC, and T_C , are needed.

The final condition can be calculated directly from the circuit by observing that for $t > 5T_C$ the step responses approach a constant, or dc, value. Under the dc condition a capacitor acts like an open circuit and an inductor acts like a short circuit, so the final value of the state variable can be calculated using resistance circuit analysis methods.

Similarly the dc analysis method can be used to determine the initial condition in many practical situations. One common situation is a circuit containing a switch that remains in one state for a period of time that is long compared with the circuit time constant. If the switch is closed for a long period of time, then

the state variable approaches a final value determined by the dc input. If the switch is now opened at $t = 0$, a transient occurs in which the state variable is driven to a new final condition.

The initial condition at $t = 0$ is the dc value of the state variable for the circuit configuration that existed before the switch was opened at $t = 0$. The switching action cannot cause an instantaneous change in the initial condition because capacitor voltage and inductor current are continuous functions of time. In other words, opening a switch at $t = 0$ marks the boundary between two eras. The dc condition of the state variable for the $t < 0$ era is the initial condition for the $t > 0$ era that follows. The parameters IC, FC, and T_C in switched dynamic circuits are found using the following steps:

- Step 1:** Find the initial condition IC by applying dc analysis to the circuit configuration for $t < 0$.
- Step 2:** Find the final condition FC by applying dc analysis to the circuit configuration for $t \geq 0$.
- Step 3:** Find the time constant T_C of the circuit with the switch in the position for $t \geq 0$.
- Step 4:** Write the step response directly using Eqs. (112) without formulating and solving the circuit differential equation.

Example 28. For the circuit shown in Fig. 90a the switch has been closed for a long time. At $t = 0$ it

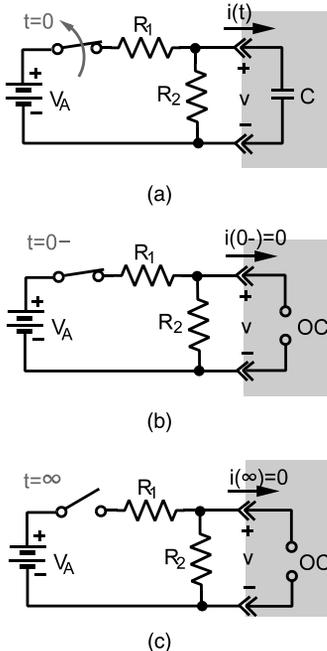

Fig. 90 Solving switched dynamic circuit using initial and final conditions.¹

opens. Find the capacitor voltage $v(t)$ and current $i(t)$ for $t \geq 0$.

Solution

Step 1: The initial condition is found by dc analysis of the circuit configuration in Fig. 90b where the switch is closed. Using voltage division the initial capacitor voltage is found to be

$$v_C(0^-) = IC = \frac{R_2 V_0}{R_1 + R_2}$$

Step 2: The final condition is found by dc analysis of the circuit configuration in Fig. 90c where the switch is open. Five time constants after the switch is opened the circuit has no practical dc excitation, so the final value of the capacitor voltage is zero.

Step 3: The circuit in Fig. 90c also is used to calculate the time constant. Since R_1 is connected in series with an open switch, the capacitor sees an equivalent resistance of only R_2 . For $t \geq 0$ the time constant is $R_2 C$. Using Eq. (112) the capacitor voltage for $t \geq 0$ is

$$v_C(t) = (IC - FC)e^{-t/T_C} + FC \quad t \geq 0$$

$$v_C(t) = \frac{R_2 V_A}{R_1 + R_2} e^{-t/(R_2 C)} t \geq 0$$

This result is a zero-input response, since there is no excitation for $t \geq 0$. To complete the analysis, the capacitor current is found by using its element constraint:

$$i_C(t) = C \frac{dv_C}{dt} = -\frac{V_0}{R_1 + R_2} e^{-t/(R_2 C)} \quad t \geq 0$$

For $t < 0$ the initial-condition circuit in Fig. 90b points out that $i_C(0^-) = 0$ since the capacitor acts like an open circuit.

Example 29. The switch in Fig. 91a has been open for a “long time” and is closed at $t = 0$. Find the inductor current for $t > 0$.

Solution. The initial condition is found using the circuit in Fig. 91b. By series equivalence the initial current is

$$i(0^-) = IC = \frac{V_0}{R_1 + R_2}$$

The final condition and the time constant are determined from the circuit in Fig. 91c. Closing the switch shorts out R_2 and the final condition and time constant for $t > 0$ are

$$i(\infty) = FC = \frac{V_0}{R_1} \quad T_C = \frac{L}{R_N} = \frac{L}{R_1}$$

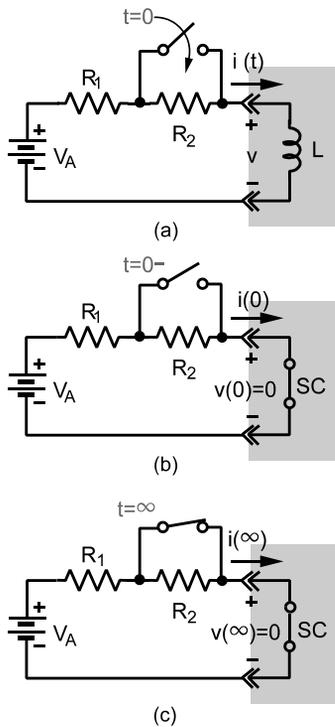

Fig. 91 (From Ref. 1.)

Using Eq. (112) the inductor current for $t \geq 0$ is

$$i(t) = (IC - FC)e^{-t/T_C} + FC \quad t \geq 0$$

$$i(t) = \left[\frac{V_0}{R_1 + R_2} - \frac{V_0}{R_1} \right] e^{-R_1 t/L} + \frac{V_0}{R_1} \quad A \quad t \geq 0$$

First-Order Circuit Response to Other Than dc Signals The response of linear circuits to a variety of signal inputs is an important concept in electrical engineering. Of particular importance is the response to a step reviewed in the previous section to the exponential and sinusoid. If the input to the RC circuit in Fig. 88 is an exponential or a sinusoid, then the circuit differential equation is written as

$$\begin{aligned} \text{Exponential input: } R_T C \frac{dv(t)}{dt} + v(t) &= V_A e^{-\alpha t} u(t) \\ \text{Sinusoidal input: } R_T C \frac{dv(t)}{dt} + v(t) &= V_A \cos \omega t u(t) \end{aligned} \quad (113)$$

The inputs on the right side of Eq. (113) are signals that start at $t = 0$ through some action such as closing a

switch. A solution function $v(t)$ is needed that satisfies Eq. (113) for $t \geq 0$, and that meets the prescribed initial condition $v(0) = V_0$.

As with the step response, the solution is divided into two parts: natural response and forced response. The natural response is of the form

$$v_N(t) = K e^{-t/(R_T C)}$$

The natural response of a first-order circuit always has this form because it is a general solution of the homogeneous equation with input set to zero. The form of the natural response depends on physical characteristics of the circuit and is independent of the input.

The forced response depends on both the circuit and the nature of the forcing function. The forced response is a particular solution of the equation

$$\begin{aligned} \text{Exponential input: } R_T C \frac{dv_F(t)}{dt} + v_F(t) &= V_A e^{-\alpha t} \quad t \geq 0 \end{aligned} \quad (114)$$

$$\begin{aligned} \text{Sinusoidal input: } R_T C \frac{dv_F(t)}{dt} + v_F(t) &= V_A \cos \omega t \quad t \geq 0 \end{aligned}$$

This equation requires that $v_F(t)$ plus $R_T C$ times its first derivative add to produce either an exponential or a sinusoidal waveform for $t \geq 0$. The only way this can happen is for $v_F(t)$ and its derivative to be either an exponential of the same decay or sinusoids of the same frequency. This requirement brings to mind the derivative property of the exponential or the sinusoid. Hence one chooses a solution in the form of

$$\begin{aligned} \text{Exponential: } v_F(t) &= K_F e^{-\alpha t} \\ \text{Sinusoidal: } v_F(t) &= K_A \cos \omega t + K_B \sin \omega t \end{aligned}$$

In this expression the constant K_F or the Fourier coefficient K_A and K_B are unknown. The approach we are using is called the method of undetermined coefficients. The unknown coefficients are found by inserting the forced solution $v_F(t)$ into the differential equation and equating the coefficient of the exponential in that case or of the sine and cosine terms. This yields the following:

$$\begin{aligned} \text{Exponential: } K_F &= \frac{V_A}{1 - \alpha R_T C} \\ \text{Sinusoidal: } K_A &= \frac{V_A}{1 + (\omega R_T C)^2} \\ K_B &= \frac{\omega R_T C V_A}{1 + (\omega R_T C)^2} \end{aligned}$$

The undetermined coefficients are now known, since these equations express constants in terms of known

circuit parameters ($R_T C$) and known input signal parameters (ω and v_A).

The forced and natural responses are combined and the initial condition used to find the remaining unknown constant K :

$$\text{Exponential: } K = V_0 + \frac{V_A}{R_T C \alpha - 1}$$

$$\text{Sinusoidal: } K = V_0 - \frac{V_A}{1 + (\omega R_T C)^2}$$

Combining these together yields the function $v(t)$ that satisfies the differential equation and the initial conditions:

$$v(t) = \left\{ \underbrace{\left[V_0 + \frac{V_A}{R_T C \alpha - 1} \right] e^{-t/(R_T C)}}_{\text{Natural response}} - \underbrace{\frac{V_A}{R_T C \alpha - 1} e^{-\alpha t}}_{\text{Forced response}} \right\} u(t) \quad \text{V}$$

$$= \left\{ \underbrace{\left[V_0 - \frac{V_A}{1 + (\omega R_T C)^2} \right] e^{-t/(R_T C)}}_{\text{Natural response}} + \underbrace{\frac{V_A}{1 + (\omega R_T C)^2} (\cos \omega t + \omega R_T C \sin \omega t)}_{\text{Forced response}} \right\} \times u(t) \quad \text{V} \quad (115)$$

Equations (115) are the complete responses of the RC circuit for an initial condition V_0 and either an exponential or a sinusoidal input.

5.2 Second-Order Circuits

Second-order circuits contain two energy storage elements that cannot be replaced by a single equivalent element. They are called *second-order circuits* because the circuit differential equation involves the second derivative of the dependent variable. The series RLC circuit will illustrate almost all of the basic concepts of second-order circuits.

The circuit in Fig. 92a has an inductor and a capacitor connected in series. The source-resistor circuit can be reduced to the Thevenin equivalent shown in Fig. 92b. Applying KVL around the loop on the right side of the interface and the two i - v characteristics of

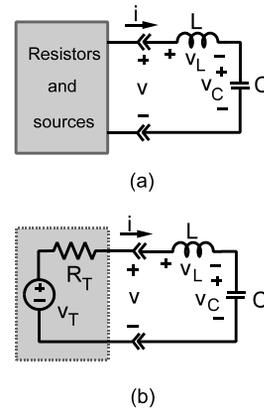

Fig. 92 Series RLC circuit.¹

the inductor and capacitor yields

$$LC \frac{d^2 v_C(t)}{dt^2} + R_T C \frac{dv_C(t)}{dt} + v_C(t) = v_T(t)$$

$$v_L(t) + v_R(t) + v_C(t) = v_T(t) \quad (116)$$

In effect, this is a KVL equation around the loop in Fig. 92b, where the inductor and resistor voltages have been expressed in terms of the capacitor voltage.

The Thevenin voltage $v_T(t)$ is a known driving force. The initial conditions are determined by the values of the capacitor voltage and inductor current at $t = 0$, that is, V_0 and I_0 :

$$v_C(0) = V_0 \quad \text{and} \quad \frac{dv_C}{dt}(0) = \frac{1}{C} i(0) = \frac{I_0}{C}$$

The circuit dynamic response for $t \geq 0$ can be divided into two components: (1) the zero-input response caused by the initial conditions and (2) the zero-state response caused by driving forces applied after $t = 0$. With $v_T = 0$ (zero input) Eq. (116) becomes

$$LC \frac{d^2 v_C(t)}{dt^2} + R_T C \frac{dv_C(t)}{dt} + v_C(t) = 0$$

This result is a second-order homogeneous differential equation in the capacitor voltage. Inserting a trial solution of $v_{CN}(t) = K e^{st}$ into the above equation results in the following *characteristic equation* of the series RLC circuit:

$$LCs^2 + R_T Cs + 1 = 0$$

In general, the above quadratic characteristic equation has two roots:

$$s_1, s_2 = \frac{-R_T C \pm \sqrt{(R_T C)^2 - 4LC}}{2LC}$$

The roots can have three distinct possibilities:

Case A: If $(R_T C)^2 - 4LC > 0$, the discriminant is positive and there are two real, unequal roots ($s_1 = -\alpha_1 \neq s_2 = -\alpha_2$).

Case B: If $(R_T C)^2 - 4LC = 0$, the discriminant vanishes and there are two real, equal roots ($s_1 = s_2 = -\alpha$).

Case C: If $(R_T C)^2 - 4LC < 0$, the discriminant is negative and there are two complex conjugate roots ($s_1 = -\alpha - j\beta$ and $s_2 = -\alpha + j\beta$).

Second-Order Circuit Zero-Input Response

Since the characteristic equation has two roots, there are two solutions to the homogeneous differential equation:

$$v_{C1}(t) = K_1 e^{s_1 t} \quad \text{and} \quad v_{C2}(t) = K_2 e^{s_2 t}$$

Therefore, the general solution for the zero-input response is of the form

$$v_C(t) = K_1 e^{s_1 t} + K_2 e^{s_2 t} \quad (117)$$

The constants K_1 and K_2 can be found using the initial conditions:

$$v_C(t) = \frac{s_2 V_0 - I_0/C}{s_2 - s_1} e^{s_1 t} + \frac{-s_1 V_0 + I_0/C}{s_2 - s_1} e^{s_2 t} \quad t \geq 0 \quad (118)$$

Equation (118) is the general zero-input response of the series RLC circuit. The response depends on two initial conditions, V_0 and I_0 , and the circuit parameters R_T , L , and C since s_1 and s_2 are the roots of the characteristic equation $LCs^2 + R_T Cs + 1 = 0$. The response has different waveforms depending on whether the roots s_1 and s_2 fall under case A, B, or C.

For case A the two roots are real and distinct. Using the notation $s_1 = -\alpha_1$ and $s_2 = -\alpha_2$, the form of the zero-input response for $t \geq 0$ is

$$v_C(t) = \left[\frac{\alpha_2 V_0 + I_0/C}{\alpha_2 - \alpha_1} \right] e^{-\alpha_1 t} - \left[\frac{\alpha_1 V_0 + I_0/C}{\alpha_2 - \alpha_1} \right] e^{-\alpha_2 t} \quad t \geq 0$$

This form is called the *overdamped response*. The waveform has two time constants $1/\alpha_1$ and $1/\alpha_2$.

With case B the roots are real and equal. Using the notation $s_1 = s_2 = -\alpha$, the general form becomes

$$v_C(t) = V_0 e^{-\alpha t} + \left(\alpha V_0 + \frac{I_0}{C} \right) t e^{-\alpha t} \quad t \geq 0$$

This special form is called the *critically damped response*. The critically damped response includes an exponential and a damped ramp waveform.

Case C produces complex-conjugate roots of the form $s_1 = -\alpha - j\beta$ and $s_2 = -\alpha + j\beta$. The form of case C is

$$v_C(t) = V_0 e^{-\alpha t} \cos \beta t + \left(\frac{\alpha V_0 + I_0/C}{\beta} \right) e^{-\alpha t} \sin \beta t \quad t \geq 0$$

This form is called the *underdamped response*. The underdamped response contains a damped sinusoid waveform where the real part of the roots (α) provides the damping term in the exponential, while the imaginary part (β) define the frequency of the sinusoidal oscillation.

Second-Order Circuit Step Response The general second-order linear differential equation with a step function input has the form

$$a_2 \frac{d^2 y(t)}{dt^2} + a_1 \frac{dy(t)}{dt} + a_0 y(t) = Au(t)$$

where $y(t)$ is a voltage or current response, $Au(t)$ is the step function input, and a_2 , a_1 , and a_0 are constant coefficients. The step response is the general solution of this differential equation for $t \geq 0$. The step response can be found by partitioning $y(t)$ into forced and natural components:

$$y(t) = y_N(t) + y_F(t)$$

The natural response $y_N(t)$ is the general solution of the homogeneous equation (input set to zero), while the forced response $y_F(t)$ is a particular solution of the equation

$$a_2 \frac{d^2 y_F(t)}{dt^2} + a_1 \frac{dy_F(t)}{dt} + a_0 y_F(t) = A \quad t \geq 0$$

The particular solution is simply $y_F = A/a_0$.

In a second-order circuit the zero-state and natural responses take one of the three possible forms: overdamped, critically damped, or underdamped. To describe the three possible forms, two parameters are used: ω_0 , the *undamped natural frequency*, and ζ , the *damping ratio*. Using these two parameters, the general homogeneous equation is written in the form

$$\frac{d^2 y_N(t)}{dt^2} + 2\zeta\omega_0 \frac{dy_N(t)}{dt} + \omega_0^2 y_N(t) = 0$$

The above equation is written in *standard form* of the second-order linear differential equation. When a

second-order equation is arranged in this format, its damping ratio and undamped natural frequency can be readily found by equating its coefficient with those in the standard form. For example, in the standard form the homogeneous equation for the series RLC circuit is

$$\frac{d^2 v_C(t)}{dt^2} + \frac{R_T}{L} \frac{dv_C(t)}{dt} + \frac{1}{LC} v_C(t) = 0$$

Equating like terms yields

$$\omega_0^2 = \frac{1}{LC} \quad \text{and} \quad 2\zeta\omega_0 = \frac{R_T}{L}$$

for the series RLC circuit. Note that the circuit elements determine the values of the parameters ω_0 and ζ . The characteristic equation is $s^2 + 2\zeta\omega_0 s + \omega_0^2 = 0$ and its roots are

$$s_1, s_2 = \omega_0 \left(-\zeta \pm \sqrt{\zeta^2 - 1} \right)$$

The expression under the radical define the form of the roots and depends only on the damping ratio ζ :

Case A: For $\zeta > 1$ the discriminant is positive and there are two unequal, real roots

$$s_1, s_2 = -\alpha_1, -\alpha_2 = \omega_0 \left(-\zeta \pm \sqrt{\zeta^2 - 1} \right)$$

and the natural response is of the form

$$y_N(t) = K_1 e^{-\alpha_1 t} + K_2 e^{-\alpha_2 t} \quad t \geq 0 \quad (119)$$

Case B: For $\zeta = 1$ the discriminant vanishes and there are two real, equal roots,

$$s_1 = s_2 = -\alpha = -\zeta\omega_0$$

and the natural response is of the form

$$y_N(t) = K_1 e^{-\alpha t} + K_2 t e^{-\alpha t} \quad t \geq 0 \quad (120)$$

Case C: For $\zeta < 1$, the discriminant is negative leading to two complex, conjugate roots $s_1, s_2 = -\alpha \pm j\beta$, where $\alpha = \zeta\omega_0$ and $\beta = \omega_0\sqrt{1 - \zeta^2}$ and the natural response is of the form

$$y_N(t) = e^{-\alpha t} (K_1 \cos \beta t + K_2 \sin \beta t) \quad t \geq 0 \quad (121)$$

In other words, for $\zeta > 1$ the natural response is overdamped, for $\zeta = 1$ the natural response is critically damped, and for $\zeta < 1$ the response is underdamped.

Combining the forced and natural responses yields the step response of the general second-order differential equation in the form

$$y(t) = y_N(t) + \frac{A}{a_0} \quad t \geq 0$$

The factor A/a_0 is the forced response. The natural response $y_N(t)$ takes one of the forms in Eqs. (119)–(121) depending on the value of the damping ratio. The constants K_1 and K_2 in the natural response can be evaluated from the initial conditions.

Example 30. The series RLC circuit in Fig. 93 is driven by a step function and is in the zero state at $t = 0$. Find the capacitor voltage for $t \geq 0$.

Solution. This is a series RLC circuit so the differential equation for the capacitor voltage is

$$10^{-6} \frac{d^2 v_C(t)}{dt^2} + 0.5 \times 10^{-3} \frac{dv_C(t)}{dt} + v_C(t) = 10 \quad t \geq 0$$

By inspection the forced response is $v_{CF}(t) = 10$ V. In standard format the homogeneous equation is

$$\frac{d^2 v_{CN}(t)}{dt^2} + 500 \frac{dv_{CN}(t)}{dt} + 10^6 v_{CN}(t) = 0 \quad t \geq 0$$

Comparing this format, the standard form yields

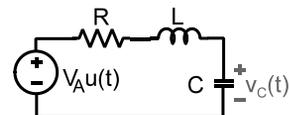

$$\omega_0^2 = 10^6 \quad \text{and} \quad 2\zeta\omega_0 = 500$$

so that $\omega_0 = 1000$ and $\zeta = 0.25$. Since $\zeta < 1$, the natural response is underdamped (case C) and has the form

$$\alpha = \zeta\omega_0 = 250 \text{ Np}$$

$$\beta = \omega_0\sqrt{1 - \zeta^2} = 968 \text{ rad/sec}$$

$$v_{CN}(t) = K_1 e^{-250t} \cos 968t + K_2 e^{-250t} \sin 968t$$

$$V_A = 10 \text{ V} \quad C = 0.5 \mu\text{F} \\ R = 1 \text{ k}\Omega \quad L = 2 \text{ H}$$

Fig. 93 (From Ref. 1.)

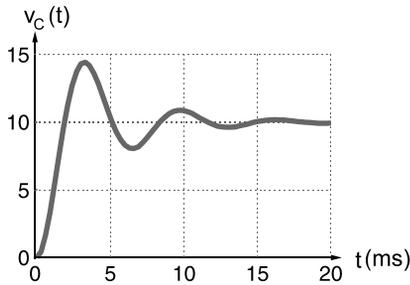

Fig. 94 (From Ref. 1.)

The general solution of the circuit differential equation is the sum of the forced and natural responses:

$$v_C(t) = 10 + K_1 e^{-250t} \cos 968t + K_2 e^{-250t} \sin 968t \quad t \geq 0$$

The constants K_1 and K_2 are determined by the initial conditions. The circuit is in the zero state at $t = 0$, so the initial conditions are $v_C(0) = 0$ and $i_L(0) = 0$. Applying the initial-condition constraints to the general solution yields two equations in the constants K_1 and K_2 :

$$v_C(0) = 10 + K_1 = 0$$

$$\frac{dv_C}{dt}(0) = -250 K_1 + 968 K_2 = 0$$

These equations yield $K_1 = -10$ and $K_2 = -2.58$. The step response of the capacitor voltage step response is

$$v_C(t) = 10 - 10e^{-250t} \cos 968t - 2.58e^{-250t} \sin 968t \quad \text{V} \quad t \geq 0$$

A plot of $v_C(t)$ versus time is shown in Fig. 94. The waveform and its first derivative at $t = 0$ satisfy the initial conditions. The natural response decays to zero so the forced response determines the final value of $v_C(\infty) = 10$ V. Beginning at $t = 0$ the response climbs rapidly but overshoots the final value several times before eventually settling down. The damped sinusoidal behavior results from the fact that $\zeta < 1$, producing an underdamped natural response.

6 FREQUENCY RESPONSE

Linear circuits are often characterized by their behavior to sinusoids, in particular, how they process signals versus frequency. Audio, communication, instrumentation, and control systems all require signal processing that depends at least in part on their frequency response.

6.1 Transfer Functions and Input Impedance

The proportionality property of linear circuits states that the output is proportional to the input. In the phasor domain the proportionality factor is a rational function of $j\omega$ called a *transfer function*. More formally, in the phasor domain a transfer function is defined as the ratio of the output phasor to the input phasor with *all initial conditions set to zero*:

$$\text{Transfer function} = \frac{\text{Output phasor}}{\text{Input phasor}} = H(j\omega)$$

To study the role of transfer functions in determining circuit responses is to write the phasor domain input–output relationship as

$$Y(j\omega) = H(j\omega) \cdot X(j\omega) \quad (122)$$

where $H(j\omega)$ is the transfer function, $X(j\omega)$ is the input signal transform (a voltage or a current phasor), and $Y(j\omega)$ is the output signal transform (also a voltage or current phasor). Figure 95 shows a block diagram representation of the phasor domain input–output relationship.

In an *analysis* problem the circuit defined by $H(j\omega)$ and the input $X(j\omega)$ are known and the response $Y(j\omega)$ is sought. In a *design* problem the circuit is unknown. The input and the desired output or their ratio $H(j\omega) = Y(j\omega)/X(j\omega)$ are given, and the objective is to devise a circuit that realizes the specific input–output relationship. A linear circuit analysis problem has a unique solution, but a design problem may have one, many, or even no solution. Choosing the best of several solutions is referred to as an *evaluation* problem.

There are two major types of functions that help define a circuit: input impedance and transfer functions. *Input impedance* relates the voltage and current at a pair of terminals called a port. The input impedance $Z(j\omega)$ of the one-port circuit in Fig. 96 is defined as

$$Z(j\omega) = \frac{V(j\omega)}{I(j\omega)} \quad (123)$$

When the one port is driven by a current source, the response is $V(j\omega) = Z(j\omega)I(j\omega)$. On the other hand, when the one port is driven by a voltage source, the response is $I(j\omega) = [Z(j\omega)]^{-1} V(j\omega)$.

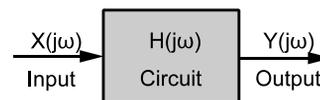

Fig. 95 Block diagram for phasor domain input–output relationship.¹

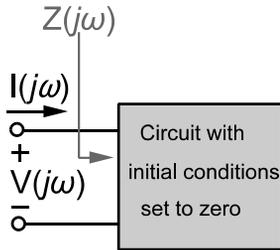

Fig. 96 One-port circuit.¹

The term input impedance means that the circuit is driven at one port and the response is observed at the same port. The impedances of the three basic circuit elements $Z_R(j\omega)$, $Z_L(j\omega)$, and $Z_C(j\omega)$ are elementary examples of input impedances. The equivalent impedances found by combining elements in series and parallel are also effectively input impedances. The terms input impedance, *driving-point impedance*, and *equivalent impedance* are synonymous. Input impedance is useful in impedance-matching circuits at their interface and to help determine if *loading* will be an issue.

Transfer functions are usually of greater interest in signal-processing applications than input impedances because they describe how a signal is modified by passing through a circuit. A *transfer function* relates an input and response (or output) at different ports in the circuit. Since the input and output signals can be either a current or a voltage, four kinds of transfer functions can be defined

$$\begin{aligned}
 H_V(j\omega) &= \text{voltage transfer function} = \frac{V_2(j\omega)}{V_1(j\omega)} \\
 H_Y(j\omega) &= \text{transfer admittance} = \frac{I_2(j\omega)}{V_1(j\omega)} \\
 H_I(j\omega) &= \text{current transfer function} = \frac{I_2(j\omega)}{I_1(j\omega)} \\
 H_Z(j\omega) &= \text{transfer impedance} = \frac{V_2(j\omega)}{I_1(j\omega)}
 \end{aligned}
 \tag{124}$$

The functions $H_V(j\omega)$ and $H_I(j\omega)$ are dimensionless since the input and output signals have the same units. The function $H_Z(j\omega)$ has units of ohms and $H_Y(j\omega)$ has unit of siemens.

Transfer functions always involve an input applied at one port and a response observed at a different port in the circuit. It is important to realize that a transfer function is only valid for a given input port and the specific output port. They cannot be turned upside down like the input impedance. For example, the voltage transfer function $H_V(j\omega)$ relates the voltage $V_1(j\omega)$ applied at the input port to the voltage response $V_2(j\omega)$ observed at the output port in Fig. 95. The voltage transfer function for signal transmission in the opposite direction is usually *not* $1/H_V(j\omega)$.

Determining Transfer Functions The divider circuits in Fig. 97 occur so frequently that it is worth taking time to develop their transfer functions in general terms. Using phasor domain analysis the voltage transfer function of a voltage divider circuit is

$$H_V(j\omega) = \frac{V_2(j\omega)}{V_1(j\omega)} = \frac{Z_2(j\omega)}{Z_1(j\omega) + Z_2(j\omega)}$$

Similarly, using phasor domain current division in Fig. 97b results in the current transfer function of a current divider circuit:

$$\begin{aligned}
 H_I(j\omega) &= \frac{I_2(j\omega)}{I_1(j\omega)} = \frac{1/[Z_2(j\omega)]}{1/[Z_1(j\omega)] + 1/[Z_2(j\omega)]} \\
 &= \frac{Z_1(j\omega)}{Z_1(j\omega) + Z_2(j\omega)}
 \end{aligned}$$

By series equivalence the driving-point impedance at the input of the voltage divider is $Z_{EQ}(j\omega) = Z_1(j\omega) + Z_2(j\omega)$. By parallel equivalence the driving-point impedance at the input of the current divider is $Z_{EQ}(j\omega) = 1/[1/Z_1(j\omega) + 1/Z_2(j\omega)]$.

Two other useful circuits are the inverting and noninverting op amp configuration shown in Fig. 98.

The voltage transfer function of the inverting circuit in Fig. 98a is

$$H_V(j\omega) = \frac{V_2(j\omega)}{V_1(j\omega)} = -\frac{Z_2(j\omega)}{Z_1(j\omega)}$$

The input impedance of this circuit is simply $Z_1(j\omega)$ since $v_B(j\omega) = 0$. The effect of $Z_1(j\omega)$ should be studied when connecting it to another circuit or a nonideal source since it can cause undesired loading.

For the noninverting circuit in Fig. 98b the voltage transfer function is

$$H_V(j\omega) = \frac{V_2(j\omega)}{V_1(j\omega)} = \frac{Z_1(j\omega) + Z_2(j\omega)}{Z_1(j\omega)}$$

The ideal op amp draws no current at its input terminals, so theoretically the input impedance of the noninverting circuit is infinite in practice it is quite high, upward of $10^{10} \Omega$.

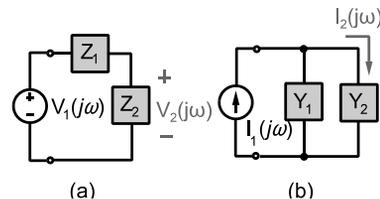

Fig. 97 Basic divider circuits: (a) voltage divider; (b) current divider.¹

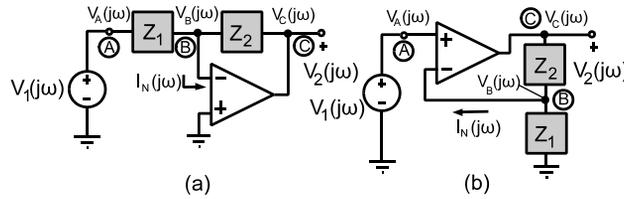

Fig. 98 Basic op amp circuits: (a) inverting amplifier; (b) noninverting amplifier.¹

Example 31. For the circuit in Fig. 99, find (a) the input impedance seen by the voltage source and (b) the voltage transfer function $H_V(j\omega) = V_2(j\omega)/V_1(j\omega)$.

Solution

- (a) The circuit is a voltage divider. First find the equivalent impedances of the two legs of the divider. The two elements in parallel combine to produce the series leg impedance $Z_1(j\omega)$:

$$Z_1(j\omega) = \frac{1}{\frac{1}{R_1 j\omega} + 1/R_1} = \frac{R_1}{R_1 C_1 j\omega + 1}$$

The two elements in series combine to produce shunt (parallel) leg impedance $Z_2(j\omega)$:

$$Z_2(j\omega) = R_2 + \frac{1}{C_2 j\omega} = \frac{R_2 C_2 j\omega + 1}{C_2 j\omega}$$

Using series equivalence, the input impedance seen at the input is

$$\begin{aligned} Z_{EQ}(j\omega) &= Z_1(j\omega) + Z_2(j\omega) \\ &= \frac{R_1 C_1 R_2 C_2 (j\omega)^2 + (R_1 C_1 + R_2 C_2 + R_1 C_2) j\omega + 1}{C_2 j\omega (R_1 C_1 j\omega + 1)} \end{aligned}$$

- (b) Using voltage division, the voltage transfer function is

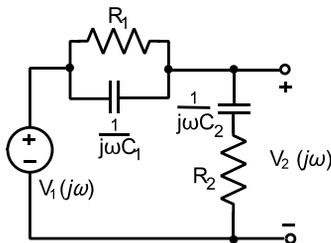

Fig. 99 (From Ref. 1.)

$$\begin{aligned} H_V(j\omega) &= \frac{Z_2(j\omega)}{Z_{EQ}(j\omega)} \\ &= \frac{(R_1 C_1 j\omega + 1)(R_2 C_2 j\omega + 1)}{R_1 C_1 R_2 C_2 (j\omega)^2 + (R_1 C_1 + R_2 C_2 + R_1 C_2) j\omega + 1} \end{aligned}$$

Example 32

- (a) Find the driving-point impedance seen by the voltage source in Fig. 100.
 (b) Find the voltage transfer function $H_V(j\omega) = V_2(j\omega)/V_1(j\omega)$ of the circuit.
 (c) If $R_1 = 1 \text{ k}\Omega$, $R_2 = 10 \text{ k}\Omega$, $C_1 = 10 \text{ nF}$, and $C_2 = 1 \text{ }\mu\text{F}$, evaluate the driving-point impedance and the transfer function.

Solution. The circuit is an inverting op amp configuration. The input impedance and voltage transfer function of this configuration are

$$Z_{IN}(j\omega) = Z_1(j\omega) \quad \text{and} \quad H_V(j\omega) = -\frac{Z_2(j\omega)}{Z_1(j\omega)}$$

- (a) The input impedance is

$$Z_1(j\omega) = R_1 + \frac{1}{j\omega C_1} = \frac{R_1 C_1 j\omega + 1}{j\omega C_1}$$

- (b) The feedback impedance is

$$Z_2(j\omega) = \frac{1}{j\omega C_2 + 1/R_2} = \frac{R_2}{R_2 C_2 j\omega + 1}$$

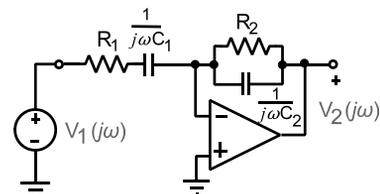

Fig. 100 (From Ref. 1.)

and the voltage transfer function is

$$H_V(j\omega) = -\frac{Z_2(j\omega)}{Z_1(j\omega)}$$

$$= -\frac{R_2 C_1 j\omega}{(R_1 C_1 j\omega + 1)(R_2 C_2 j\omega + 1)}$$

(c) For the values of R 's and C 's given

$$Z_1(j\omega) = \frac{1000(j\omega + 10^5)}{j\omega}$$

and

$$H_V(j\omega) = -\frac{1000j\omega}{(j\omega + 100)(j\omega + 10^5)}$$

6.2 Cascade Connection and Chain Rule

Signal-processing circuits often involve a *cascade connection* in which the output voltage of one circuit serves as the input to the next stage. In some cases, the overall voltage transfer function of the cascade can be related to the transfer functions of the individual stages by a *chain rule*:

$$H_V(j\omega) = H_{V1}(j\omega) \times H_{V2}(j\omega) \times \dots \times H_{Vk}(j\omega) \tag{125}$$

where $H_{V1}, H_{V2}, \dots, H_{Vk}$ are the voltage transfer functions of the individual stages when operated separately. It is important to understand when the chain rule applies since it greatly simplifies the analysis and design of cascade circuits.

Figure 101 shows two RC circuits or stages connected in cascade at an interface. When disconnected

and operated separately, the transfer functions of each stage are easily found using voltage division as follows:

$$H_{V1}(j\omega) = \frac{R}{R + 1/j\omega C} = \frac{Rj\omega C}{Rj\omega C + 1}$$

$$H_{V2}(j\omega) = \frac{1/j\omega C}{R + 1/j\omega C} = \frac{1}{Rj\omega C + 1}$$

When connected in cascade the output of the first stage serves as the input to the second stage. If the chain rule applies, the overall transfer function would be expected to be

$$H_V(j\omega) = \frac{V_3(j\omega)}{V_1(j\omega)} = \left(\frac{V_2(j\omega)}{V_1(j\omega)}\right) \left(\frac{V_3(j\omega)}{V_2(j\omega)}\right)$$

$$= H_{V1}(j\omega) \times H_{V2}(j\omega)$$

$$= \underbrace{\left(\frac{Rj\omega C}{Rj\omega C + 1}\right)}_{\text{1st stage}} \underbrace{\left(\frac{1}{Rj\omega C + 1}\right)}_{\text{2nd stage}}$$

$$= \frac{Rj\omega C}{(Rj\omega C)^2 + 2Rj\omega C + 1}$$

combined

However, the overall transfer function of this circuit is actually found to be

$$H_V(j\omega) = \frac{Rj\omega C}{(Rj\omega C)^2 + 3Rj\omega C + 1}$$

which disagrees with the chain rule result.

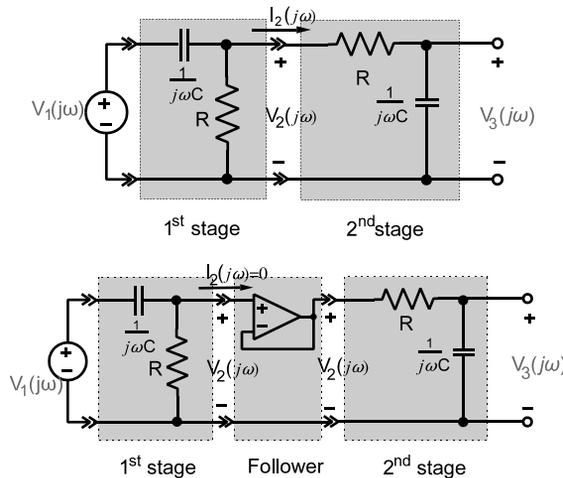

Fig. 101 (a) Two-port circuits connected in cascade. (b) Cascade connection with voltage follower isolation.¹

The reason for the discrepancy is that when they are connected in cascade the second circuit “loads” the first circuit. That is, the voltage divider rule requires the current $I_2(j\omega)$ in Fig. 101a be zero. The no-load condition $I_2(j\omega) = 0$ is valid when the stages operate separately, but when connected together the current is no longer zero. The chain rule does not apply here because loading caused by the second stage alters the transfer function of both stages.

The loading problem goes away when an op amp voltage follower is inserted between the RC circuit stages (Fig. 101b). With this modification the chain rule in Eq. (125) applies because the voltage follower isolates the two RC circuits. Recall that ideally a voltage follower has infinite input resistance and zero output resistance. Therefore, the follower does not draw any current from the first RC circuit [$I_2(j\omega) = 0$] and its transfer function of “1” allows $V_2(j\omega)$ to be applied directly across the input of the second RC circuit.

The chain rule in Eq. (125) applies if connecting a stage does not change or load the output of the preceding stage. Loading can be avoided by connecting an op amp voltage follower between stages. More importantly, loading does not occur if the output of the preceding stage is the output of an op amp or controlled source unless the load resistance is very low. These elements act very close to ideal voltage sources whose outputs are unchanged by connecting the subsequent stage.

For example, in the top representation of the two circuits in Fig. 102 are connected in a cascade with circuit C1 appearing first in the cascade followed by circuit C2. The chain rule applies to this configuration

because the output of circuit C1 is an op amp that can handle the load presented by circuit C2. On the other hand, if the stages are interchanged so that the op amp circuit C1 follows the RC circuit C2 in the cascade, then the chain rule would not apply because the input impedance of circuit C1 would then load the output of circuit C2.

6.3 Frequency Response Descriptors

The relationships between the input and output sinusoids are important to frequency-sensitive circuits and can be summarized in the following statements.

Realizing the circuit transfer function is usually a complex function of ω , its effect on the sinusoidal steady-state response can be found through its *gain* function $|H(j\omega)|$ and *phase* function $\angle H(j\omega)$ as follows:

$$\text{Magnitude of } H(j\omega) = |H(j\omega)| = \frac{\text{output amplitude}}{\text{input amplitude}}$$

$$\text{Angle of } H(j\omega) = \angle H(j\omega)$$

$$= \text{output phase} - \text{input phase}$$

Taken together the gain and phase functions show how the circuit modifies the input amplitude and phase angle to produce the output sinusoid. These two functions define the *frequency response* of the circuit since they are frequency-dependent functions that relate the sinusoidal steady-state input and output. The gain and phase functions can be expressed mathematically or

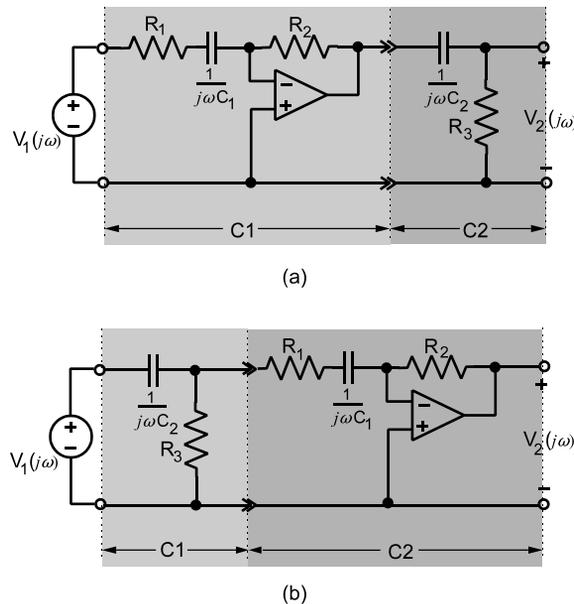

Fig. 102 Effects of stage location on loading.¹

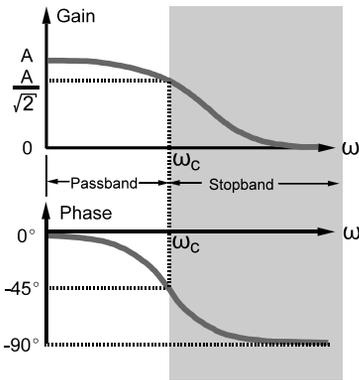

Fig. 103 Frequency response plots.¹

presented graphically as in Fig. 103, which shows an example frequency response plot called a Bode diagram. These diagrams can be constructed by hand but are readily and more accurately produced by simulation and mathematical software products.

The terminology used to describe the frequency response of circuits and systems is based on the form of the gain plot. For example, at high frequencies the gain in Fig. 103 falls off so that output signals in this frequency range are reduced in amplitude. The range of frequencies over which the output is significantly attenuated is called the *stopband*. At low frequencies the gain is essentially constant and there is relatively little attenuation. The frequency range over which there is little attenuation is called a *passband*. The frequency associated with the boundary between a passband and an adjacent stopband is called the *cutoff frequency* ($\omega_c = 2\pi f_c$). In general, the transition from the passband to the stopband is gradual so the precise location of the cutoff frequency is a matter of definition. The most widely used definition specifies the cutoff frequency to be the frequency at which the gain has decreased by a factor of $1/\sqrt{2} = 0.707$ from its maximum value in the passband.

Again this definition is arbitrary, since there is no sharp boundary between a passband and an adjacent stopband. However, the definition is motivated by the fact that the power delivered to a resistance by a sinusoidal current or voltage waveform is proportional to the square of its amplitude. At a cutoff frequency the gain is reduced by a factor of $1/\sqrt{2}$ and the square of the output amplitude is reduced by a factor of $\frac{1}{2}$. For this reason the cutoff frequency is also called the *half-power frequency*. In filter design the region from where the output amplitude is reduced by 0.707 and a second frequency wherein the output must have decayed to some specific value is called the transition region. This region is where much of the filter design attention is focused. How rapidly a filter transitions from the cutoff frequency to some necessary attenuation is what occupies much of the efforts of filter designers.

Additional frequency response descriptors are based on the four prototype gain characteristics shown in Fig. 104. A *low-pass* gain characteristic has a single passband extending from zero frequency (dc) to the cutoff frequency. A *high-pass* gain characteristic has a single passband extending from the cutoff frequency to infinite frequency. A *bandpass* gain has a single passband with two cutoff frequencies neither of which is zero or infinite. Finally, the *bandstop* gain has a single stopband with two cutoff frequencies neither of which is zero or infinite.

The *bandwidth* of a gain characteristic is defined as the frequency range spanned by its passband. The bandwidth (BW) of a low-pass circuit is equal to its cutoff frequency ($BW = \omega_c$). The bandwidth of a high-pass characteristic is infinite since its passband extends to infinity. For the bandpass and bandstop cases in Fig. 104 the bandwidth is the difference in the two cutoff frequencies:

$$BW = \omega_{c2} - \omega_{c1} \tag{126}$$

For the bandstop case Eq. (126) defines the width of the stopband rather than the passband.

The gain responses in Fig. 104 have different characteristics at zero and infinite frequency:

Prototype	Gain at $\omega = 0$	Gain at $\omega = \infty$
Low pass	Finite	0
High pass	0	Finite
Bandpass	0	0
Bandstop	Finite	Finite

Since these extreme values form a unique pattern, the type of gain response can be inferred from the values of $|H(0)|$ and $|H(\infty)|$. These endpoint values in turn are usually determined by the impedance of capacitors and inductors in the circuit. In the sinusoidal steady state the impedances of these elements are

$$Z_C(j\omega) = \frac{1}{j\omega C} \quad \text{and} \quad Z_L(j\omega) = j\omega L$$

These impedances vary with respect to frequency. An inductor's impedance increases linearly with increasing frequency, while that of a capacitor varies inversely with frequency. They form a unique pattern at zero and infinite frequency:

Element	Impedance (Ω) at $\omega = 0$ (dc)	Impedance (Ω) at $\omega = \infty$
Capacitor ($1/j\omega C$)	Infinite (open circuit)	0 (short circuit)
Inductor ($j\omega L$)	0 (short circuit)	Infinite (open circuit)
Resistor (R)	R	R

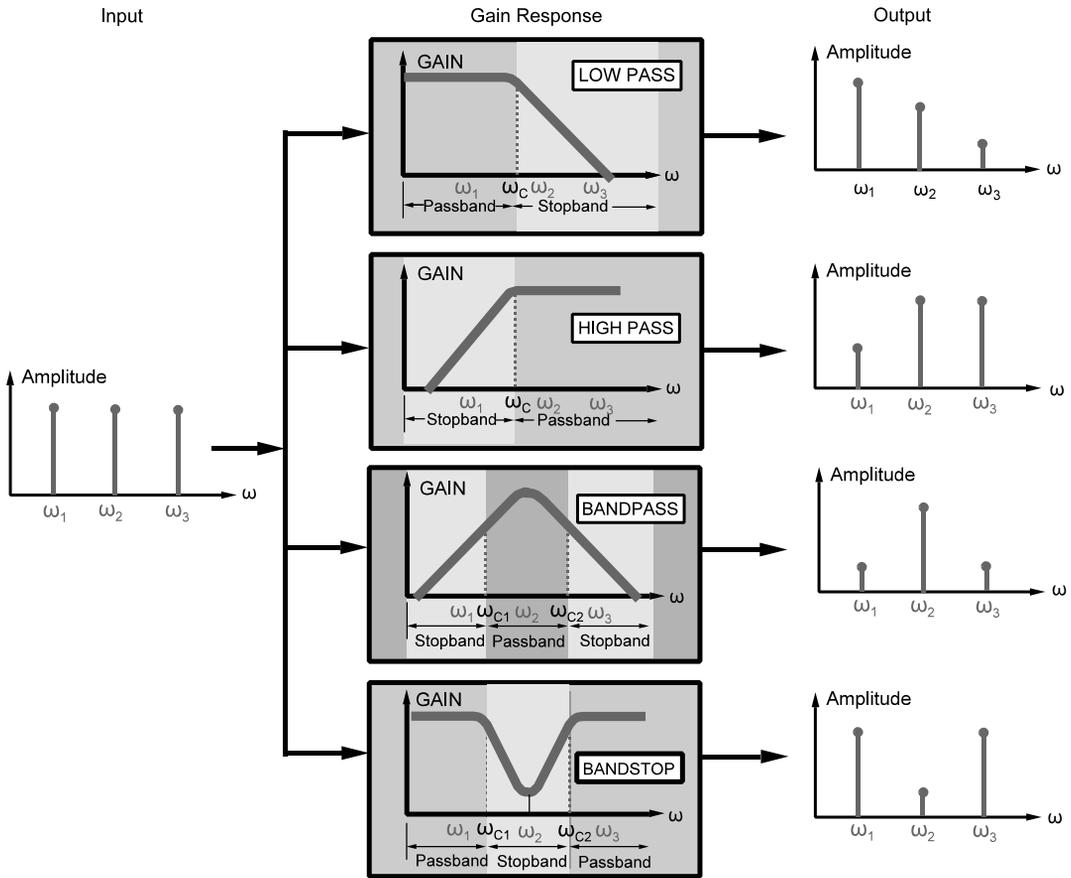

Fig. 104 Four basic gain responses.¹

These observations often allow one to infer the type of gain response and hence the type of filter directly from the circuit itself without finding the transfer functions.

Frequency response plots are almost always made using logarithmic scales for the frequency variable. The reason is that the frequency ranges of interest often span several orders of magnitude. A logarithmic frequency scale compresses the data range and highlights important features in the gain and phase responses. The use of a logarithmic frequency scale involves some special terminology. Any frequency range whose endpoints have a 2 : 1 ratio is called an *octave*. Any range whose endpoints have a 10 : 1 ratio is called a *decade*. For example, the frequency range from 10 to 20 Hz is one octave, as is the range from 20 to 40 MHz. The standard UHF (ultrahigh frequency) band spans one decade from 0.3 to 3 GHz.

In frequency response plots the gain $|H(j\omega)|$ is often expressed in *decibels* (dB), defined as

$$|H(j\omega)|_{\text{dB}} = 20 \log_{10} |H(j\omega)|$$

The gain in decibels can be positive, negative, or zero. A gain of 0 dB means that $|H(j\omega)| = 1$; that is, the input and output amplitudes are equal. Positive decibel gains mean the output amplitude exceeds the input since $|H(j\omega)| > 1$ and the circuit is said to *amplify* the signal. A negative decibel gain means the output amplitude is smaller than the input since $|H(j\omega)| < 1$ and the circuit is said to *attenuate* the signal. A cutoff frequency occurs when the gain is reduced from its maximum passband value by a factor $1/\sqrt{2}$ or 3 dB. For this reason the cutoff is also called the *3-dB down frequency*.

6.4 First-Order Frequency Response and Filter Design

Frequency-selective circuits are fundamental to all types of systems. First-order filters are simple to design and can be effective for many common applications.

First-Order Low-Pass Response A first-order low-pass transfer function can be written as

$$H(j\omega) = \frac{K}{j\omega + \alpha}$$

The constants K and α are real. The constant K can be positive or negative, but α must be positive so that the natural response of the circuit is stable.

The gain and phase functions are given as

$$|H(j\omega)| = \frac{|K|}{\sqrt{\omega^2 + \alpha^2}} \quad (127)$$

$$\angle H(j\omega) = \angle K - \tan^{-1}(\omega/\alpha)$$

The gain function is a positive number. Since K is real, the angle of K ($\angle K$) is either 0° when $K > 0$ or $\pm 180^\circ$ when $K < 0$. An example of a negative K occurs in an inverting op amp configuration where $H(j\omega) = -Z_2(j\omega)/Z_1(j\omega)$.

Figure 105 shows the gain and phase functions versus normalized frequency ω_c/α . The maximum passband gain occurs at $\omega = 0$ where $|H(0)| = |K|/\alpha$. As frequency increases, the gain gradually decreases until at $\omega = \alpha$:

$$|H(j\alpha)| = \frac{|K|}{\sqrt{\alpha^2 + \alpha^2}} = \frac{|K|}{\sqrt{2}} \rightarrow \alpha = \frac{|H(0)|}{\sqrt{2}}$$

That is, the cutoff frequency of the first-order low-pass transfer function is $\omega_c = \alpha$. The graph of the gain function in Fig. 105a displays a low-pass characteristic with a finite dc gain and zero infinite frequency gain.

The low- and high-frequency gain asymptotes shown in Fig. 105a are especially important. The

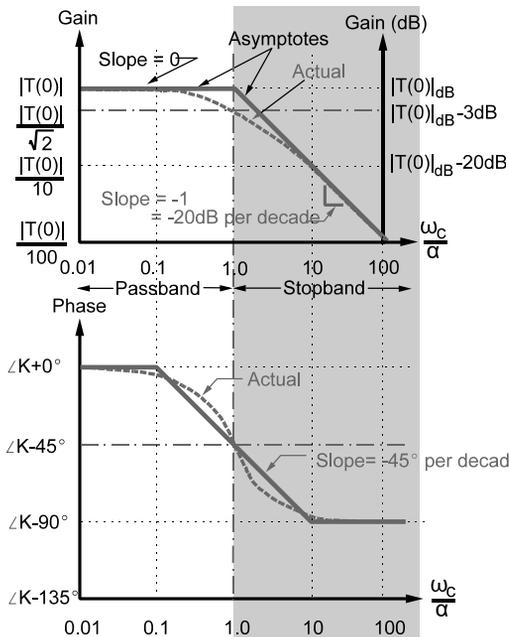

Fig. 105 First-order low-pass Bode plots.¹

low-frequency asymptote is the horizontal line and the high-frequency asymptote is the sloped line. At low frequencies ($\omega \ll \alpha$) the gain approaches $|H(j\omega)| \rightarrow |K|/\alpha$. At high frequencies ($\omega \gg \alpha$) the gain approaches $|H(j\omega)| \rightarrow |K|/\omega$. The intersection of the two asymptotes occurs when $|K|/\alpha = |K|/\omega$. The intersection forms a “corner” at $\omega = \alpha$, so the cutoff frequency is also called the *corner frequency*.

The high-frequency gain asymptote decreases by a factor of 10 (-20 dB) whenever the frequency increases by a factor of 10 (one decade). As a result the high-frequency asymptote has a slope of -1 or -20 dB/decade and the low-frequency asymptote has a slope of 0 or 0 dB/decade. These two asymptotes provide a straight-line approximation to the gain response that differs from the true response by a maximum of 3 dB at the corner frequency.

The semilog plot of the phase shift of the first-order low-pass transfer function is shown in Fig. 105b. At $\omega = \alpha$ the phase angle in Eq. (127) is $\angle K - 45^\circ$. At low frequency ($\omega < \alpha$) the phase angle approaches $\angle K$ and at high frequencies ($\omega > \alpha$) the phase approaches $\angle K - 90^\circ$. Almost all of the -90° phase change occurs in the two-decade range from $\omega/\alpha = 0.1$ to $\omega/\alpha = 10$. The straight-line segments in Fig. 105b provide an approximation of the phase response. The phase approximation below $\omega/\alpha = 0.1$ is $\theta = \angle K$ and above $\omega/\alpha = 10$ is $H\angle\theta = \angle K - 90^\circ$. Between these values the phase approximation is a straight line that begins at $H\angle\theta = \angle K$, passes through $H\angle\theta = \angle K - 45^\circ$ at the cutoff frequency, and reaches $H\angle\theta = \angle K - 90^\circ$ at $\omega/\alpha = 10$. The slope of this line segment is -45° /decade since the total phase change is -90° over a two-decade range.

To construct the *straight-line approximations* for a first-order low-pass transfer function, two parameters are needed, the value of $H(0)$ and α . The parameter α defines the cutoff frequency and the value of $H(0)$ defines the passband gain $|H(0)|$ and the low-frequency phase $\angle H(0)$. The required quantities $H(0)$ and α can be determined directly from the transfer function $H(j\omega)$ and can often be estimated by inspecting the circuit itself.

Example 33. Design a low-pass filter with a passband gain of 4 and a cutoff frequency of 100 rad/sec.

Solution. See Fig. 106. Start with an inverting amplifier configuration since a gain is required:

$$H(j\omega) = -\frac{Z_2(j\omega)}{Z_1(j\omega)}$$

$$Z_1(j\omega) = R_1 \quad \text{and}$$

$$Z_2(j\omega) = \frac{1}{j\omega C_2 + 1/R_2} = \frac{R_2}{R_2 C_2 j\omega + 1}$$

$$H(j\omega) = -\frac{R_2}{R_1} \times \frac{1}{R_2 C_2 j\omega + 1}$$

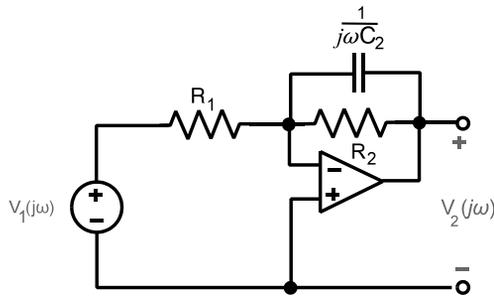

Fig. 106 (From Ref. 1.)

Rearrange the standard low-pass form as

$$H(j\omega) = \frac{K/\alpha}{j\omega/\alpha + 1}$$

$$\omega_C = \alpha = \frac{1}{R_2 C_2} \quad \text{and} \quad H(0) = -\frac{R_2}{R_1}$$

The design constraints require that $\omega_C = 1/R_2 C_2 = 100$ and $|H(0)| = R_2/R_1 = 4$. Selecting $R_1 = 10 \text{ k}\Omega$ requires $R_2 = 40 \text{ k}\Omega$ and $C = 250 \text{ nF}$.

First-Order High-Pass Response A first-order high-pass transfer function is written as

$$H(j\omega) = \frac{Kj\omega}{j\omega + \alpha}$$

The high-pass function differs from the low pass case by the introduction of a $j\omega$ in the numerator, resulting in the function becoming zero at $\omega = 0$. Solving for the gain and phase functions yields

$$|H(j\omega)| = \frac{|K|\omega}{\sqrt{\omega^2 + \alpha^2}}$$

$$\angle H(j\omega) = \angle K + 90^\circ - \tan^{-1}\left(\frac{\omega}{\alpha}\right) \quad (128)$$

Figure 107 shows the gain and phase functions versus normalized frequency ω/α . The maximum gain occurs at high frequency ($\omega > \alpha$) where $|H(j\omega)| \approx |K|$. At low frequency ($\omega < \alpha$) the gain approaches $|K|\omega/\alpha$. At $\omega = \alpha$ the gain is

$$|H(j\alpha)| = \frac{|K|\alpha}{\sqrt{\alpha^2 + \alpha^2}} = \frac{|K|}{\sqrt{2}}$$

which means the cutoff frequency is $\omega_C = \alpha$. The gain response plot in Fig. 107a displays a high-pass characteristic with a passband extending from $\omega = \alpha$ to infinity and a stopband between zero frequency and $\omega = \alpha$.

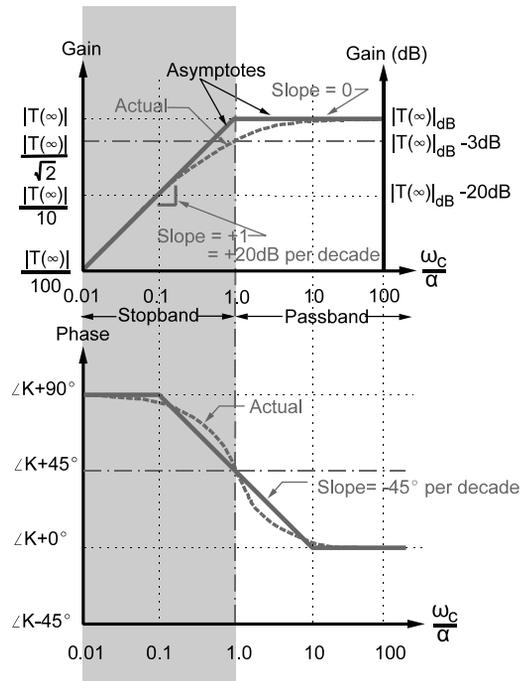

Fig. 107 First-order high-pass Bode plots.¹

The low- and high-frequency gain asymptotes approximate the gain response in Fig. 107a. The high-frequency asymptote ($\omega > \alpha$) is the horizontal line whose ordinate is $|K|$ (slope = 0 or 0 dB/decade). The low-frequency asymptote ($\omega < \alpha$) is a line of the form $|K|\omega/\alpha$ (slope = +1 or +20 dB/decade). The intersection of these two asymptotes occurs when $|K|\omega/\alpha = |K|$, which define a corner frequency at $\omega = \alpha$.

The semilog plot of the phase shift of the first-order high-pass function is shown in Fig. 107b. The phase shift approaches $\angle K$ at high frequency, passes through $\angle K + 45^\circ$ at the cutoff frequency, and approaches $\angle K + 90^\circ$ at low frequency. Most of the 90° phase change occurs over the two-decade range centered on the cutoff frequency. The phase shift can be approximated by the straight-line segments shown in the Fig. 107b. As in the low-pass case, $\angle K$ is 0° when K is positive and $\pm 180^\circ$ when K is negative.

Like the low-pass function, the first-order high-pass frequency response can be approximated by straight-line segments. To construct these lines, we need two parameters, $H(\infty)$, and α . The parameter α define the cutoff frequency and the quantity $H(\infty)$ gives the passband gain $|H(\infty)|$ and the high-frequency phase angle $\angle H(\infty)$. The quantities $H(\infty)$ and α can be determined directly from the transfer function or estimated directly from the circuit in some cases. The straight line shows the first-order high-pass response

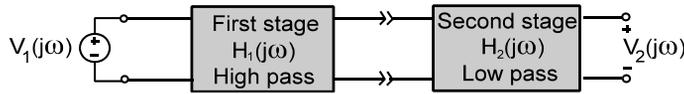

Fig. 108 Cascade connection of high- and low-pass circuits.¹

can be characterized by calculating the gain and phase over a two-decade band from one decade below to one decade above the cutoff frequency.

Bandpass and Bandstop Responses Using First-Order Circuits The first-order high- and low-pass circuits can be used in a building block fashion to produce a circuit with bandpass and bandstop responses. Figure 108 shows a cascade connection of first-order high- and low-pass circuits. When the second stage does not load the first, the overall transfer function can be found by the chain rule:

$$H(j\omega) = H_1(j\omega) \times H_2(j\omega)$$

$$= \underbrace{\left(\frac{K_1 j\omega}{j\omega + \alpha_1}\right)}_{\text{high pass}} \underbrace{\left(\frac{K_2}{j\omega + \alpha_2}\right)}_{\text{low pass}}$$

Solving for the gain response yields

$$|H(j\omega)| = \underbrace{\left(\frac{|K_1|\omega}{\sqrt{\omega^2 + \alpha_1^2}}\right)}_{\text{high pass}} \underbrace{\left(\frac{|K_2|}{\sqrt{\omega^2 + \alpha_2^2}}\right)}_{\text{low pass}}$$

Note the gain of the cascade is zero at $\omega = 0$ and at infinite frequency.

When $\alpha_1 < \alpha_2$ the high-pass cutoff frequency is much lower than the low-pass cutoff frequency, and the overall transfer function has a bandpass characteristic. At low frequencies ($\omega < \alpha_1 < \alpha_2$) the gain approaches $|H(j\omega)| \rightarrow |K_1 K_2| \omega / \alpha_1 \alpha_2$. At midfrequencies ($\alpha_1 < \omega < \alpha_2$) the gain approaches $|H(j\omega)| \rightarrow |K_1 K_2| / \alpha_2$. The low- and midfrequency asymptotes intersect when $|K_1 K_2| \omega / \alpha_1 \alpha_2 = |K_1 K_2| / \alpha_2$ at $\omega = \alpha_1$, that is, at the cutoff frequency of the high-pass stage. At high frequencies ($\alpha_1 < \alpha_2 < \omega$) the gain approaches $|H(j\omega)| \rightarrow |K_1 K_2| / \omega$. The high- and midfrequency asymptotes intersect when $|K_1 K_2| / \omega = |K_1 K_2| / \alpha_2$ at $\omega = \alpha_2$, that is, at the cutoff frequency of the low-pass stage. The plot of these asymptotes in Fig. 109 shows that the asymptotic gain exhibits a passband between α_1 and α_2 . Input sinusoids whose frequencies are outside of this range fall in one of the two stopbands.

In the bandpass cascade connection the input signal must pass both a low- and a high-pass stage to reach the output. In the parallel connection in Fig. 110 the

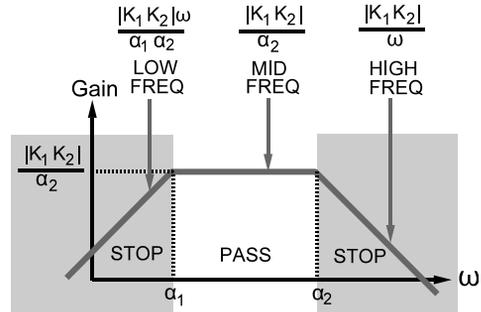

Fig. 109 Bandpass gain characteristic.¹

input can reach the output via either a low- or a high-pass path. The overall transfer function is the sum of the low- and high-pass transfer functions:

$$|H(j\omega)| = \underbrace{\left(\frac{|K_1|\omega}{\sqrt{\omega^2 + \alpha_1^2}}\right)}_{\text{high pass}} + \underbrace{\left(\frac{|K_2|}{\sqrt{\omega^2 + \alpha_2^2}}\right)}_{\text{low pass}}$$

Any sinusoid whose frequency falls in either passband will find its way to the output unscathed. An input sinusoid whose frequency falls in both stopbands will be attenuated.

When $\alpha_1 > \alpha_2$, the high-pass cutoff frequency is much higher than the low-pass cutoff frequency, and the overall transfer function has a bandstop gain response as shown in Fig. 111. At low frequencies ($\omega < \alpha_2 < \alpha_1$) the gain of the high-pass function is negligible and the overall gain approaches $|H(j\omega)| \rightarrow |K_2| / \alpha_2$, which is the passband gain of the low-pass function. At high frequencies ($\alpha_2 < \alpha_1 < \omega$) the low-pass function is negligible and the overall gain approaches $|H(j\omega)| \rightarrow |K_1|$, which is the passband gain of the high-pass function. With a bandstop function the two passbands normally have the same gain, hence $|K_1| = |K_2| / \alpha_2$. Between these two passbands there is a stopband. For $\omega > \alpha_2$ the low-pass asymptote is $|K_2| / \omega$, and for $\omega < \alpha_1$ the high-pass asymptote is $|K_1| \omega / \alpha_1$. The asymptotes intersect at $\omega^2 = \alpha_1 |K_2| / |K_1|$. But equal gains in the two passband frequencies requires $|K_1| = |K_2| / \alpha_2$, so the intersection frequency is $\omega = \sqrt{\alpha_1 \alpha_2}$. Below this frequency the stopband attenuation is determined by the low-pass

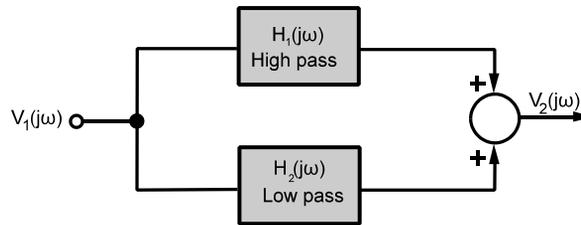

Fig. 110 Parallel connection of high- and low-pass circuits.¹

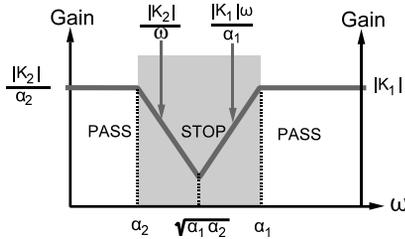

Fig. 111 Bandstop gain characteristic.¹

function and above this frequency the attenuation is governed by the high-pass function.

Analysis of the transfer functions illustrates that the asymptotic gain plots of the first-order functions can help one understand and describe other types of gain response. The asymptotic response in Figs. 109 and 111 are a reasonably good approximation as long as the two first-order cutoff frequencies are widely separated. The asymptotic analysis gives insight to see that to study the passband and stopband characteristics in greater detail one needs to calculate gain and phase responses on a frequency range from a decade below the lowest cutoff frequency to a decade above the highest. This frequency range could be very wide, since the two cutoff frequencies may be separated by several decades. Mathematical and simulation software packages can produce very accurate frequency response plots.

Example 34. Design a first-order bandpass circuit with a passband gain of 10 and cutoff frequencies at 20 Hz and 20 kHz.

Solution. A cascade connection of first-order low- and high-pass building blocks will satisfy the design. The required transfer function has the form

$$H(j\omega) = H_1(j\omega) \times H_2(j\omega) = \underbrace{\left(\frac{K_1 j\omega}{j\omega + \alpha_1}\right)}_{\text{high pass}} \underbrace{\left(\frac{K_2}{j\omega + \alpha_2}\right)}_{\text{low pass}}$$

with the following constraints:

$$\begin{aligned} \text{Lower cutoff frequency: } \alpha_1 &= 2\pi(20) = 40\pi \text{ rad/s} \\ \text{Upper cutoff frequency: } \alpha_2 &= 2\pi(20 \times 10^3) = 4\pi \times 10^4 \text{ rad/s} \\ \text{Midband gain: } \frac{|K_1 K_2|}{\alpha_2} &= 10 \end{aligned}$$

With numerical values inserted, the required transfer function is

$$H(j\omega) = \underbrace{\left[\frac{j\omega}{j\omega + 40\pi}\right]}_{\text{high pass}} \underbrace{[10]}_{\text{gain}} \underbrace{\left[\frac{40\pi \times 10^4}{j\omega + 40\pi \times 10^4}\right]}_{\text{low pass}}$$

This transfer function can be realized using the high-pass/low-pass cascade circuit in Fig. 112. The first stage is a passive RC high-pass circuit and the third stage is a passive RL low-pass circuit. The noninverting op amp second stage serves two purposes: (a) It isolates the first and third stages, so the chain rule applies, and (b) it supplies the midband gain. Using the chain rule, the transfer function of this circuit is

$$H(j\omega) = \underbrace{\left[\frac{j\omega}{j\omega + 1/RC}\right]}_{\text{high pass}} \underbrace{\left[\frac{R_1 + R_2}{R_1}\right]}_{\text{gain}} \underbrace{\left[\frac{R/L}{j\omega + R/L}\right]}_{\text{low pass}}$$

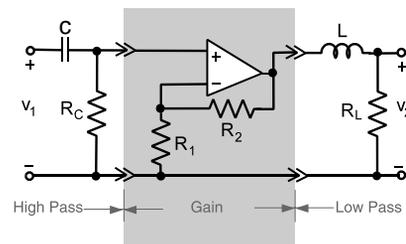

Fig. 112 (From Ref. 1.)

Comparing this to the required transfer function leads to the following design constraints:

High-Pass Stage: $R_C C = 1/40\pi$. Let $R_C = 100 \text{ k}\Omega$. Then $C = 79.6 \text{ nF}$.

Gain Stage: $(R_1 + R_2)/R_1 = 10$. Let $R_1 = 10 \text{ k}\Omega$. Then $R_2 = 90 \text{ k}\Omega$.

Low-Pass Stage: $R_L/L = 40000\pi$. Let $R_L = 200 \text{ k}\Omega$. Then $L = 0.628 \text{ H}$.

6.5 Second-Order RLC Filters

Simple second-order low-pass, high-pass, or band pass filter can be made using series or parallel RLC circuits. Series or parallel RLC circuits can be connected to produce the following transfer functions:

$$\begin{aligned}
 H(j\omega)_{LP} &= \frac{K}{-\omega^2 + 2\zeta\omega_0 j\omega + \omega_0^2} \\
 H(j\omega)_{HP} &= \frac{-K\omega^2}{-\omega^2 + 2\zeta\omega_0 j\omega + \omega_0^2} \\
 H(j\omega)_{BP} &= \frac{Kj\omega}{-\omega^2 + 2\zeta\omega_0 j\omega + \omega_0^2}
 \end{aligned}
 \tag{129}$$

where for a series RLC circuit

$$\omega_0 = \sqrt{LC} \quad \text{and} \quad \zeta = \frac{R}{2}\sqrt{\frac{C}{L}}$$

The undamped natural frequency ω_0 is related to the cutoff frequency in the high- and low-pass cases and is the center frequency in the band pass case. Zeta (ζ) is the damping ratio and determines the nature of the roots of the equation that translates to how quickly a transition is made from the passband to the stopband. In the band pass case ζ helps define the bandwidth of the circuit, that is, $B = 2\zeta\omega_0$. Figure 113 shows how a series RLC circuit can be connected to achieve the transfer functions given in Eq. (129). The gain $|H(j\omega)|$ plots of these circuits are shown in Figs. 114–116.

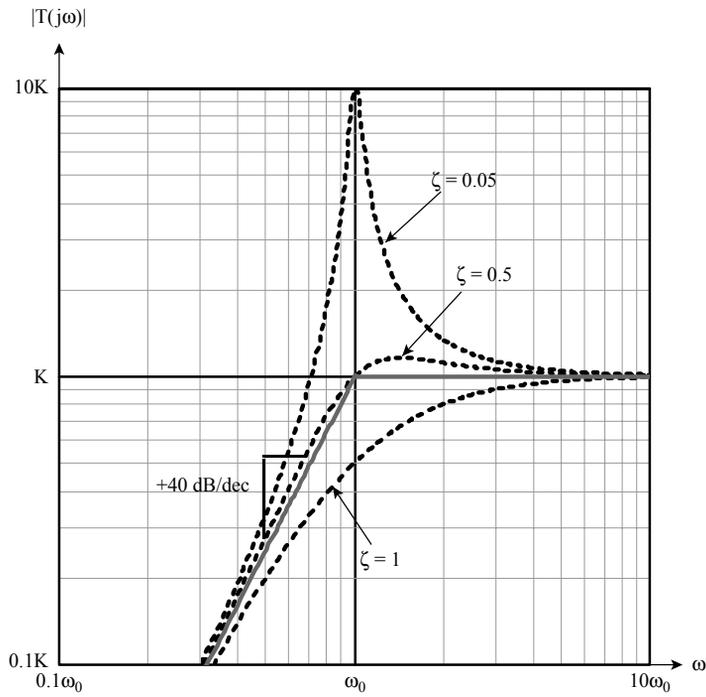

Fig. 115 Second-order high-pass gain responses.¹

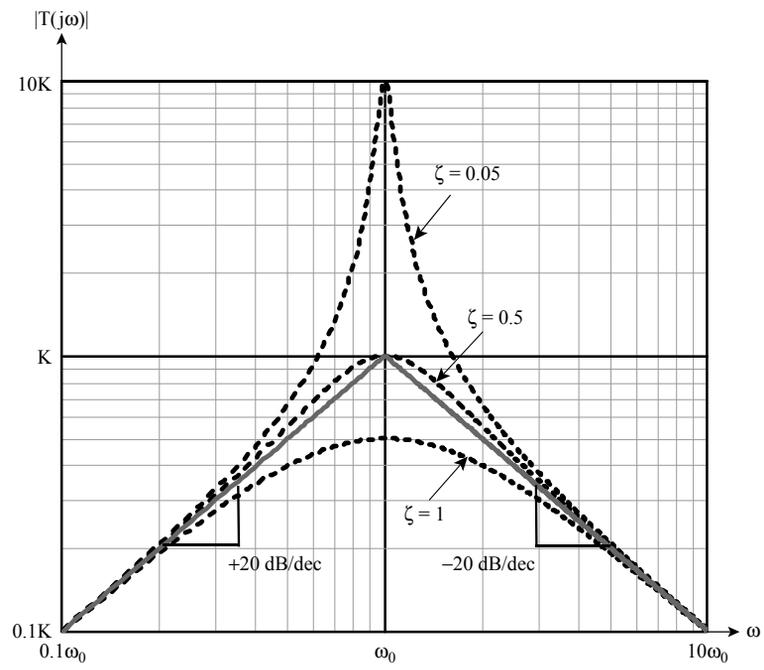

Fig. 116 Second-order bandpass gain responses.¹

6.6 Compound Filters

Compound filter are higher order filter obtained by cascading lower order designs. *Ladder circuits* are an important class of compound filters. Two of the more common passive ladder circuits are the *constant-k* and the *m-derived* filters either of which can be configure using a *T section*, *π section*, *L section* (Fig. 117), or combinations thereof, the bridge-T network and parallel-T network.

Active filters are generally designed using first-second-, or third-order modules such as the *Sallen–Key* configuration shown in Fig. 118a and b, and the *Delyannies–Friend* configuration shown in Fig. 118c and d. The filter are then developed using an algorithmic approach following the *Butterworth*, *elliptical*, or *Tchebycheff* realizations.

1 BIPOLAR TRANSISTORS

John D. Cressler

The basic concept of the bipolar junction transistor (BJT) was patented by Shockley in 1947¹, but

the BJT was not experimentally realized until 1951.² Unlike the point contact transistor demonstrated earlier in 1947, the BJT can be completely formed *inside* the semiconductor crystal, and thus it proved to be more manufacturable and reliable and better suited

for use in integrated circuits. In a real sense, the BJT was the device that launched the microelectronics revolution and, hence, spawned the *Information Age*. Until the widespread emergence of complementary metal–oxide–semiconductor (CMOS) technology in the 1980s, the BJT was the dominant semiconductor technology in microelectronics, and even today represents a significant fraction of the global semiconductor market.

At its most basic level the BJT consists of two back-to-back pn junctions ($p-n-p$ or $n-p-n$ depending on the doping polarity), in which the intermediate n or p region is made as thin as possible. In this configuration the resultant three-terminal (emitter–base–collector) device exhibits current amplification (current gain) and thus acts as a “transistor” that can be used to build a wide variety of electronic circuits. Modern applications of the BJT are varied and range from high-speed digital integrated circuits in mainframe computers, to precision analog circuits, to radio frequency (RF) circuits found in radio communications systems.

Compared to CMOS, the BJT exhibits higher output current per unit length, larger transconductance (g_m) per unit length, faster switching speeds (particularly under capacitive loading), and excellent properties for many analog and RF applications (e.g., lower $1/f$ and broadband noise). Today, frequency response above 50 GHz and circuit switching speeds below 20 ps are readily attainable using conventional fabrication techniques. The primary drawback of BJT circuits compared to CMOS circuits lies in their larger dc power dissipation and increased fabrication complexity, although in applications requiring the fastest possible switching speeds, the BJT remains the device of choice. Figure 1 shows unloaded emitter-coupled logic (ECL) gate delay for today’s technology

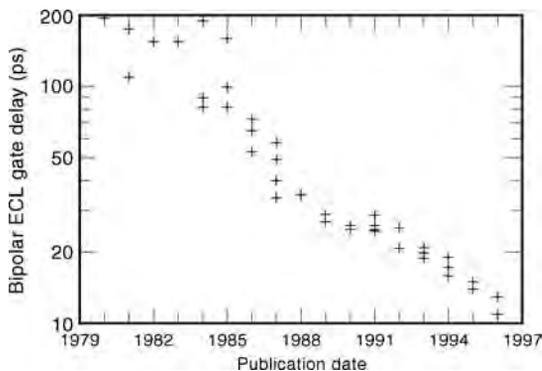

Fig. 1 Unloaded ECL gate delay (as function of publication date) showing rapid decrease in delay with technology evolution.

and indicates that state-of-the-art BJT technology is rapidly approaching 10 ps switching times.

In this section we review the essentials of modern bipolar technology, the operational principles of the BJT, second-order high-injection effects, issues associated with further technology advancements, and some future directions. Interested readers are referred to Refs. 3–5 for review articles on modern BJT technology, and to Ref. 6 for an interesting historical perspective on the development of the BJT.

1.1 Double-Polysilicon Bipolar Technology

In contrast to the depictions commonly found in many standard electronics textbooks, BJT technology has evolved radically in the past 15 years, from double-diffused, large geometry, non-self-aligned structures to very compact, self-aligned, “double-polysilicon” structures. Figure 2 shows a schematic cross section of a modern double-polysilicon BJT. This device has deep-trench and shallow-trench isolation to separate one transistor from the next, a p^+ polysilicon extrinsic base contact, an n^+ polysilicon emitter contact, and an ion-implanted intrinsic base region. The two polysilicon layers (hence the name *double-polysilicon*) act as both diffusion sources for the emitter and extrinsic base dopants as well as low-resistance contact layers. In addition, to form the active region of the transistor, a “hole” is etched into the p^+ polysilicon layer, and afterwards a thin dielectric “spacer” oxide is formed. In this manner, the emitter and extrinsic base regions are fabricated without the need of an additional lithography step (“self-aligned”), thereby dramatically reducing the size of the transistor and hence the associated parasitic resistances and capacitances of the structure. The first double-polysilicon BJT structures appeared in the early 1980s^{7,8} and today completely dominate the high-performance BJT technology market. The reader is referred to Refs. 9–15 for specific BJT technology examples in the recent literature.

The doping profile from the intrinsic region of a state-of-the-art double-polysilicon BJT is shown in Fig. 3. The transistor from which this doping profile was measured has a peak cutoff frequency of about 40 GHz¹⁴, and is typical of the state of the art. The emitter polysilicon layer is doped as heavily as possible with arsenic or phosphorus, and given a sort rapid-thermal-annealing (RTA) step to out-diffuse the dopants from the polysilicon layer. Typical metallurgical emitter–base junction depths range from 25 to 45 nm in modern BJT technologies. The collector region directly under the active region of the transistor is formed by local ion implantation of phosphorus. A collector doping of about $1 \times 10^{17} \text{ cm}^{-3}$ at the base–collector junction is adequate to obtain a peak cutoff frequency of 40 GHz at a collector-to-emitter breakdown voltage (BV_{CEO}) of about 3.5 V, consistent with the needs of digital ECL circuits. The intrinsic

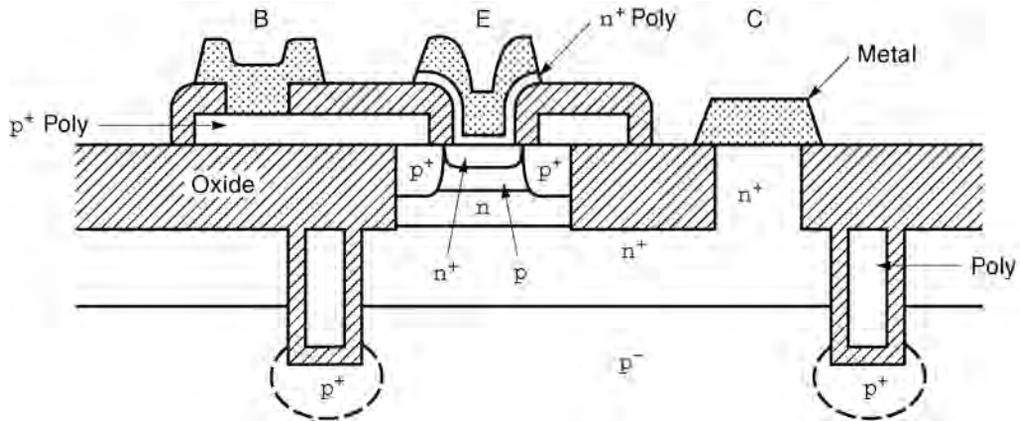

Fig. 2 Schematic device cross section of modern double-polysilicon self-aligned bipolar transistor.

base region is also formed by low-energy ion implantation of boron. Resultant base widths range from about 60 to 150 nm at the state of the art, with peak base doping levels in the range of $3\text{--}5 \times 10^{18} \text{ cm}^{-3}$. A traditional (measurable) metric describing the base profile in a BJT is the intrinsic base sheet resistance (R_{bi}), which can be written in terms of the integrated base

doping (N_{ab}) according to

$$R_{bi} = \left[q \int_0^{W_b} \mu_{pb}(x) N_{ab}(x) dx \right]^{-1} \quad (1)$$

In Eq. (1), μ_{pb} is the position-dependent hole mobility in the base and W_b is the neutral base width. Typical

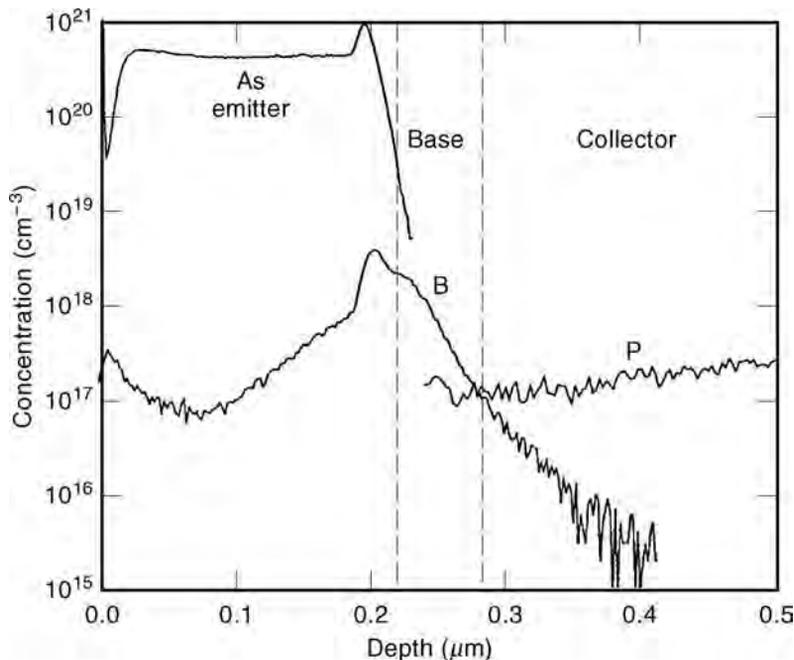

Fig. 3 Measured secondary ion mass spectroscopy (SIMS) doping profile from ion-implanted base bipolar technology with 40-GHz peak cutoff frequency.¹⁴

R_{bi} values in modern BJT technologies range from 10 to 15 kW/f.

1.2 Theory of Operation

Basic Physics The BJT is in essence a barrier-controlled device. A voltage bias is applied to the emitter–base junction such that we modulate the size of the potential barrier seen by the electrons moving from emitter to base, and thus can (exponentially) modulate the current flowin through the transistor. To best illustrate this process, we have used a one-dimensional device simulator called SCORPIO.¹⁶ SCORPIO is known as a “drift diffusion” simulator because it solves the electron and hole drift diffusion transport equations self-consistently with Poisson’s equation and the electron and hole current-continuity equations (see, e.g., Ref. 6 for a formulation of these equations and the inherent assumptions on their use). These five equations, together with the appropriate boundary conditions completely describe the BJT.

Figure 4 depicts a “toy” doping profil of the ideal BJT being simulated. Both the layer thicknesses and doping levels are consistent with those found in modern BJTs, although the constancy of the doping profil in each region is idealized and hence unrealistic. Figure 5 shows the resultant electron energy band diagram of this device at zero bias (equilibrium). The base potential barrier seen by the electrons in the emitter is clearly evident. The equilibrium carrier concentrations for each region are shown in Fig. 6. The majority carrier densities are simply given by the doping level in each region, while the minority carrier densities are obtained by use of the “law of mass action” according to the following:

$$p_{e0} = \frac{n_{ie}^2}{N_{de}} \quad n_{e0} = N_{de} \quad (\text{emitter}) \quad (2)$$

$$p_{b0} = N_{ab} \quad n_{b0} = \frac{n_{ib}^2}{N_{ab}} \quad (\text{base}) \quad (3)$$

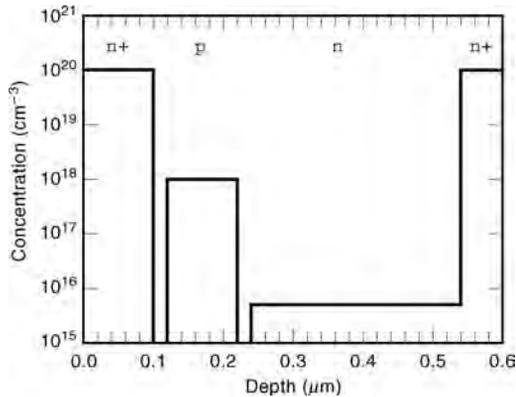

Fig. 4 Doping profile of hypothetical bipolar transistor used in one-dimensional SCORPIO simulations.

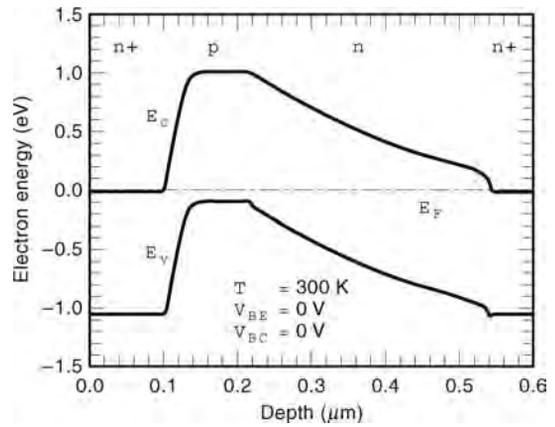

Fig. 5 Simulated zero-bias energy band diagram of hypothetical bipolar transistor depicted in Fig. 4.

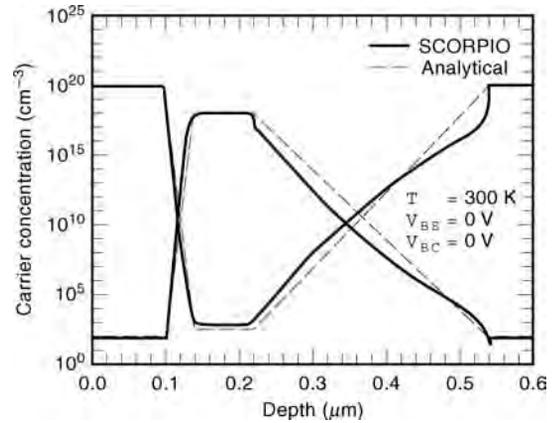

Fig. 6 Simulated electron and hole concentrations of hypothetical bipolar transistor depicted in Fig. 4. Also shown are analytical calculations.

$$p_{c0} = \frac{n_{i0}^2}{N_{dc}} \quad n_{c0} = N_{dc} \quad (\text{collector}) \quad (4)$$

where n_{i0} is the intrinsic carrier density, the subscripts e , b , and c represent the emitter, base, and collector regions, respectively, N is the doping density, and,

$$n_{ie}^2 = n_{i0}^2 e^{\Delta E_{ge}^{\text{app}}/kT} = N_C N_V e^{-E_g/kT} e^{\Delta E_{ge}^{\text{app}}/kT} \quad (5)$$

$$n_{ib}^2 = n_{i0}^2 e^{\Delta E_{gb}^{\text{app}}/kT} = N_C N_V e^{-E_g/kT} e^{\Delta E_{gb}^{\text{app}}/kT} \quad (6)$$

where $\Delta E_{ge}^{\text{app}}$ and $\Delta E_{gb}^{\text{app}}$ represent the heavy-doping-induced apparent bandgap narrowing.¹⁷ The resultant

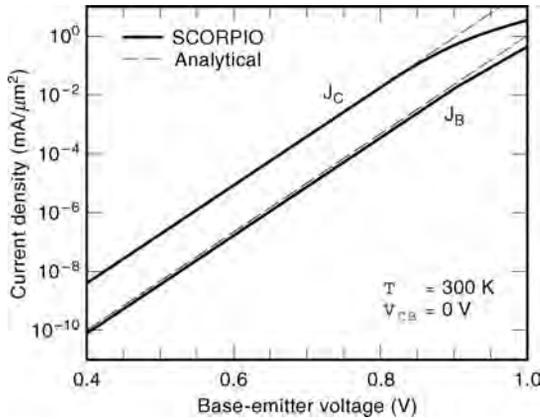

Fig. 7 Simulated collector and base current densities as function of emitter–base bias. Also shown are analytical calculations.

collector current density (J_C) and base current density (J_B) from this structure are shown in Fig. 7. Observe that the BJT exhibits useful current gain ($\beta = J_C/J_B$) over a wide operating range.

The basic operational principles of the BJT can be described as follows. If we imagine forward biasing the emitter–base junction, and reverse biasing the base–collector junction (i.e., forward-active mode), electrons from the heavily doped emitter are injected into and diffuse across the base region and are collected at the collector contact, thereby giving rise to a useful collector current. At the same time, if the base region is thin enough, the base current consists primarily of the back-injected hole current from base to emitter. Because the emitter is doped heavily with respect to the base, the ratio of forward-injected (emitter-to-base) electron current to back-injected (base to emitter) hole current is large (roughly equal to the ratio of emitter-to-base doping), and the BJT exhibits useful current gain. It is critical that the intermediate base region be kept as thin as possible because (a) we do not want electrons traversing the base to have sufficient time to recombine with holes before they reach the collector contact, and (b) the transit time of the electrons through the base typically limits the frequency response and, hence, the speed of the transistor. In the forward-active mode, a schematic representation of the magnitude of the various currents flowing in an ideal BJT is illustrated in Fig. 8.⁶

Current–Voltage Characteristics For simplicity, we will limit this discussion to the currents flowing in the BJT under forward-active bias. Other bias regimes (e.g., saturation) are not typically encountered in high-speed circuits such as ECL. The reader is referred to Refs. 17–19 for a discussion of other operating regimes. In this case, for a BJT with a position-dependent base doping profile the collector current

density can be expressed as²⁰

$$J_C = \frac{q[e^{qV_{BE}/kT} - 1]}{\int_0^{W_b} \frac{N_{ab}(x) dx}{D_{nb}(x)n_{ib}^2(x)}} \quad (7)$$

We see then that the collector current density in a BJT depends on the details of the base doping profile [more specifically the integrated base charge, and, hence, R_{bi} given in Eq. (1)]. The base current density can be obtained in a similar manner, except that the physics of the polysilicon emitter contact must be properly accounted for.^{21,22} For the “transparent emitter domain” in which the holes injected from the base to emitter do not recombine before reaching the emitter contact, the base current density can be written as

$$J_B = \frac{q[e^{qV_{BE}/kT} - 1]}{\int_0^{W_e} \frac{N_{de}(x) dx}{D_{pe}(x)n_{ie}^2} + \frac{N_{de}(W_e)}{S_{pe}n_{ie}^2(W_e)}} \quad (8)$$

where S_{pe} is the “surface recombination velocity” characterizing the polysilicon emitter contact.²¹ More detailed base current density expressions can be found in Refs. 21 and 22. Observe that in this transparent domain, the base current density depends on the specifics of the emitter doping profile as well as the influence of the polysilicon emitter contact.

For position-independent base and emitter doping profiles with no polysilicon emitter contact, Eqs. (8) simplify to their familiar forms:

$$J_C \cong \left[\frac{qD_{nb}n_{ib}^2}{W_bN_{ab}} \right] e^{qV_{BE}/kT} \quad (9)$$

$$J_B \cong \left[\frac{qD_{pe}n_{ie}^2}{L_{pe}N_{de}} \right] e^{qV_{BE}/kT} \quad (10)$$

from which the ideal BJT current gain can be obtained

$$\beta \cong \frac{D_{nb}L_{pe}N_{de}}{D_{pe}W_bN_{ab}} e^{(\Delta E_{gb}^{app} - \Delta E_{gb}^{app})/kT} \propto \frac{N_{de}}{N_{ab}} \quad (11)$$

Thus, the current gain of the BJT depends on the ratio of emitter-to-base doping level. Given this fact, it is not surprising that the actual ratio of emitter-to-base doping level is typically found to be 100 (refer to Fig. 4), a common value for β in modern technologies. Note as well, however, from Eq. (11) that the ideal current gain in a BJT is reduced by the exponential dependence of the heavy-doping-induced bandgap narrowing parameters (the exponent is negative because the emitter is more heavily doped than the base). This latter dependence is also responsible for determining the temperature dependence of β in a BJT.

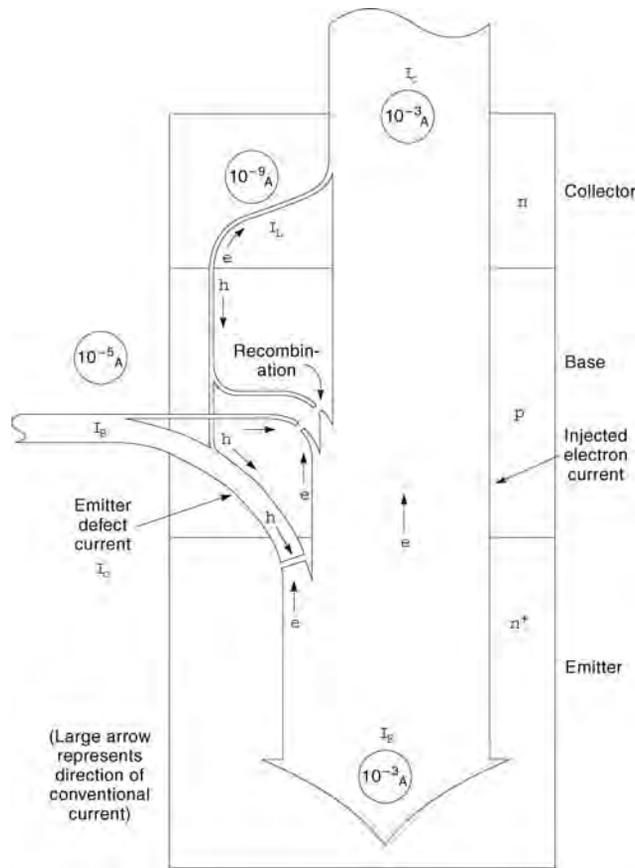

Fig. 8 Schematic current flow distributions in realistic bipolar transistor.

If one compares the measured I - V characteristics of a BJT with those expected from Eqs. (9)–(11), substantial deviations are typically observed, as depicted schematically in Figs. 9 and 10 (the dashed lines represent the ideal results). Referring to Fig. 9, at low current levels, base current nonideality is the result of emitter–base space-charge region recombination effects; at high current levels, the deviations are the result of various “high-injection” effects (discussed in what follows). Only over an intermediate bias range are ideal characteristics usually observed. Figure 11 shows typical measured I - V characteristics (a so-called Gummel plot) from the same 40-GHz profil depicted in Fig. 3.¹⁴ The inset of Fig. 3 shows the linear “output characteristics” of the BJT. The shape and doping level of the collector profil controls the breakdown characteristics of the device. In this case, the collector-to-emitter breakdown voltage (BV_{CEO}) is approximately 3.3 V, typical for a high-performance digital BJT technology.

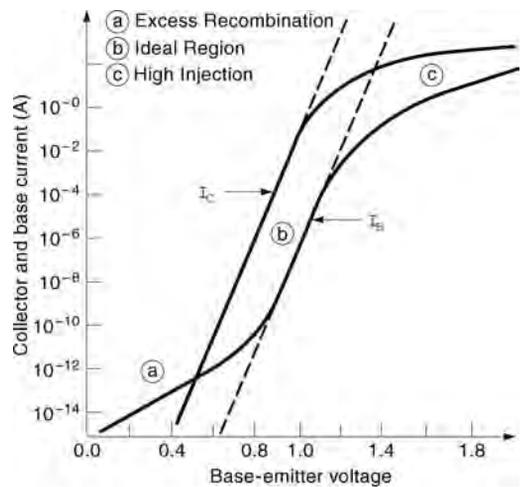

Fig. 9 Schematic Gummel characteristics for realistic bipolar transistor.

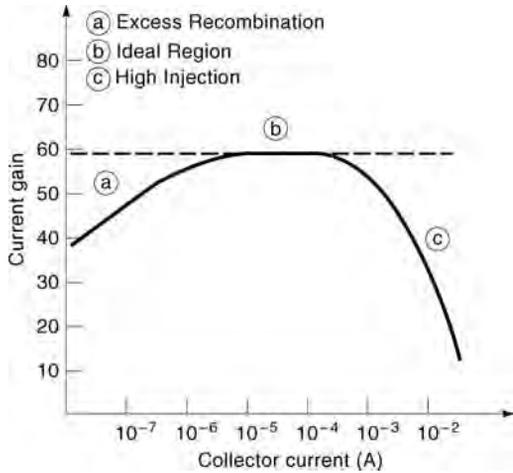

Fig. 10 Schematic current gain versus bias for realistic bipolar transistor.

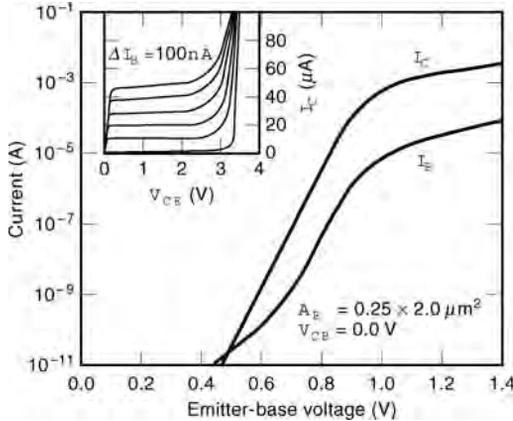

Fig. 11 Measured Gummel characteristics for scaled 0.25- μm double-polysilicon bipolar technology.¹⁴ Inset shows common-emitter breakdown characteristics of transistor.

Frequency Response The frequency response of a BJT is determined by both the intrinsic speed of the carriers through the device (transit time), as well as the parasitic resistances and capacitances of the transistor. Two primary figure of merit are used to characterize the frequency response of a BJT, the unity gain cutoff frequency (f_T) and the maximum oscillation frequency (f_{max}). Using a small-signal hybrid- π model both f_T and f_{max} can be derived (17), yielding

$$f_T = \frac{1}{2\pi\tau_{ec}} = \left[\frac{1}{g_m}(C_{be} + C_{bc}) + \tau_b + \tau_e + \tau_c \right]^{-1} \tag{12}$$

$$f_T = \left[\frac{kT}{qI_c}(C_{be} + C_{bc}) + \frac{W_b^2}{\eta D_{nb}} + \frac{1}{\beta_{ac}} \left(\frac{W_e}{S_{pe}} + \frac{W_e^2}{2D_{pe}} \right) + \frac{W_{bc}}{2v_s} + r_c C_{bc} \right]^{-1} \tag{13}$$

and

$$f_{max} = \sqrt{\frac{f_T}{8\pi C_{bc} R_b}} \tag{14}$$

In Eqs. (12)–(14), g_m is the transconductance ($\partial I_C/\partial V_{BE}$), C_{be} and C_{bc} are the base–emitter and base–collector capacitances, τ_b , τ_e , and τ_c are the base, emitter, and collector transit times, respectively, v_s is the saturation velocity (1×10^7 cm/s), η accounts for any doping-gradient-induced electric fields in the base, and R_b is the base resistance; f_T and, hence, f_{max} is typically limited by τ_b in conventional Si–BJT technologies. A major advantage of ion-implanted base, double-polysilicon BJT technology is that the base width can be made very small (typically < 150 nm), and thus the intrinsic frequency response quite large. Figure 12 shows measured f_T data as a function of bias current for a variety of device sizes for the doping profile shown in Fig. 3.¹⁴

ECL Gate Delay Due to its nonsaturating properties and high logical functionality, the ECL is the highest speed bipolar logic family and is in widespread use in the high-speed digital bipolar world. Figure 13 shows a simplified two-phase ECL logic gate. A common large-signal performance figure of merit is the unloaded

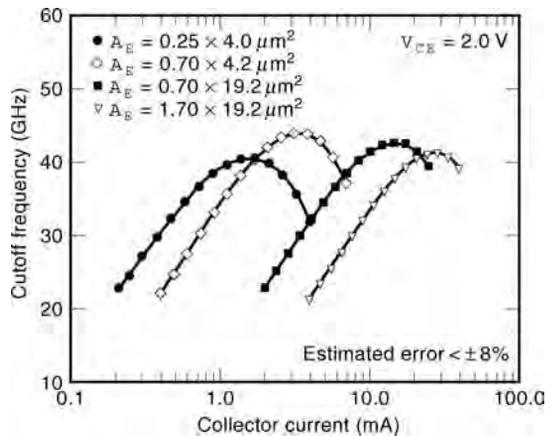

Fig. 12 Measured cutoff frequency as function of collector¹⁴ current for scaled 0.25- μm double-polysilicon bipolar technology. Shown are a variety of device geometries.

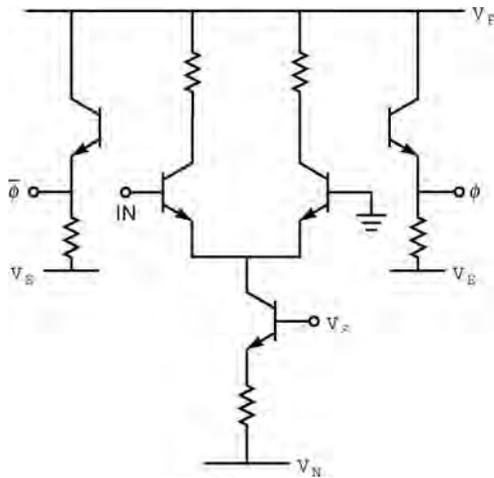

Fig. 13 Circuit schematic of two-phase ECL gate.

ECL gate delay, which can be measured using a “ring oscillator.” A ring oscillator is essentially a delay chain of ECL inverters with output tied back to its input, thus rendering the resultant circuit unstable (Fig. 14). From the period of the oscillation (Fig. 15), the average gate delay can be determined for a given bias current. Multiple ring oscillators can then be configured to operate at various bias currents, and hence the “power delay” characteristics of the BJT technology determined (average gate delay is plotted as a function of average power dissipation—or current in this case, because the supply voltage is constant). Figure 16 shows a typical measured ECL power delay curve.¹⁴ A minimum ECL gate delay of 20.8 ps is achieved with this technology. Observe that the speed of the ECL gate becomes faster as the average switch current increases, until some minimum value of delay is reached. To better understand the functional shape of the power delay curve, asymptotic expressions can be developed using a weighted time constant approach.²³ Under low-current (or low-power) conditions, the ECL gate delay is given by

$$\tau_{\text{ECL}}(\text{low power}) \cong R_{CC} \sum_{k=1}^n a_k C_k \quad (15)$$

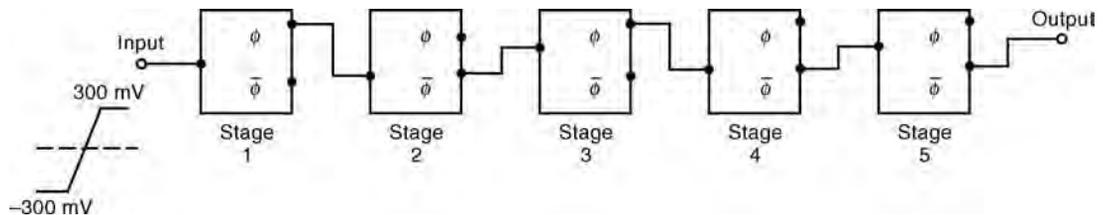

Fig. 14 Schematic representation of ECL ring oscillator circuit configuration.

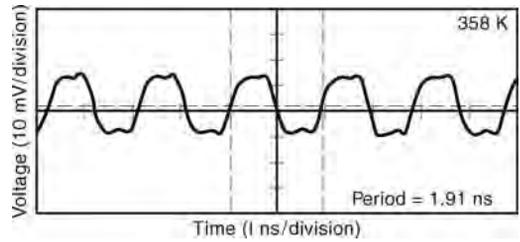

Fig. 15 Measured output waveform from ECL ring oscillator.

$$= \frac{V_L}{I_{CS}} [a_1 C_{bc} + a_2 C_{be} + a_3 C_{cs} + a_4 C_w + \dots] \quad (16)$$

$$\propto \frac{1}{I_{CS}} \propto \frac{1}{\text{power}} \quad (17)$$

while under high current (or power) conditions the ECL gate delay can be written as

$$\tau_{\text{ECL}}(\text{high power}) \cong C_{\text{diff}} \sum_{k=1}^n b_k R_k \quad (18)$$

$$= \frac{q\tau_{ec} I_{CS}}{kT} [b_1 R_{bi} + b_2 B_{bx} + b_3 R_e + b_4 R_c + \dots] \quad (19)$$

$$\propto I_{CS} \propto \text{power} \quad (20)$$

In Eqs. (15)–(20), R_{CC} is the circuit pull-up resistor, V_L is the logic swing, a_k and b_k are delay “weighting factors,” I_{CS} is the switch current, and C_{diff} is the transistor diffusion capacitance. We see then that at low currents, the parasitic capacitances dominate the ECL delay with a delay that is reciprocally proportional to the power dissipation, whereas at high currents, the parasitic resistances dominate the ECL delay, yielding a delay that is proportional to power dissipation. It is thus physically significant to plot the log of the ECL delay as a function of the log of the power (or current), as shown in Fig. 16. Also shown in Fig. 16 are large-signal circuit simulation results using the compact model depicted in Fig. 17, which confirm the stated dependence of delay on power.

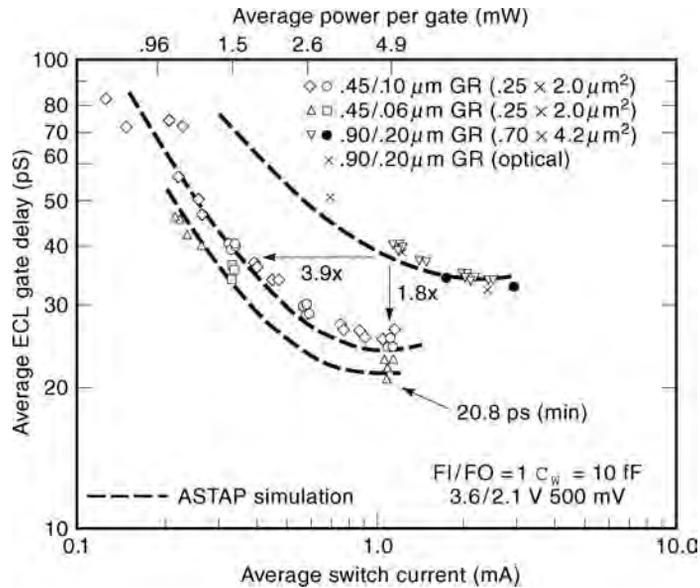

Fig. 16 The ECL power delay characteristics for scaled 0.25- μm double-polysilicon bipolar technology.¹⁴ Minimum delay of 20.8 ps is achieved. The ECL circuits were operated on 3.6/2.1-V power supplies at 500-mV logic swing. Fan-in (FI) and fan-out (FO) of one was used. Impact of transistor scaling from 0.90/0.20- μm lithography to 0.45/0.06- μm lithography is indicated. Also shown are circuit simulations calibrated to data using compact circuit model implemented in ASTAP.

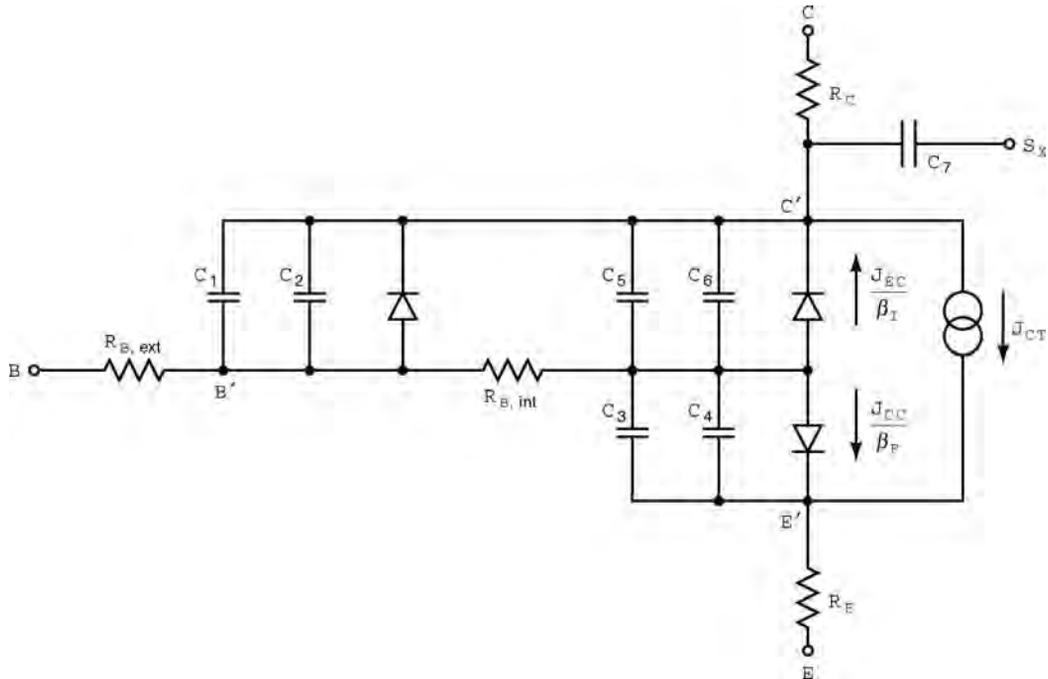

Fig. 17 Compact circuit model used in ASTAP circuit simulations.

1.3 High-Injection Effects

Substantial deviations from ideal behavior occur for BJTs operating at high current densities (as a rule of thumb, for $J_C \sim 1.0 \text{ mA}/\mu\text{m}^2$ in a modern high-performance technology). This deviation from simple theory can be observed in the premature roll-off of both the current gain and the cutoff frequency at high current densities, as shown in Figs. 10–12. These so-called high-injection effects are particularly important because most high-performance BJT circuits will be biased at high current densities in order to achieve maximum transistor performance. High injection in a BJT can generally be defined as that current density at which the injected minority carrier density (e.g., electrons in the base) becomes comparable to the local doping density. High-injection effects are generally the result of a number of competing physical mechanisms in the collector, base, and emitter regions and are thus difficult to analyze together theoretically. In this work we will simply emphasize the physical origin of each high-injection phenomenon region by region, discuss their impact on device performance, and give some rule-of-thumb design guidelines. The interested reader is referred to Ref. 6 for a more in-depth theoretical discussion.

Collector Region Collector region high-injection effects in BJTs can be divided into two separate phenomena: (a) Kirk effect, sometimes referred to as “base push-out”²⁴; and (b) quasi-saturation. The physical origin of the Kirk effect is as follows. As the collector current density continues to rise, the electron density in the base–collector space-charge region is no longer negligible and modifies the electric field distribution in the junction. At sufficiently high current density, the (positive) background space charge

due to the donor doping in the collector (N_{+dc}) is compensated by the injected electrons, and the electric field in the junction collapses, thereby “pushing” the original base region deeper into the collector (Figs. 18 and 19). Because both β and f_T depend reciprocally on W_b , this injection-induced increase in effective base width causes a strong degradation in both parameters. Approximate theoretical analysis can be used to determine the critical current density at which the Kirk effect is triggered, resulting in a BJT design equation

$$J_{\text{Kirk}} \cong qv_s N_{dc} \left(1 + \frac{2\varepsilon V_{BC}}{qW_{\text{epi}}^2 N_{dc}} \right) \quad (21)$$

From Eq. (21) it is apparent that increasing the collector doping level is the most efficient method of delaying the onset of the Kirk effect, although this will have a detrimental impact on the BV_{CEO} and collector–base capacitance of the transistor. As the Kirk effect is typically the limiting high-injection phenomenon in modern high-performance BJTs, a fundamental trade-off thus exists between peak f_T and BV_{CEO} .

The second major collector region high-injection phenomenon is called “quasi-saturation.” At a basic level, quasi-saturation is the result of the finite collector resistance of the n -type epi layer separating the base from the heavily doped subcollector in a BJT. At sufficiently high current levels, the infrared (IR) drop associated with the collector epi becomes large enough to internally forward bias the base–collector junction, even though an external reverse bias on the collector is applied. For instance, for a collector resistance of $1 \text{ k}\Omega$ and a collector current of 2 mA , an internal voltage drop of 2 V is obtained. If the BJT

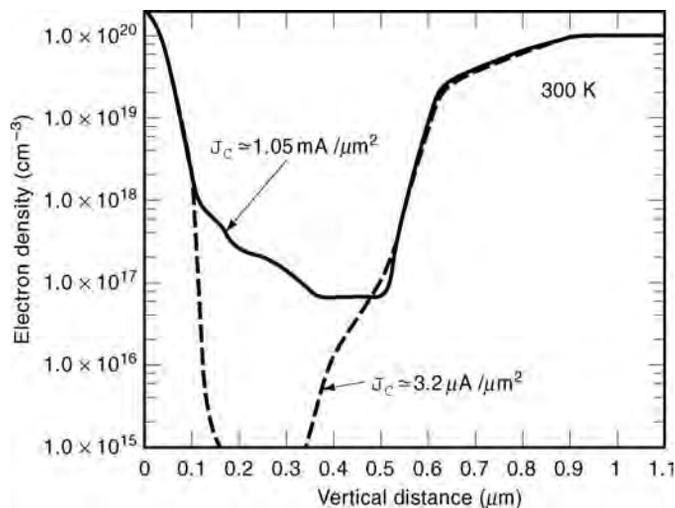

Fig. 18 Simulated electron profile in bipolar transistor at both low injection ($3.2 \mu\text{A}/\mu\text{m}^2$) and high injection ($1.05 \text{ mA}/\mu\text{m}^2$).

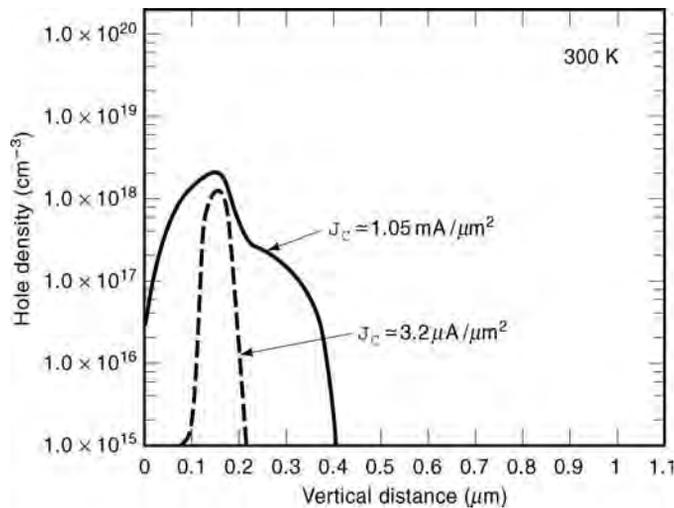

Fig. 19 Simulated hole profile in bipolar transistor at both low injection ($3.2 \mu\text{A}/\mu\text{m}^2$) and high injection ($1.05 \text{ mA}/\mu\text{m}^2$). Observe that at high-injection levels hole profile in base exceeds local doping level (as indicated by low-injection result), and holes are present in (n -type) collector region.

were biased at a base–collector reverse voltage of 1 V, then the internal base–collector junction would be forward-biased by 1 V, artificially saturating the transistor. With both base–emitter and base–collector junctions forward biased, the dc signature of quasi-saturation is a strong increase in base current together with a “clipping” of the collector current. Dynamically, quasi-saturation has a strong negative impact on the f_T and, hence, circuit speed because excess minority charge is injected into the base region under saturation. Theoretically, quasi-saturation is difficult to model because the resistance of the epi layer is strongly bias-dependent and the collector doping profile in real devices is highly position dependent. In a well-designed high-performance BJT, the Kirk effect is much more important than quasi-saturation.

Base Region High injection in the base region of a BJT leads to two major degradation mechanisms: (a) the Webster–Rittner effect,^{25,26} sometimes known as “base conductivity modulation,” and (b) emitter current crowding. In the Webster–Rittner effect, the large electron density in the base region under high injection is no longer small compared to the doping in the base. To maintain charge neutrality in the neutral base, the hole density must therefore rise (refer to Figs. 18 and 19), changing the (low-injection) Shockley boundary condition at the emitter–base junction, and effectively doubling the electron diffusivity in the base. The result is a different voltage dependence of the collector current, which changes to one-half the slope of the exponential low-injection collector current

according to

$$J_C (\text{Webster–Rittner}) \cong \left[\frac{q2D_{nb}n_{ib}(0)}{W_b} \right] e^{qV_{BE}/2kT} \quad (22)$$

This slope change of J_C has a detrimental impact on the current gain, although in practice for high-performance BJTs, the Kirk effect typically onsets before the Webster–Rittner effect because the base is much more heavily doped than the collector.

Emitter current crowding is the result of the finite lateral resistance associated with the intrinsic base profile (i.e., R_{bi}). Because the collector current depends on the actual base–emitter voltage applied at the junction itself, rather than that applied at the base and emitter terminals, large base currents flowing at high-injection levels can produce a lateral voltage drop across the base. This yields a lateral distribution in the actual base–emitter voltage at the junction, resulting in higher bias at the emitter periphery than in the center of the device. In essence, then, the collector current “crowds” to the emitter edge where the static and dynamic properties of the device are generally worse, and can even produce “thermal runaway” and catastrophic device burnout. This is typically only a problem in large geometry power transistors, not high-speed digital technologies. In addition, as the base current is a factor of β smaller than the collector current, emitter current crowding is not generally a problem unless there is very large base resistance in the device.

Emitter Region Because it is very heavily doped, the emitter region in modern BJTs always operate in

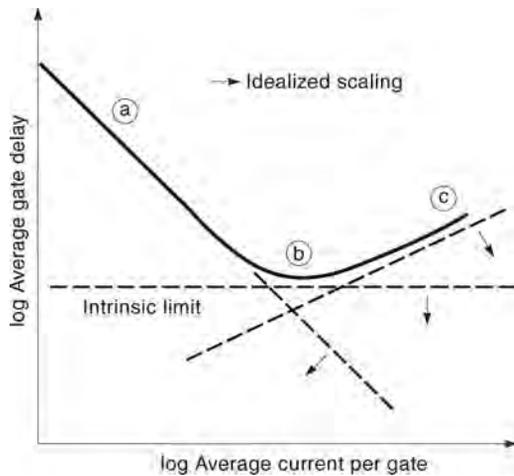

Fig. 20 The ECL power delay characteristics showing impact of idealized scaling.

low injection. Thus, the only significant emitter region high-injection effect is the result of the finite emitter resistance of the transistor. Because polysilicon emitter contacts in fact exhibit reasonably high specific contact resistance (e.g., $20\text{--}60\ \Omega\ \mu\text{m}^2$), however, emitter resistance (R_E) can be a serious design constraint. Emitter resistance degrades the collector and base currents exponentially as it decreases the applied base-emitter voltage according to

$$I_C = I_{C0} e^{q(V_{BE} - I_E R_E)/kT} \quad (23)$$

$$I_B = I_{B0} e^{q(V_{BE} - I_E R_E)/kT} \quad (24)$$

For instance, for a $1.0\text{-}\mu\text{m}^2$ emitter area transistor operating at a collector current of 1.0 mA, a specific emitter contact resistance of $60\ \Omega\ \mu\text{m}^2$ results in an emitter-base voltage loss of 60 mV, yielding a $10\times$ decrease in collector current. Proper process optimization associated with the polysilicon emitter contact is key to obtaining a robust high-speed BJT technology, particularly as the emitter geometry shrinks.

1.4 Scaling Issues

Device miniaturization (“scaling”) has been a dominant theme in bipolar technology over the past 15 years, and has produced a monotonic decrease in circuit delay over that period (refer to Fig. 1). In general, optimized BJT scaling requires a coordinated reduction in both lateral and vertical transistor dimensions, as well as a change in circuit operating point.²³ Unlike in CMOS technology, BJT circuit operating voltages (for conventional circuits such as ECL) cannot be scaled because the junction built-in voltage is only weakly dependent on doping. The

evolution of BJT technology from non-self-aligned, double-diffused transistor structures to self-aligned, ion-implanted, double-polysilicon transistor structures was the focus for BJT scaling in the 1980s. During the 1990s more emphasis has been placed on vertical profile scaling and a progression toward both forms of advanced lithography [e.g., deep ultraviolet (UV) or electron beam lithography], low-thermal budget processing, and structural innovation to continue the advances in circuit speed over time.

Figure 20 represents an idealized ECL power delay curve and indicates the three principle regions that require attention during optimized scaling. In region (a), which is dominated by parasitic transistor capacitances [see Eqs. (15)–(17)], a reduction in lithography, and hence decrease in transistor size, is effective in reducing circuit delay at low current levels. Region (b) is dominated by the intrinsic speed of the transistor (i.e., τ_{ec}). Thinning the vertical profile particularly the base width, is key to reducing the ECL delay at intermediate current levels. The evolution of ion implantation has proven key to realizing viable sub-150-nm metallurgical base widths in modern BJT technologies. In region (c), the ECL delay is dominated by base resistance and high-injection roll-off of the frequency response of the device [Eqs. (18)–(20)]. Doping the base and collector regions more heavily is successful in improving the delay at very high current levels, although tradeoffs exist. For instance, doping the base more heavily decreases the peak f_T of the transistor (due to a lower electron mobility), and, hence, degrades the speed in region (b) at intermediate current levels. In addition, increasing the collector doping level to improve the high-injection performance in region (c) effectively increases the collector-base capacitance, degrading the ECL delay in region (a) at low-current levels. Optimized scaling is thus a complex tradeoff between many different profile design issues.

Clever solutions to certain scaling tradeoffs have emerged over the years and include, for instance, the now pervasive use of the so-called self-aligned, implanted collector (SIC) process. In an SIC process (see Ref. 10), phosphorus is implanted through the emitter window in the base polysilicon layer (either before or after sidewall spacer formation) to increase the collector doping level locally under the intrinsic device without increasing the collector-base capacitance in the extrinsic transistor.

Figure 21 and 22 show the results of a recent BJT lithographic scaling experiment.¹⁴ In this study a comparison was made between BJTs fabricated using three different lithographies ($0.09\text{-}\mu\text{m}/0.20\text{-}\mu\text{m}$ lithographic linewidth/lithographic overlay, $0.45\ \mu\text{m}/0.10\ \mu\text{m}$, and $0.45\ \mu\text{m}/0.06\ \mu\text{m}$). The latter two processes used advanced electron-beam lithography. As can be seen, the impact of scaling on device parameters is dramatic, resulting in an expected improvement in ECL delay across the entire power delay characteristic, and a minimum ECL gate delay of 20.8 ps (Fig. 16).

Fig. 21 Comparison of measured device parameters as function of scaling for: (1) 0.90/0.20 μm (lithographic image/overlay); (2) 0.45/0.10 μm ; and (3) 0.45/0.06 μm transistors.¹⁴ Lumped ASTAP parameters are extracted from calibrated simulations of ECL ring oscillator data.

Nonetheless, practical limits do exist for conventional ion-implanted, double-polysilicon BJT technology. Obtaining metallurgical basewidths below 80–100 nm with reasonable base resistance using low-energy ion implantation is very difficult and places a practical limit of about 40–50 GHz on the resultant f_T of such transistors (see Fig. 12, which corresponds to the doping profile shown in Fig. 2). In addition, circuit operating voltages limit the useful BV_{CEO} of the transistor to about 3.0 V, and thus place a practical limit on collector doping levels of about $1 \times 10^{17} \text{ cm}^{-3}$ and a consequent maximum operating current density of about 1–2 $\text{mA}/\mu\text{m}^2$. The emitter junction depth (and, hence, the thermal process associated with the polysilicon emitter) is limited to about 25–30 nm because the emitter–base space charge region must lie inside the single-crystal emitter region to avoid the generation/recombination centers associated with the heavily defective polysilicon region. More advanced profiles can be obtained using epitaxial growth techniques, as will be discussed in the next section.

1.5 Future Directions

Despite the continual improvements in speed that BJT technology has enjoyed over the past 15 years, and the inherent superiority of the analog and digital properties of BJTs compared to field-effect transistors (FETs), the world market for BJT integrated circuits (ICs) has

steadily eroded. This is due to both the improved performance of FET technology as gate lengths are scaled into the submicron domain, the widespread emergence of CMOS with its low power delay product, and the decreased cost associated with CMOS ICs compared to competing bipolar technologies. To confront this situation, many bipolar + CMOS (BiCMOS) technologies have been developed that seek to combine low-power CMOS with high-performance BJTs. The reader is referred to Ref. 4 for an examination of the process integration issues associated with modern BiCMOS technologies.

In addition, there are several areas of current research with the potential to extend BJT technology well into the twenty-first century; they include: (a) complementary bipolar technology, (b) Silicon-on-insulator (SOI) bipolar technology, and (c) silicon–germanium (SiGe) bipolar technology. Each of these three research areas seeks to improve either the power dissipation associated with conventional BJT circuit families such as ECL, or improve the transistor performance to levels not possible in Si BJTs and thus to capture new and emerging IC markets.

Complementary Bipolar Technology Complementary bipolar (C-bipolar) technology, which combines $n-p-n$ and $p-n-p$ transistors on the same chip, has been used for decades. In conventional usage, the $n-p-n$ BJT is a standard, vertical high-performance

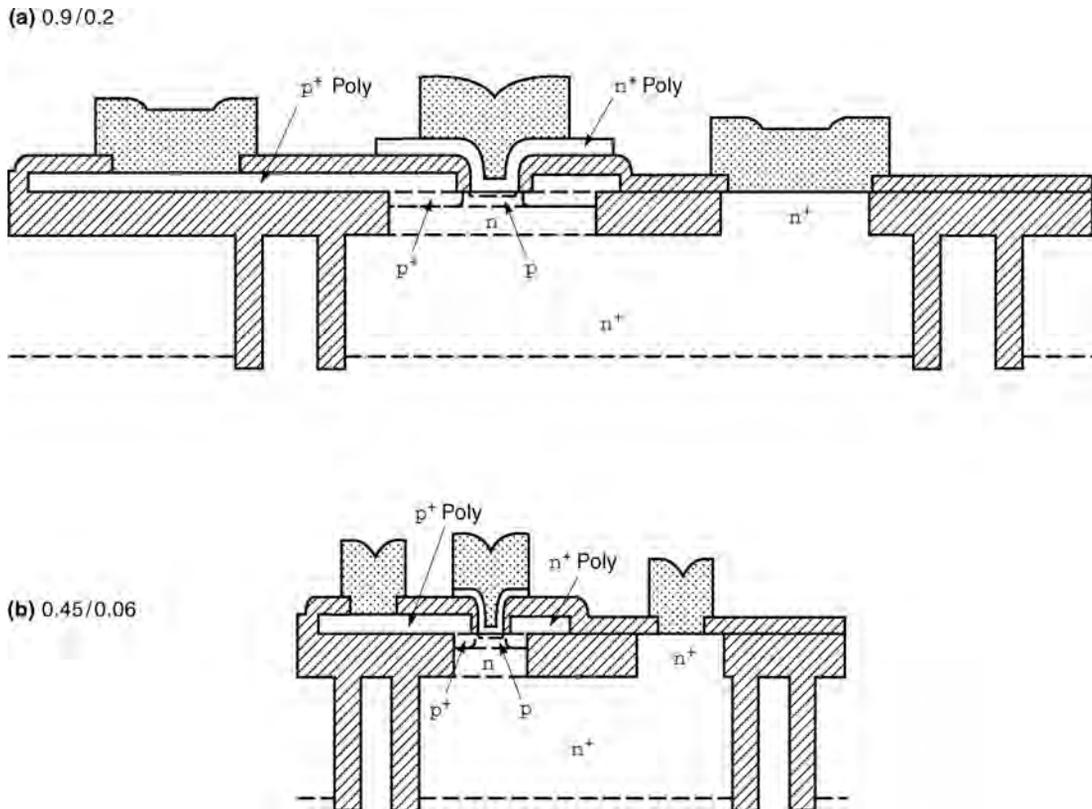

Fig. 22 Scaled comparison of (a) a 0.90/0.20- μm (lithographic image/overlay) transistor with (b) a 0.90/0.06- μm transistor.

transistor, while the $p-n-p$ BJT is typically a slow-speed lateral device used only in analog circuits such as current sources where high speed is unnecessary. Modern implementations of C-bipolar technology, on the other hand, combine a high-performance vertical $n-p-n$ BJT and a high-performance vertical $p-n-p$ BJT (see, e.g., Refs. 27 and 28). The resulting IC technology, though inherently more complex than a traditional $n-p-n$ only BJT technology, opens many new possibilities for novel high-speed, low-power circuit families. New C-bipolar circuit families such as accoupled push-pull emitter-coupled logic (ACPP-ECL) and nonthreshold logic with complementary emitter-follower (NTL-CEF) offer dramatic improvements in power delay product compared to conventional ECL (Fig. 23).

Silicon-on-Insulator Bipolar Technology Silicon-on-insulator IC technologies have existed since the 1960s but have emerged recently as a potential scaling path for advanced CMOS technologies. In SOI technology, a buried oxide dielectric layer is placed below the active Si region, either by ion implantation (SIMOX) or by wafer bonding (BESOI). For the

CMOS implementation, the active Si region is made thin, so that it is fully depleted during normal device operation, resulting in improved subthreshold slope, better leakage properties at elevated temperatures, and improved dynamic performance due primarily to the reduction in parasitic source/drain capacitance. Given this development, it is natural to implement a lateral BJT together with the SOI-CMOS to form an SOI-BiCMOS technology. While lateral BJTs are not generally considered high-speed transistors, the reduction in parasitic capacitance in the lateral BJT, together with clever structural schemes which allow very aggressive base widths to be realized, have resulted in impressive performance.²⁹

SiGe Bipolar Technology Attempts to reduce the base widths of modern BJT technologies below 100 nm typically rely on epitaxial growth techniques. A recent high-visibility avenue of research has been the incorporation of small amounts of germanium (Ge) into these epitaxial films to tailor the properties of the BJT selectively while maintaining compatibility with conventional Si fabrication techniques. The resultant

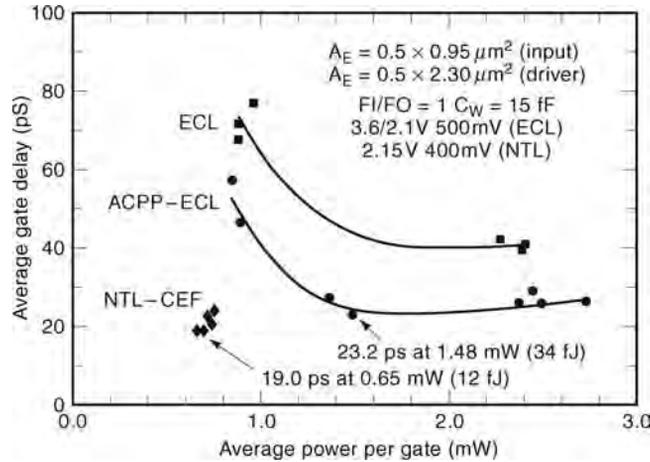

Fig. 23 Measured power delay characteristics from an advanced complementary bipolar technology.²⁷ Three circuit families are compared: (1) conventional (*nnpn*-only) ECL, (2) ACPP-ECL, and (3) nonthreshold logic with complementary emitter-(NTL-CEF). The NTL-CEF circuit achieved a minimum power delay product of 12 fJ.

device, called an SiGe heterojunction bipolar transistor (HBT), involves introducing strained epitaxial SiGe alloys into the base region of the transistor, and represents the first practical bandgap-engineered device in Si technology (refer to Refs. 30–32, and references contained within, for reviews of SiGe HBTs).

Compared to an Si BJT with an identical doping profile the SiGe HBT has significantly enhanced current gain, cutoff frequency, Early voltage (output conductance), and current gain Early voltage product, according to Refs. 31 and 32,

$$\frac{J_{C\text{SiGe}}}{J_{C\text{Si}}} = \frac{\beta_{\text{SiGe}}}{\beta_{\text{Si}}} = \gamma\eta \frac{\Delta E_{g,\text{Ge}}(\text{grade})/kT e^{\Delta E_{g,\text{Ge}}(0)/kT}}{1 - e^{-\Delta E_{g,\text{Ge}}(\text{grade})/kT}} \quad (25)$$

$$\frac{\tau_{b,\text{SiGe}}}{\tau_{b,\text{Si}}} \alpha \frac{f_{T,\text{Si}}}{f_{T,\text{SiGe}}} = \frac{2}{\eta} \left(\frac{kT}{\Delta E_{g,\text{Ge}}(\text{grade})} \right) \left[1 - \frac{1 - e^{-\Delta E_{g,\text{Ge}}(\text{grade})/kT}}{\Delta E_{g,\text{Ge}}(\text{grade})/kT} \right] \quad (26)$$

$$\frac{V_{A,\text{SiGe}}}{V_{A,\text{Si}}} = e^{\Delta E_{g,\text{Ge}}(\text{grade})/kT} \left[\frac{1 - e^{-\Delta E_{g,\text{Ge}}(\text{grade})/kT}}{\Delta E_{g,\text{Ge}}(\text{grade})/kT} \right] \quad (27)$$

$$\frac{\beta V_{A|\text{SiGe}}}{\beta V_{A|\text{Si}}} = \gamma\eta e^{\Delta E_{g,\text{Ge}}(0)/kT} e^{\Delta E_{g,\text{Ge}}(\text{grade})/kT} \quad (28)$$

where $\Delta E_{g,\text{Ge}}(0)$ is the Ge-induced band offset at the emitter–base junction, $\Delta E_{g,\text{Ge}}(\text{grade}) = \Delta E_{g,\text{Ge}}$

$(W_b) - \Delta E_{g,\text{Ge}}(0)$ is the base bandgap grading factor, and γ, η are the strain-induced density-of-states reduction and mobility enhancement factors, respectively. With its improved transistor performance compared to Si BJTs and compatibility with standard Si fabrication processes, SiGe HBT technology is expected to pose a threat to more costly compound semiconductor technologies such as GaAs for emerging high-speed communications applications. Figure 24 shows a representative SiGe doping profile. Observe that the Ge is introduced only in the base region of the transistor. Experimental results comparing a SiGe HBT and a Si BJT having identical layout and doping profile are shown in Figs. 25 and 26 and indicate that significant enhancements compared to comparably designed Si devices are possible. It is now clear that cutoff frequencies well above 300 GHz are possible using SiGe HBT technology, and thus SiGe represents the next evolutionary step in Si BJT technology.

2 DATA ACQUISITION AND CONVERSION

Kavita Nair, Chris Zillmer, Dennis Polla, and Ramesh Hargani

Data acquisition and conversion pertain to the generation of signals from sensors, their conditioning, and their conversion into a digital format. In this section we describe typical sensors that generate signals and examples of data converter topologies suitable for sensor interfaces. We restrict ourselves to integrated implementations of sensors and sensor interface circuits. In particular, we target sensors and sensor interfaces that are compatible with CMOS fabrication technologies.

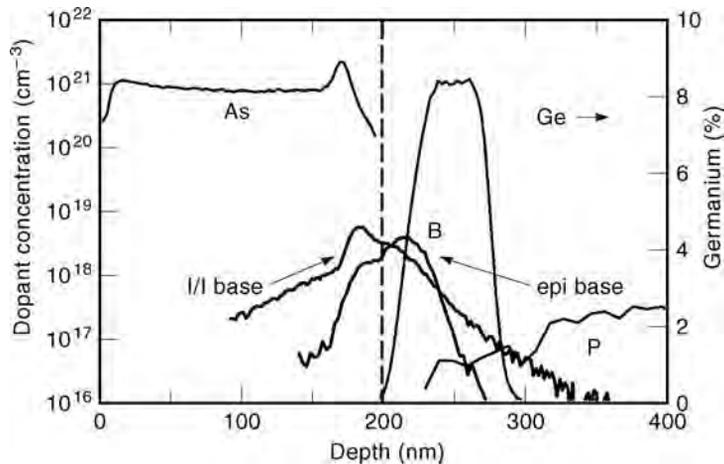

Fig. 24 Measured secondary ion mass spectroscopy (SIMS) doping profile comparing a 60-GHz cutoff frequency epitaxial SiGe base bipolar technology with an aggressive (40-GHz cutoff frequency) ion-implanted (I/I) base bipolar technology.

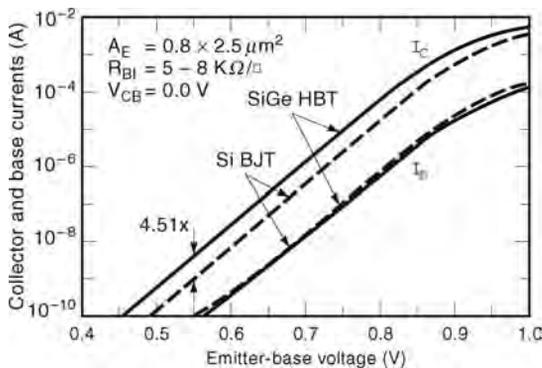

Fig. 25 Measured Gummel characteristics for SiGe and Si transistors with comparable doping profiles. Expected enhancement in collector current ($4.51\times$) can be observed.

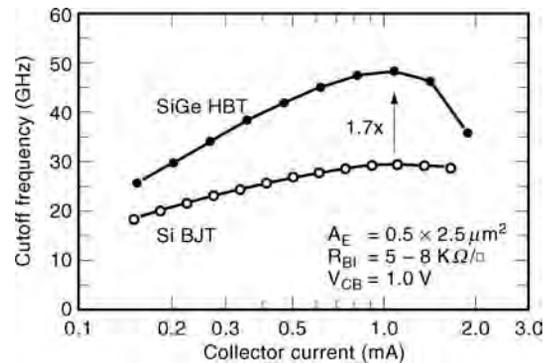

Fig. 26 Measured cutoff frequency as a function of collector current for SiGe and Si transistors with comparable doping profiles. The expected enhancement in collector current ($1.71\times$) can be observed.

This section is organized as follows. First, we describe some examples of sensors and sensor interfaces; then we describe some sample data converter topologies. After that, we provide two complete design examples.

2.1 Sensors

Sensors are devices that respond to a physical or chemical stimulus and generate an output that can be used as a measure of the stimulus. The sensed inputs can be of many types: chemical, mechanical, electrical, magnetic, thermal, and so on. The input signal sensed by the sensor is then processed (amplified converted from analog to digital, etc.) by some signal conditioning electronics, and the output transducer converts this

processed signal into the appropriate output form. The primary purpose of interface electronics is to convert the sensor's signal into a format that is more compatible with the electronic system that controls the sensing system. The electric signals generated by sensors are usually small in amplitude. In addition to this, sensors often exhibit errors, such as offsets, drift, and nonlinearities that can be compensated for with the correct interface circuitry. Analog elements have been improved substantially to achieve high speed and high accuracy; however, for many applications digital is still the preferred format. The sensors yield a wide variety of electric output signals: voltages, currents, resistances, and capacitances. The signal conditioning

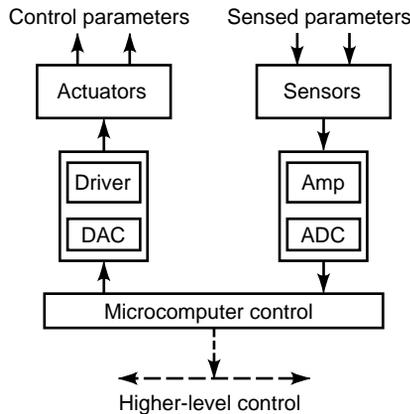

Fig. 27 Overall system architecture of a sensor–actuator control system.

circuitry modify the input signal into a format suitable for the follow-on data converter.

Figure 27 shows the system architecture for a sensor–actuator-based control system. The sensor(s) senses the external physical and chemical parameters and converts them into an electrical format. The sensed data are processed and digitized using integrated circuitry and transmitted to the host controller. The host uses this information to make the appropriate decisions, and information is fed back to the external environment through a set of actuators.³³ These microprocessor-based controllers have revolutionized the design and use of instrumentation systems by allowing system operation to be defined in software, thus permitting a substantial increase in signal-processing and user–interface features. In general, a power supply is also connected to these blocks but is not explicitly shown in Fig. 27. If a sensor can provide a signal without a power supply, it is referred to as a self-generating sensor.

Integrated sensors are used in many applications, including automotive, manufacturing, environmental monitoring, avionics, and defense. In the past few years, integrated sensors that monolithically combine the sensor structure and some signal-processing interface electronics on the same substrate have begun to emerge. By combining microsensors and circuits, integrated smart sensors increase accuracy, dynamic range, and reliability and at the same time reduce size and cost. Some examples of semiconductor sensors are pressure sensors used in pneumatic systems, magnetic sensors used in position control, temperature sensors used in automotive systems, chemical sensors used in biological diagnostic systems, and acoustic emission sensors used in structural diagnostics.

We now illustrate the use of sensors and sensor interfaces with the two most common types of sensors: resistive and capacitive sensors. We then describe

two complete sensor systems that include an acoustic emission sensor and a temperature sensor.

Resistive Sensors Sensors based on the variation of electric resistance are called *resistive* sensors. They can be further classified according to the physical quantity that they measure: thermal, magnetic, optical, and so on.

A *potentiometer* is a simple resistance measurement device in which the resistance is proportional to its length. However, the linearity of a potentiometer is limited because its resistance is not perfectly uniform. The resistance value also drifts with temperature. Applications of potentiometers are in the measurement of linear or rotary displacements.

Another simple and commonly used resistive sensor is the *strain gauge*, which is based on the variation of the resistance of a conductor or semiconductor when subjected to a mechanical stress. The variation in the resistance of a metal is given by³⁴

$$R = R_0(1 + G\varepsilon) \quad (29)$$

where R_0 is the resistance when there is no applied stress, G is the *gauge factor*, and ε is the strain. There are a number of limitations on strain gauges, such as temperature dependence, light dependence, and inaccuracies in the measurement of a nonuniform surface; but in spite of these limitations, they are among the most popular sensors because of their small size and linearity.

Some of the applications of the strain gauge are in measuring force, torque, flow, acceleration, and pressure. Figure 28 shows a micromachined piezoresistive cantilever beam used as a strain gauge sensor. Strain gauges are capable of detecting deformations as small as $10 \mu\text{m}$ or lower.

A resistance temperature detector (RTD) is a temperature detector based on the variation in electric resistance. An increase in temperature increases the vibrations of atoms around their equilibrium positions,

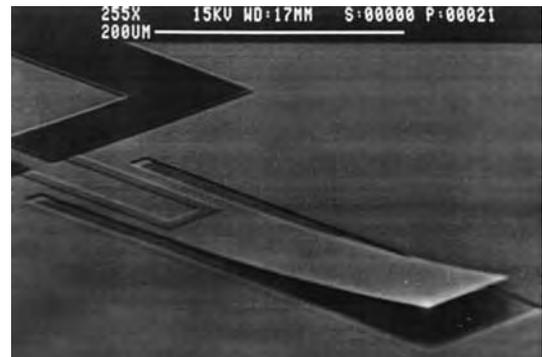

Fig. 28 Micromachined piezoresistive cantilever beam used as strain gauge sensor.

and this increases the resistance in a metal: Thus there is a positive temperature coefficient of resistance. The complete temperature dependence can be expressed³⁴ as

$$R = R_0(1 + \alpha_1 T + \alpha_2 T^2 + \dots + \alpha_n T^n) \quad (30)$$

where T is the temperature difference from the reference and R_0 is the resistance at the reference temperature.

The main advantages of these sensors are their high sensitivity, repeatability, and low cost. There are some limitations too. First, to avoid destruction through self-heating, the RTD cannot measure temperatures near the melting point of the metal. Second, the change in temperature may cause physical deformations in the sensor. Additionally, for each metal there is only a small range over which the RTD is linear. The most common metals used for RTDs are platinum, nickel, and copper.

Thermistors are also temperature-dependent resistors but are made of semiconductors rather than metals. The temperature dependence of the resistance of a semiconductor is due to the variation in the available charge carriers. Semiconductors have a negative temperature coefficient, as the resistance is inversely proportional to the number of charge carriers. The temperature dependence of thermistors is given by³⁴

$$R_T = R_0 \exp \left[B \left(\frac{1}{T} - \frac{1}{T_0} \right) \right] \quad (31)$$

where T_0 is the reference temperature, R_0 is the resistance at T_0 , and B is the characteristic temperature of the material, which itself is temperature dependent. The limitations and advantages of a thermistor are similar to those of an RTD, except that the thermistor is less stable. There are many types of thermistors available, and each type has its own applications. The foil and bead types are suitable for temperature measurement, whereas the disk and rod types are suitable for temperature control. Some of the applications of thermistors are in the measurement of temperature, flow, level, and time delay. Two simple applications of thermistors are discussed below.

Light-dependent resistors, or LDRs, are devices whose resistance varies as a function of the illumination. LDRs are also known as photoconductors. The conductivity is primarily dependent on the number of carriers in the conduction band of the semiconductor material used. The basic working of the photoconductor is as follows. The valence and conduction bands in a semiconductor are quite close to each other. With increased illumination, electrons are excited from the valence to the conduction band, which increases the conductivity (reduces the resistance). The relation between resistance and optical radiation or illumination is given by³⁴

$$R = AE^{-\alpha} \quad (32)$$

where A and α are process constants, R is the resistance, and E is the illumination.

An important limitation of LDRs is their nonlinearity. Also, their sensitivity is limited by fluctuations caused by changes in temperature. Finally, the spectral response of LDRs is very narrow and primarily depends on the type of material used.

Some of the most common LDRs are made of PbS, CdS, and PbSe. Some applications of LDRs are shutter control in cameras and contrast and brightness control in television receivers.

Measurement Techniques for Resistive Sensors.

Various measurement techniques can be used with resistive sensors. The basic requirement for any measurement circuitry is a power supply to convert the change in resistance into a measurable output signal. In addition, it is often necessary to custom-build interface circuits for some sensors. For example, we may be required to add a linearization circuit for thermistors.

Resistance measurements can be made by either the deflection method or the nulling method. In the deflection method the actual current through the resistance or the voltage across the resistance is measured. In the nulling method a bridge is used.

The two-readings method is a fundamental approach to resistance measurement. A known resistance is placed in series with the unknown resistance as shown in Fig. 29. The voltage is then measured across each of them. The two voltages can be written as

$$V_K = \frac{V}{R_K + R_U} R_K \quad (33)$$

$$V_U = \frac{V}{R_K + R_U} R_U \quad (34)$$

where V is the supply voltage, V_K and R_K are the known voltage and resistance, and V_U and R_U are the unknown voltage and resistance. Thus from the above equations R_U can be written as follows:

$$R_U = R_K \frac{V_U}{V_K} \quad (35)$$

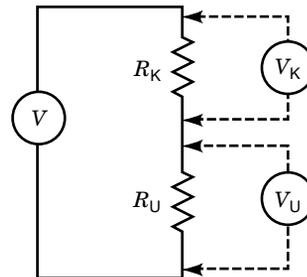

Fig. 29 Two-readings method for resistance measurement.

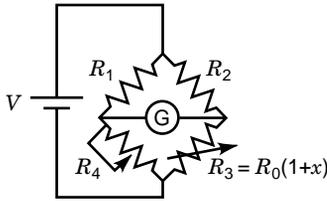

Fig. 30 Simple Wheatstone bridge measurement method.

A similar method is the *voltage divider* in which the unknown resistance is once again calculated from known voltages and resistances. It is easier to resolve small voltage changes for low voltages than it is for high voltages. Thus to measure small changes in resistance, another voltage divider is placed in parallel to the one with the sensor. The parallel voltage dividers are designed to give the same voltage for no input. Thus the signal obtained by taking the difference between their output signals is totally dependent on the measured signal. This method of measuring small changes using parallel voltage dividers is called the *Wheatstone bridge method*.^{34,34a,35,36} A simple Wheatstone bridge measurement method is shown in Fig. 30.

The Wheatstone bridge is balanced with the help of a feedback system, which adjusts the value of the standard resistor until the current through the galvanometer is zero. Once this is done, the value for R_3 is given by

$$R_3 = R_4 \frac{R_2}{R_1} \tag{36}$$

Thus the resistance R_3 is directly proportional to the change required in R_4 in order to balance the circuit.

The Wheatstone bridge can also be used for deflection measurement. In this case, instead of measuring the change needed to balance the bridge, the voltage difference between the bridge outputs is measured or the current through the center arm is measured. This method is shown in Fig. 30. When the bridge is completely balanced (i.e., $x = 0$), k is defined as follows:

$$k = \frac{R_1}{R_4} = \frac{R_2}{R_0} \tag{37}$$

Thus the voltage difference between the outputs can be written as follows:

$$V_0 = V \left(\frac{R_3}{R_2 + R_3} - \frac{R_4}{R_1 + R_4} \right) = V \frac{kx}{(k+1)(k+1+x)} \tag{38}$$

The maximum sensitivity for very small changes in x is obtained when $k = 1$.

Capacitive Sensors Recently capacitive sensors have gained popularity. They generally exhibit lower temperature sensitivity, consume less power, and provide an overall higher sensor sensitivity with higher resolution than resistive sensors. For these reasons they have begun to show up in areas where resistive sensors were the norm. They are used in many applications such as pressure sensors and accelerometers. Capacitive sensors typically have one fixed plate and one moving plate that responds to the applied measurand. The capacitance between two plates separated by a distance d is given by $C = \epsilon A/d$, where ϵ is the dielectric constant and A is the area of the plate. It is easily seen that the capacitance is inversely proportional to the distance d .

For capacitive sensors there are several possible interface schemes. Figure 31 shows one of the most common capacitive sensor interfaces. The circuit is simply a charge amplifier which transfers the difference of the charges on the sensor capacitor C_s and the reference capacitor C_{ref} to the integration capacitor C_I . If this interface is used in a pressure sensor, the sensing capacitor C_s can be written as the sum of the sensor capacitor value C_{s0} at zero pressure and the sensor capacitor variation $\Delta C_s(p)$ with applied pressure: $C_s = C_{s0} + \Delta C_s(p)$. In many applications C_{s0} can be 5 to 10 times larger than the full-scale sensor capacitance variation $\Delta C_s(p)_{max}$; the reference capacitor C_{ref} is used to subtract the nominal value of the sensor capacitor at half the pressure range, which is $C_{ref} = C_{s0} + \Delta C_s(p)_{max}/2$. This ensures that the transferred charge is the charge that results from the change in the capacitance. This results in a smaller integration capacitor and increased sensitivity.

This type of capacitive interface is insensitive to the parasitic capacitance between the positive and negative terminals of the opamp, since the opamp maintains a virtual ground across the two terminals of the parasitic capacitor. This type of interface is also much faster than most other capacitive interfaces; its speed of operation is determined by the opamp's settling time. This technique also allows for the amplifier's offset and flicker noise to be removed very easily by using correlated double sampling or chopper stabilization. The resolution of this interface is in most cases limited by kT/C noise and charge injection due to the switches.

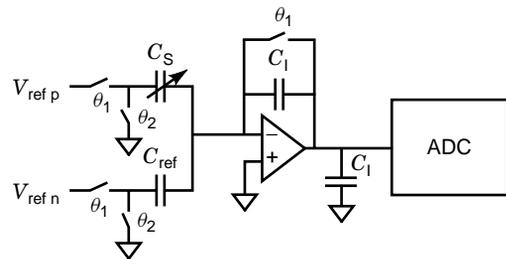

Fig. 31 Capacitive sensor interface.

There are a number of other sensor types, and two more will be discussed later in this section. However, we first describe the most common data converters that are used as part of sensor interfaces.

2.2 Data Converters

The analog signals generated and then conditioned by the signal conditioning circuit are usually converted into digital form via an analog-to-digital converter (ADC). In general, most of the signals generated by these sensors are in the low-frequency region. For this reason, certain data converter topologies are particularly well suited as sensor interface subblocks. These include the charge redistribution implementation of the successive approximation converter, along with incremental and sigma–delta converters.³⁷ In the following we shall briefly describe successive approximation (incremental) and sigma–delta converters. Incremental and sigma–delta converters are very similar, and the details of the former are later described extensively as part of a sample system design.

Successive Approximation Converter A block diagram for the successive approximation converter is shown in Fig. 32. The successive approximation topology requires N clock cycles to perform an N -bit conversion. For this reason, a sample-and-held (S/H) version of the input signal is provided to the negative input of the comparator. The comparator controls the

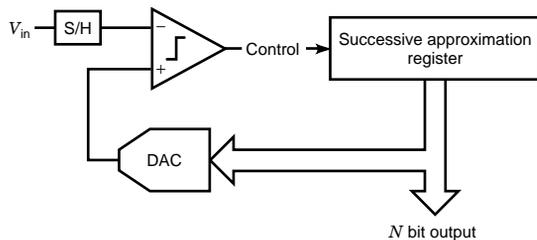

Fig. 32 Successive approximation converter: block diagram.

digital logic circuit that performs the binary search. This logic circuit is called the successive approximation register (SAR). The output of the SAR is used to drive the digital-to-analog converter (DAC) that is connected to the positive input of the comparator.

During the first clock period, the input is compared with the most significant bit (MSB). For this, the MSB is temporarily raised high. If the output of the comparator remains high, then the input lies somewhere between zero and $V_{\text{ref}}/2$ and the MSB is reset to zero. However, if the comparator output is low, then the input signal is somewhere between $V_{\text{ref}}/2$ and V_{ref} and the MSB is set high. During the next clock period the MSB-1 bit is evaluated in the same manner. This procedure is repeated so that at the end of N clock periods all N bits have been resolved.

The charge redistribution implementation of the successive approximation methodology is the most common topology in metal–oxide–semiconductor (MOS) technologies.³⁸ The circuit diagram for a 4-bit charge redistribution converter is shown in Fig. 33. In this circuit the binary weighted capacitors $\{C, C/2, \dots, C/8\}$ and the switches $\{S_1, S_2, \dots, S_5\}$ form the 4-bit scaling DAC. For each conversion the circuit operates as a sequence of three phases. During the first phase (sample), switch S_0 is closed and all the other switches S_1, S_2, \dots, S_6 are connected so that the input voltage V_{in} is sampled onto all the capacitors. During the next phase (hold), S_0 is open and the bottom plates of all the capacitors are connected to ground, that is, switches S_1, S_2, \dots, S_5 are switched to ground. The voltage V_x at the top plate of the capacitors at this time is equal to $-V_{\text{in}}$, and the total charge in all the capacitors is equal to $-2C V_{\text{in}}$. The final phase (redistribution) begins by testing the input voltage against the MSB. This is accomplished by keeping the switches S_2, S_3, \dots, S_5 connected to ground and switching S_1 and S_6 so that the bottom plate of the largest capacitor is connected to V_{ref} . The voltage at the top plate of the capacitor is equal to

$$V_x = \frac{V_{\text{ref}}}{2} - V_{\text{in}} \quad (39)$$

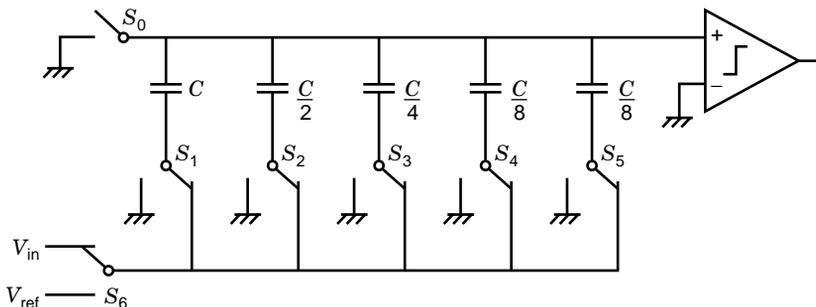

Fig. 33 Charge redistribution implementation of successive approximation architecture.

If $V_x > 0$, then the comparator output goes high, signifying that $V_{in} < V_{ref}/2$, and switch S_1 is switched back to ground. If the comparator output is low, then $V_{in} > V_{ref}/2$, and S_1 is left connected to V_{ref} and the MSB is set high. In a similar fashion the next bit, MSB-1, is evaluated. This procedure is continued until all N bits have been resolved. After the conversion process the voltage at the top plate is such that

$$V_x = -V_{in} + \left(b_3 \frac{V_{ref}}{2^1} + b_2 \frac{V_{ref}}{2^2} + b_1 \frac{V_{ref}}{2^3} + b_0 \frac{V_{ref}}{2^4} \right) \quad (40a)$$

$$- \frac{V_{ref}}{2^4} < V_x < 0 \quad (40b)$$

where b_i is 0 or 1 depending on whether bit i was set to zero or one, and LSB is the least significant bit.

One of the advantages of the charge redistribution topology is that the parasitic capacitance from the switches has little effect on its accuracy. Additionally, the clock feed-through from switch S_0 only causes an offset, and those from switches S_1, S_2, \dots, S_5 are independent of the input signal because the switches are always connected to either ground or V_{ref} . However, any mismatch in the binary ratios of the capacitors in the array causes nonlinearity, which limits the accuracy to 10 or 12 bits. Self-calibrating³⁹ techniques have been introduced that correct for errors in the binary ratios of the capacitors in charge redistribution topologies. However, these techniques are fairly complex, and for higher resolutions sigma-delta converters are the preferred topology. We now briefly describe sigma-delta converters.

Sigma-Delta Data Converters Oversampling converters sample the input at a rate larger than the Nyquist frequency. If f_s is the sampling rate, then $f_s/2f_0 = \text{OSR}$ is called the *oversampling ratio*. Oversampling converters have the advantage over Nyquist rate converters that they do not require very tight tolerances from the analog components and that they simplify the design of the antialias filter. Sigma-delta converters⁴⁰ are oversampling single-bit converters that use frequency shaping of the quantization noise to increase resolution without increasing the matching requirements for the analog components.

Figure 34 shows a block diagram for a general noise-shaping oversampled converter. In a sigma-delta converter both the ADC and DAC shown in Fig. 34 are single-bit versions and as such provide perfect linearity. The ADC, a comparator in the case of a sigma-delta converter, quantizes the output of the loop filter H_1 . The quantization process approximates an analog value by a finite-resolution digital value. This step introduces a quantization error Q_n . Further, if we assume that the quantization noise is not correlated to the input, then the system can be modeled as a linear

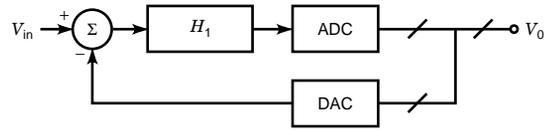

Fig. 34 Figure for general noise-shaping oversampled converter.

system. The output voltage for this system can now be written as

$$V_0 = \frac{Q_n}{1 + H_1} + \frac{V_{in} H_1}{1 + H_1} \quad (41)$$

For most sigma-delta converters H_1 has the characteristics of a low-pass filter and is usually implemented as a switched-capacitor integrator. For a first-order sigma-delta converter H_1 is realized as a simple switched-capacitor integrator, $H_1 = z^{-1}/(1 - z^{-1})$. Making this substitution in Eq. (41), we can write the transfer function for the first-order sigma-delta converter as

$$V_0 = V_{in} z^{-1} + Q_n (1 - z^{-1}) \quad (42)$$

As can be seen from Eq. (44) below, the output is a delayed version of the input plus the quantization noise multiplied by the factor $1 - z^{-1}$. This function has a high-pass characteristic with the result that the quantization noise is reduced substantially at lower frequencies and increases slightly at higher frequencies. The analog modulator shown in Fig. 34 is followed by a low-pass filter in the digital domain that removes the out-of-band quantization noise. Thus, we are left with only the in-band ($0 < f < f_0$) quantization noise. For simplicity the quantization noise is usually assumed to be white with a spectral density equal to $e_{rms} \sqrt{2/f_s}$. Further, if the OSR is sufficiently large, then we can approximate the root-mean-square (rms) noise in the signal band by

$$N_{f_0} \approx e_{rms} \frac{\pi}{3} \left(\frac{2f_0}{f_s} \right)^{3/2} \quad (43)$$

As the oversampling ratio increases, the quantization noise in the signal band decreases; for a doubling of the oversampling ratio the quantization noise drops by $20(\log 2)^{3/2} \approx 9$ dB. Therefore, for each doubling of the oversampling ratio we effectively increase the resolution of the converter by an additional 1.5 bits.

Clearly, H_1 can be replaced by other, higher order functions that have low-pass characteristics. For example, in Fig. 35 we show a second-order modulator. This modulator uses one forward delay integrator and one feedback delay integrator to avoid stability

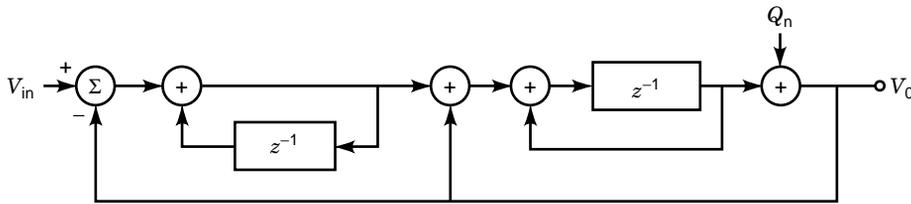

Fig. 35 Modulator for second-order oversampled converter.

problems. The output voltage for this figure can be written as

$$V_0 = V_{in}z^{-1} + Q_n(1 - z^{-1})^2 \quad (44)$$

The quantization noise is shaped by a second-order difference equation. This serves to further reduce the quantization noise at low frequencies, with the result that the noise power in the signal bandwidth falls by 15 dB for every doubling of the oversampling ratio. Alternatively, the resolution increases by 2.5 bits for every doubling of the oversampling ratio. In general, increasing the order of the filter will reduce the necessary oversampling ratio for a given resolution. However, for stability reasons, topologies other than the simple Candy-style⁴¹ modulator discussed above are required for filter orders greater than two. Topologies that avoid this stability problem include the multistage delta-sigma (MASH) and interpolative topologies.³⁷

For low-frequency inputs, the white-noise assumption for the quantization noise breaks down. This results in tones that reduce the effective resolution of lower order sigma-delta converters. Incremental converters utilize this observation to simplify the low-pass filter that follows the sigma-delta converter. Details for the incremental converter are discussed below.

We now consider two system design examples. The first is an acoustic emission sensor system and the second is a temperature measurement system.

2.3 System Design Examples

We illustrate the sensor and sensor interface scenario with two examples. The first uses a piezoelectric acoustic emission sensor interfaced with a charge amplifier and a data converter. The second describes an integrated temperature sensor.

Acoustic Emission Sensing System Acoustic emission sensors are microsensors that are used for the detection of acoustic signals. These devices use elastic acoustic waves at high frequencies to measure physical, chemical, and biological quantities. Typically, integrated acoustic sensors can be made to be extremely sensitive and also to have a large dynamic range. The output of these sensors is usually a frequency, a charge, or a voltage.

The piezoelectric effect is one of the most convenient ways to couple elastic waves to electrical circuits. Piezoelectricity is caused by the electric polarization produced by mechanical strain in certain crystals. Conversely, an electric polarization will induce a mechanical strain in piezoelectric crystals. As a consequence, when a voltage is applied to the electrodes of a piezoelectric film, it elongates or contracts depending on the polarity of the field. Conversely, when a mechanical force is applied to the film a voltage develops across the film. Some properties of a good piezoelectric film are wide frequency range, high elastic compliance, high output voltage, high stability in wet and chemical environments, high dielectric strength, low acoustic impedance, and low fabrication costs. Piezoelectric materials are anisotropic, and hence their electrical and mechanical properties depend on the axis of the applied electric force. The choice of the piezoelectric material depends on the application.

Crystalline quartz (SiO_2) is a natural piezoelectric substance. Some other commonly used piezoelectric materials are ferroelectric single-crystal lithium niobate (LiNbO_3) and thin films of ZnO and lead zirconium titanate (PZT). Recently, advances have been made in sensor technology with ultrasonic sensor configuration such as the surface acoustic wave (SAW) and acoustic plate mode (APM). In SAW devices the acoustic waves travel on the solid surface, and in an APM arrangement they bounce off at an acute angle between the bounding planes of a plate. The main types of acoustic wave sensors are shown in Fig. 36.⁴²

Piezoelectric thin films are particularly well suited for microsensors applications that require high reliability and superior performance. When prepared under optimal conditions piezoelectric thin films have a dense

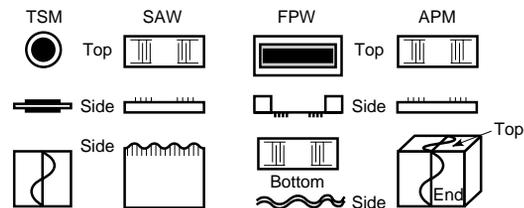

Fig. 36 Types of acoustic wave sensors.

microstructure without cracks and holes, good adherence, and good electrical properties. The three most popular materials used for thin film include ZnO (zinc oxide), AlN (aluminum nitride), and PZT (lead zirconium titanate). Deposition, sputtering, and sol-gel are some of the methods used for preparing piezo films the choice depends on the material and substrate used. ZnO thin films are prepared using laser-assisted evaporation and are often doped with lithium. Such films have excellent orientation. AlN thin films maintain a high acoustic velocity and are able to withstand extremely high temperatures. PZT thin films have a much higher piezoelectric coefficient than ZnO and AlN.

Recently, it has become possible to generate piezoelectric thin films with extremely good properties through the sol-gel process. This process consists of the following steps: synthesis of a metal-organic solution, deposition of this solution by spin coating, and a final heating that helps to crystallize the ceramic film. A cross-sectional view of a thin-film PZT sensor is shown in Fig. 37. The advantages of thin-film PZT sensors include their small size, which allows them to be positioned virtually anywhere, and their ability to operate at high frequencies.

Measurement Techniques. The different modes of use for an acoustic sensor are summarized in Fig. 38. Using either a resonator-transducer or a delay line, measurements can be made on the device itself or incorporated into an oscillator circuit. There are

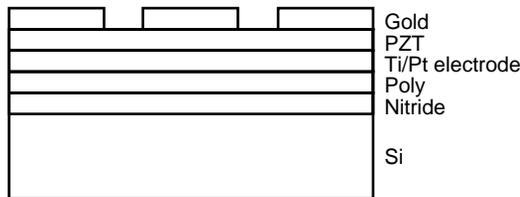

Fig. 37 Cross-sectional view of thin-film PZT sensor.

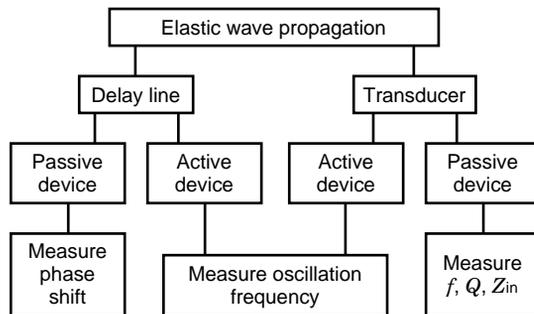

Fig. 38 Different measurement techniques for acoustic sensors.

basically two ways to implement this measurement technique: active or passive. In the case of passive bulk-wave resonators, we measure the resonant frequency to infer the wavelength and hence the velocity. Likewise, for passive delay lines the phase shift between the input and the output of the transducer, which are separated by a known distance, yields the velocity. On the other hand, for active resonators or delay-line oscillators, the frequency can be directly measured with the help of a digital counter.

As an example, let us consider the complete design and implementation of an integrated acoustic emission sensor with low-power signal-conditioning circuitry for the detection of cracks and unusual wear in aircraft and submarines. Within a health and usage monitoring system, it is necessary by some means, either directly or indirectly, to monitor the condition of critical components, for example, airframe, gearboxes, and turbine blades. The overall aim is to replace the current practice of planned maintenance with a regime of required maintenance. Typical parameters used include stress (or strain), pressure, torque, temperature, vibration, and crack detection. In this example, acoustic emission sensors are used for crack detection. The thin-film piezoelectric sensor, coupled to an aircraft component, senses the outgoing ultrasonic waves from any acoustic emission event as shown in Fig. 39. The magnitude of the output signal is proportional to the magnitude of the acoustic emission event. For our example design, the acoustic emission signal bandwidth varies from 50 kHz to approximately 1 MHz. Mixed in with the desired acoustic emission signal is vibration noise due to fretting of the mechanical parts. However, this noise is limited to about 100 kHz and is easily filtered out.

Due to the acoustic emission event, the piezoelectric sensor generates a charge on the top and bottom plates of the sensor. There are two basic methods of interfacing to this sensor. We can use either a voltage amplifier (Fig. 40) or a charge amplifier (Fig. 41).

In general, the charge amplifier interface provides a number of advantages. First, it is not affected by parasitic capacitances at the input of the amplifier. Second, the output voltage at the piezoelectric sensor is very small. This is because the piezoelectric material, PZT, that is used for its high piezoelectric coefficient

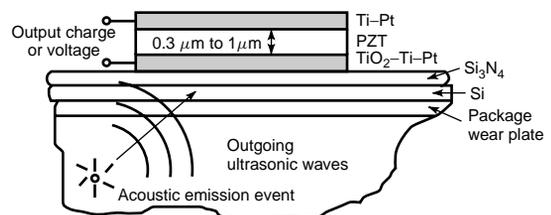

Fig. 39 Acoustic emission sensor.

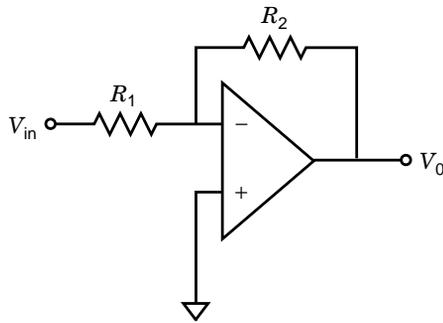

Fig. 40 Voltage amplifier.

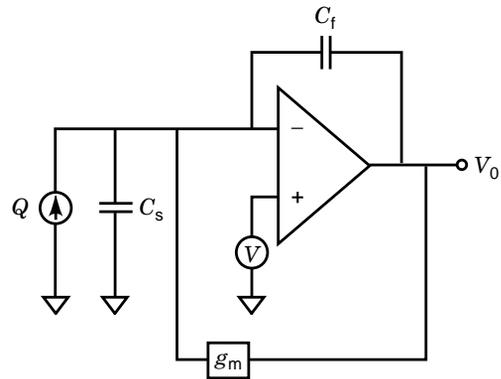

Fig. 42 Modified charge amplifier circuit.

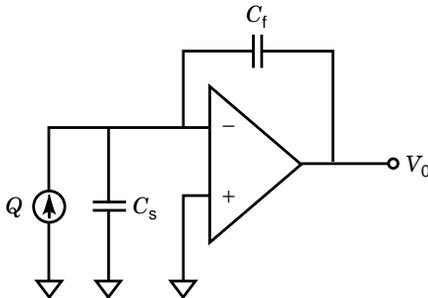

Fig. 41 Charge amplifier.

also has a very high dielectric constant. As shown below, the output voltage is proportional to the charge and inversely proportional to the dielectric constant:

$$V = \frac{Q}{C} = \frac{Q}{\epsilon A/d} = \frac{eSA}{\epsilon A/d} = \frac{eSd}{\epsilon} \quad (45)$$

[The output voltage can also be written in terms of the strain S , the distance d , the electron charge e , and the dielectric constant ϵ as shown in Eq. (47).] For these and other reasons the charge amplifier interface was selected for our design example.

The charge amplifier circuit shown in Fig. 41 is in its simplest form. The charge Q and capacitance C_s are used to model the sensor charge and sensor capacitance. The inverting terminal of the operational amplifier is a virtual ground, and no charge flows into the operational amplifier inputs. Therefore, any charge that is generated across the sensor has to flow into the feedback capacitance C_f . The output voltage developed across the feedback capacitor is inversely proportional to the value of this capacitance. The voltage gain of the circuit is given by the ratio of C_s to C_f , and hence, to obtain high gain, C_f can be made much smaller than C_s . This basic topology has a number of limitations, including low-frequency flicker

noise of the amplifier operational amplifier offset, and long-term drift. Traditionally, correlated double sampling and chopper stabilization are used to remove low-frequency noise and offset. However, as noted earlier, our signal band does not include the frequencies from dc to 50 kHz, and our maximum signal frequencies are fairly high. Therefore, an alternative design topology shown in Fig. 42 was selected to circumvent the problem.

Here, low-frequency feedback is provided to reduce the effects of offset, long-term drift, and low-frequency noise. In the modified circuit, a transconductor is connected in negative feedback. The transfer function of the modified circuit is given by

$$\frac{V_0(s)}{Q_{in}(s)} = -\frac{s(g_{ma} - g_m - C_f s)}{C_s C_f s^2 + s(C_s g_m + g_{ma} C_f) + g_{ma} g_m} \quad (46)$$

In this equation, C_s is the sensor capacitance, C_f is the feedback capacitance of the operational amplifier, g_{ma} and g_m are the transconductances of the operational amplifier and the transconductor. If the higher order terms are neglected, then Eq. (46) can be simplified to

$$\frac{V_0(s)}{Q_{in}(s)} = -\left(\frac{s}{g_m}\right) \left(\frac{1}{1 + \frac{C_s s}{g_{ma}}}\right) \quad (47)$$

From Eq. (47) it is clear that the circuit has the characteristics of a high-pass filter that is, none of the low-frequency noise or offsets affect the circuit performance.

Next, we perform a power analysis to analyze the effects of different design tradeoffs. Both MOS and bipolar transistor technologies are considered, and power and noise analysis and design tradeoffs for both technologies are presented.

Power Analysis. If MOS transistors in strong inversion (SI) are used to implement the operational amplifier then the minimum power requirement is given by

$$P = VI = \frac{V(2\pi BWC)^2}{2K(W/L)} \quad (48)$$

where BW is the signal bandwidth, C is the sensor capacitance, K is the transconductance factor, V is the output voltage, I is the supply current, and W/L is the aspect ratio of the transistor. From this equation it is clear that the power is proportional to the square of the signal bandwidth and sensor capacitance.

If, however, bipolar transistors are used to implement the operational amplifier the minimum power requirement is given by

$$P = VI = V2\pi BW U_T C \quad (49)$$

Here, U_T is the thermal voltage, which is equal to 26 mV at room temperature. From this equation it is clear that in the case of bipolar transistors, the power is linearly proportional to the signal bandwidth and sensor capacitance. This difference in the power consumption between bipolar and MOS implementations for a signal frequency of 1 MHz is shown in Fig. 43. Here we note that the power consumption for both MOS and bipolar implementations increases with increased sensor capacitance. However, for very low frequencies, the MOS devices can be operated in weak inversion (WI). In WI, MOS devices behave very similarly to bipolar devices, and hence the slopes for weak inversion and bipolar devices are initially very similar. However, at higher frequencies MOS devices are forced to operate in strong inversion and hence consume more power for the same performance.

Next, we consider the design tradeoffs in connection with device noise.

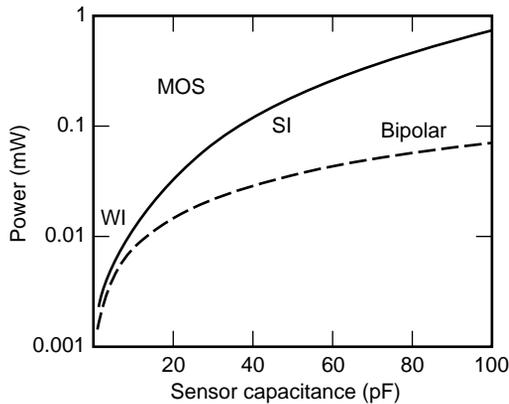

Fig. 43 Minimum power requirements versus sensor capacitance for a MOS or bipolar design.

Noise Analysis. The power spectral density for the wideband gate-referred noise for MOS transistors is given by

$$V_{nT}^2 = \frac{8kT}{3g_m} \quad (50)$$

Here, k is Boltzmann's constant, T is the temperature, g_m is the transconductance. Likewise, for bipolar transistors the power spectral density for the wide-band input-referred noise voltage is given by

$$V_{nT}^2 = 2qI_C \quad (51)$$

For both MOS and bipolar implementations the total rms input-referred noise is independent of frequency and inversely proportional to the sensor capacitance as shown in Fig. 44. Here, we note that the ratio of the noise spectral density for the MOS and the bipolar implementations is a constant equal to 4.

In summary we note that: For an MOS implementation the power consumption is proportional to the square of the sensor capacitance, whereas for a bipolar implementation it is linearly proportional to the sensor capacitance. On the other hand, the input-referred noise for both the MOS and bipolar implementations is inversely proportional to the sensor capacitance. Thus, there is a clear tradeoff between the minimum power consumption and the maximum input-referred noise. If the sensor capacitance is increased, then the input-referred noise decreases, but the power increases, and vice versa. Using the equation above, we can calculate the minimum bound on the power requirements for our application. For 10 bits of accuracy and a signal bandwidth of 1 MHz, the minimum sensor capacitance size is 5 pF and the minimum power consumption is around 500 μ W.

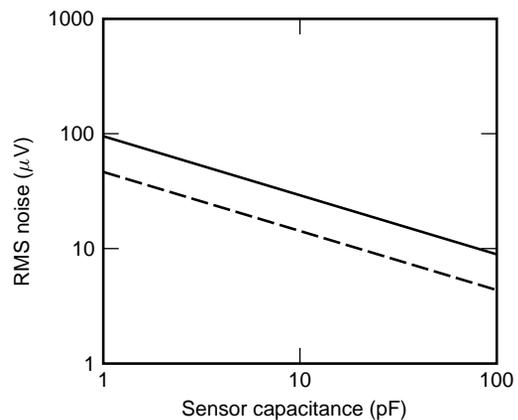

Fig. 44 Noise power spectral density versus capacitance.

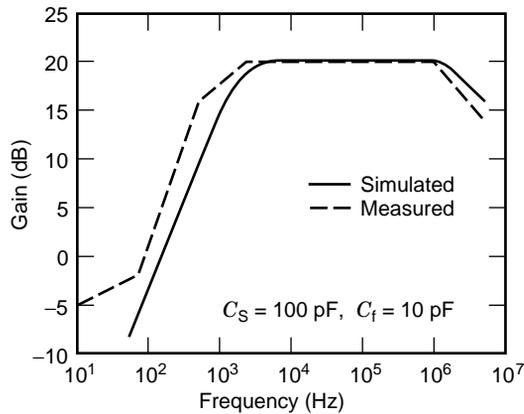

Fig. 45 Small-signal frequency response of charge amplifier.

Next, we provide some simulation and measurement results for our acoustic emission sensor system.

Results. Simulation and measurement results for the charge amplifier with a sensor capacitance of 100 pF and a feedback capacitance of 10 pF are shown in Fig. 45. For this measurement, discrete versions of the sensor and feedback capacitors were used. As expected, the signal band gain is given by the ratio of the sensor to the feedback capacitance, which is equal to 20 dB. Both measurement and simulation results agree fairly well with this value. The primary difference between the measurement and simulation results is in the low-frequency and high-frequency poles. It is expected that this is largely a result of parasitic capacitances and possibly a lower realized transconductance in comparison with the simulated value.

The charge amplifier circuit design just described converts the sensor charge into a voltage. This amplifier signal voltage is then converted to digital form using an ADC. For our implementation a 10-bit fourth-order sigma-delta implemented as a MASH topology was used. The fourth-order topology was used to keep the oversampling ratio low, as the signal frequency is fairly high. Details of this implementation are not included here; interested readers are referred to Ref. 37 for more information.

Next, we describe a complete temperature sensor system.

Temperature-Sensing System In many control systems, temperature sensors are used as the primary sensor. Additionally, as most electronic components and circuits are affected by temperature fluctuations, temperature sensors are often needed in microsensor systems to compensate for the temperature variations of the primary sensor or sensors.

Because integrated sensors can be manufactured on the same substrate as the signal-processing circuitry,

most recent temperature measurement schemes concentrate on integrated silicon temperature sensors. The resulting smart sensor is extremely small and is also able to provide extremely high performance, as all the signal processing is done on chip before the data is transmitted. This avoids the usual signal corruption that results from data transmission. The disadvantage of the smart sensor is that since all the processing is done on chip, it is no longer possible to maintain the signal preprocessing circuits in an isothermal environment. The on-chip sensor interface electronics must therefore be temperature insensitive or be compensated to provide a temperature-insensitive output.

A *smart* temperature sensor is a system that combines on the same chip all the functions needed for measurement and conversion into a digital output signal. A smart temperature sensor includes a temperature sensor, a voltage reference, an ADC, control circuitry, and calibration capabilities. A block diagram for a smart temperature sensor is shown in Fig. 46. The use of *p-n* junctions as temperature sensors and for the generation of the reference voltage signals has been reported extensively.^{43,44} A bandgap voltage reference can be generated with the help of a few *p-n* junctions. The basic principle for the operation of a bandgap voltage reference is illustrated in Fig. 47.

The base-emitter voltage V_{be} of a bipolar transistor decreases almost linearly with increasing temperature. The temperature coefficient varies with the applied current, but is approximately $-2 \text{ mV}/^\circ\text{C}$. It is also well known that the difference between the base-emitter voltages of two transistors, ΔV_{be} , operated at a constant ratio of their emitter current densities, possesses a positive temperature coefficient. At an emitter

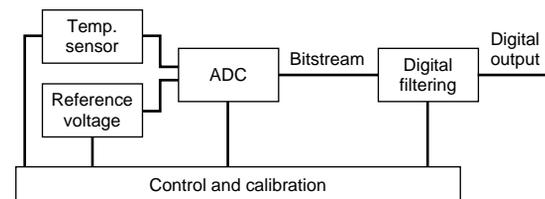

Fig. 46 Smart temperature sensor.

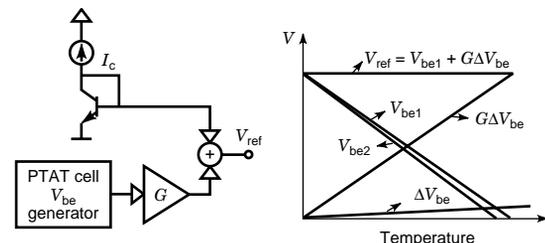

Fig. 47 Principle of bandgap reference.

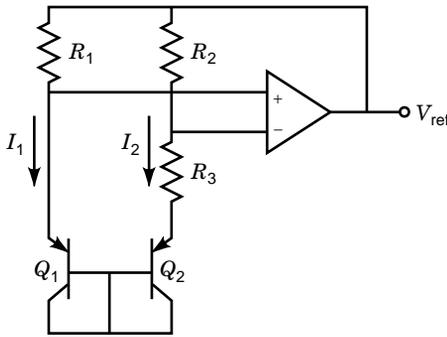

Fig. 48 Example bandgap voltage reference circuit.

current density ratio of 8, the temperature coefficient of this PTAT (proportional to absolute temperature) source is approximately $0.2 \text{ mV}/^\circ\text{C}$. Amplifying this voltage ($G\Delta V_{be}$) and adding it to a base-emitter voltage V_{be} produces a voltage reference that is independent of temperature. Many circuits have been developed to realize bandgap voltage references using this principle.^{45,46} A circuit diagram for one of the early bandgap reference implementations is shown in Fig. 48.⁴⁷

For an ideal operational amplifier the differential input voltage is equal to zero, so that resistors R_1 and R_2 have equal voltages across them. Since the voltage across the resistors is the same, the two currents I_1 and I_2 must have a ratio that is determined solely by the ratio of the resistances R_1 and R_2 . The base-emitter voltage of a diode-connected bipolar transistor is given by Eq. (52), where T is the absolute temperature of the junction, I_s is the reverse saturation current, I_d is the current through the junction, k is Boltzmann's constant, q is the electronic charge, and n is a constant that depends on the junction material and fabrication technique. To see this, we write

$$V_{be} = \frac{nkT}{q} \ln \frac{I_d + I_s}{I_s} \approx \frac{nkT}{q} \ln \frac{I_d}{I_s} \quad (52)$$

Therefore, the difference between the two base-emitter voltages (ΔV_{be}) is given by

$$\Delta V_{be} = V_{be1} - V_{be2} = \frac{nkT}{q} \ln \frac{I_1 I_{s2}}{I_2 I_{s1}} = \frac{nkT}{q} \ln \frac{R_2 I_{s2}}{R_1 I_{s1}} \quad (53)$$

This voltage appears across R_3 . Since the same current that flow through R_3 also flow through R_2 , the voltage across R_2 is given by

$$V_{R_2} = \frac{R_2}{R_3} \Delta V_{be} = \frac{R_2}{R_3} \frac{nkT}{q} \ln \frac{R_2 I_{s2}}{R_1 I_{s1}} \quad (54)$$

as desired.

The output voltage is the sum of the voltage across R_1 and the voltage across Q_1 . Since the voltage across R_1 is equal to the voltage across R_2 , the output voltage is equal to

$$V_{\text{out}} = V_{be1} + \frac{R_2}{R_3} \frac{nkT}{q} \ln \frac{R_2 I_{s2}}{R_1 I_{s1}} = V_{be1} + G \Delta V_{be} \quad (55)$$

Therefore, this circuit behaves as a bandgap reference, where the gain factor G is set by the ratios R_2/R_3 , R_2/R_1 , and I_{s2}/I_{s1} . In many designs $R_2 = R_1$ and $I_{s2} = 8I_{s1}$. Since the reverse saturation current I_s is proportional to the emitter area, to make $I_{s2} = 8I_{s1}$ we let the emitter area of Q_2 be 8 times as large as the emitter area of Q_1 .

The operational amplifier's input-referred voltage offset is the largest error source in this type of voltage reference. This voltage offset is highly temperature dependent and nonlinear, making an accurate calibration of such a reference virtually impossible. It is therefore necessary to use some type of offset cancellation technique such as autozero or chopper stabilization.⁴⁸

Another source of error is the nonzero temperature coefficient of the resistors. Usually, on-chip resistors are used in the form of polysilicon resistors or well resistors. Both of these resistor implementations tend to occupy very large amounts of chip area if low power is desired. Low-power implementations demand the use of large-value resistors, which unfortunately require large areas. Though well resistors have a much larger resistivity than polysilicon resistors, they also have a very nonlinear temperature coefficient, which makes for difficult calibration.

A solution to these problems is to use switched-capacitor circuits to implement the resistors in the voltage reference circuit. A switched-capacitor implementation makes offset removal simple and also reduces the power consumption, as the area occupied by large-value switched-capacitor resistors is significantly smaller than the area occupied by continuous-time resistors. In fact, the area occupied by switched-capacitor resistors is inversely proportional to the value of the resistance desired. Another advantage is that the temperature coefficient of on-chip poly-poly capacitors is much smaller than that of on-chip resistors, making design and calibration easier. A switched-capacitor implementation of the bandgap voltage reference is shown in Fig. 49.

The structure of this voltage reference is similar to the one shown in Fig. 48, except that the continuous time resistors have been replaced by switched-capacitor resistors, and capacitors C_T and C_F have been added. The switched capacitors emulate resistors with an effective resistance value given by

$$R_{\text{eff}} = \frac{1}{f_C C} \quad (56)$$

where f_C is the clock frequency of the switch. The feedback capacitor C_F is designed to be very small

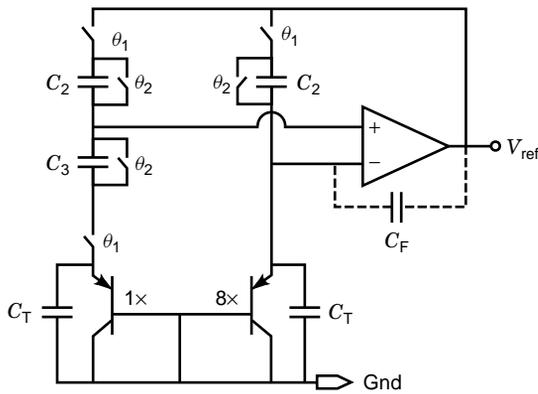

Fig. 49 Switched-capacitor implementation of bandgap reference.

and is added to ensure the operational amplifier is never in an open-loop mode of operation. The capacitors located in parallel with the diodes act as tank capacitors to ensure that current is constantly supplied to the diodes. The output of this voltage reference can similarly be calculated and is given by

$$V_{ref} = V_{be1} + \frac{C_3 nkT}{C_2 q} \ln \frac{C_1 I_{s2}}{C_2 I_{s1}} = V_{be1} + G \Delta V_{be} \tag{57}$$

which is the desired bandgap voltage reference.

Most temperature-sensing devices also use the difference between two diodes (ΔV_{be}) as the sensing element of the system. Since the temperature coefficient of ΔV_{be} is small ($\approx 0.2 \text{ mV}/^\circ\text{C}$), it is almost always amplified to a much larger value ($\approx 10 \text{ mV}/^\circ\text{C}$) for increased sensitivity. Since we already have an amplified value of ΔV_{be} in the voltage reference ($G \Delta V_{be}$), all that needs to be done is to subtract V_{be1} from the voltage reference to obtain an amplified value of ΔV_{be} .

If more sensitivity is needed, the additional amplification can be incorporated in the ADC by simply adjusting the capacitor ratio of C_A and C_B as shown in Fig. 50. Additionally, the subtraction of V_{be1} from the voltage reference can be easily accomplished with the circuit shown in Fig. 51, where V_{in1} is the output of the voltage reference, V_{in2} is equal to V_{be1} , and V_G is the negative input of the operational amplifier in the follow-on data converter. During clock cycle θ_1 the capacitor C is charged to the input voltage V_{in2} . During clock cycle θ_2 , the charge $(V_{in1} - V_{in2})/C$ is transferred. This circuit effectively does the voltage subtraction that is needed to obtain the amplified temperature-dependent output voltage ($G \Delta V_{be}$).

Incorporating the voltage reference and temperature-sensing circuitry shown in Figs. 49 and 51 into a smart temperature sensor system involves some additional circuitry. Since switched capacitors are already being used for the voltage reference and the sensing circuitry, it makes sense to use switched-capacitor technology for the ADC. A simple ADC that utilizes oversampling techniques is the incremental converter.⁴⁹ The advantage of this data converter topology, shown in Fig. 50, is its low power consumption, small area, and insensitivity to component mismatch. Additionally, in comparison with sigma-delta converters the postquantization digital low-pass filter is much simpler. It consists of just an up-down counter instead of a more complicated decimation filter. Unfortunately, the first-order incremental ADC has a relatively long conversion time, making this converter suitable only for very slow signals such as temperature.

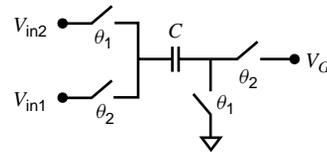

Fig. 51 Switched-capacitor subtraction circuit.

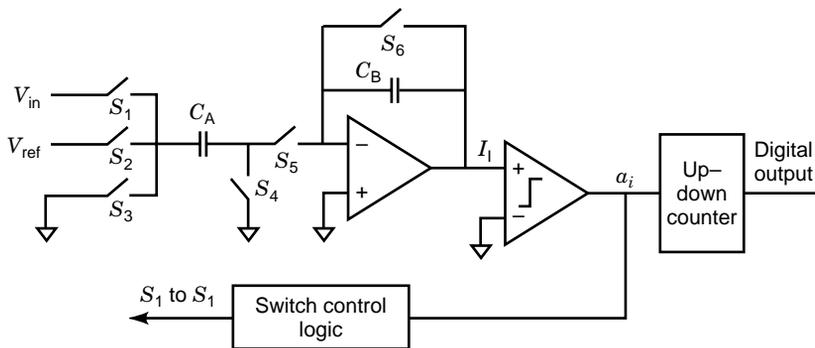

Fig. 50 Incremental ADC.

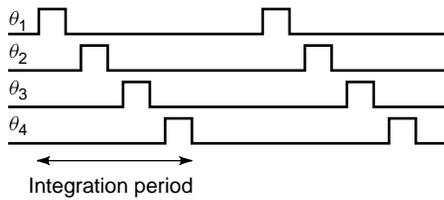

Fig. 52 Four-phase nonoverlapping clock.

The first-order incremental ADC shown in Fig. 50 is composed of a stray-insensitive switched-capacitor integrator, a comparator, switch control logic, and an up-down counter. A four-phase nonoverlapping clock as shown in Fig. 52 constitutes an integration period. The integrator output voltage is designated by $V_1[i, j]$, where i corresponds to the current integration period and j to the clock cycle (1, 2, 3, or 4).

During clock cycle θ_1 , S_1 and S_4 are closed, charging C_A to the input voltage V_{in} . During θ_2 , S_3 and S_5 are closed, transferring the charge that was stored on C_A to C_B . At the end of the charge transfer from C_A to C_B the comparator output is denoted by

$$a_i = \begin{cases} 1 & \text{if } V_1[i, 2] > 0 \\ -1 & \text{if } V_1[i, 2] < 0 \end{cases}$$

During θ_3 , S_4 is closed, and if:

$$a_i = \begin{cases} 1 & S_3 \text{ is closed} \\ -1 & S_2 \text{ is closed} \end{cases}$$

During θ_4 , S_5 is closed, and if:

$$a_i = \begin{cases} 1 & S_2 \text{ is closed} \\ -1 & S_3 \text{ is closed} \end{cases}$$

Also during θ_4 , the integrator output voltage $V_1[i, 4]$ is given by

$$V_1[i, 4] = V_1[i, 1] + \frac{C_A}{C_B} (V_{in} - a_i V_{ref}) \quad (58)$$

The final N -bit output code, denoted by D_{out} , that results from the up-down counter is obtained by evaluating the quantity

$$D_{out} = \frac{1}{n} \sum_{i=1}^n a_i \quad (59)$$

Here n is the number of integration periods, and is a function of the resolution that is required of the ADC.

The complete smart temperature sensor is shown in Fig. 53. The subtraction circuit of Fig. 51 is incorporated into the ADC by simply adding switch S_{sub} . The only difference in the operation of the incremental converter shown in Fig. 53 from the one shown in Fig. 50 is that now during θ_2 , S_3 is not closed but instead S_{sub} is closed.

The calibration of this system is done in two steps. First the voltage reference is calibrated by adjusting the ratio of C_3 and C_2 ; next the amplified sensor voltage is calibrated by adjusting the ratio of C_A and C_B . Adjusting the ratios of the capacitors is done with the use of a capacitor array that is controlled digitally. The output is an N -bit digital word.

In Fig. 54 we show measurement results for the voltage reference and final temperature output. For these results a first-pass design of the circuit in Fig. 53 was used. This design was not completely integrated and included external resistors to obtain gain. We expect final integrated results to behave similarly. Figure 54a shows the reference voltage obtained as a sum of a V_{be} and an amplified ΔV_{be} as described in Eq. (57). The x axis shows the temperature in kelvin and the y axis shows the measured output reference voltage in volts. The measured value is fairly close to the expected value except for some small experimental variations. We suspect these variations are a result of the length of time used to stabilize the temperature between temperature output measurements. The graph in Fig. 54b shows the output voltage, which is $V_{ref} - V_{be}$. As expected, this voltage varies linearly with temperature. Figure 55 shows the expected 1-bit output stream (a_i shown in Fig. 54) of the sigma-delta converter before the digital low-pass filter. This output corresponds to an input voltage equal to one-eighth of the reference voltage.

We have provided detailed designs for two complete data acquisition systems, namely an acoustic emission sensor system and a smart temperature sensor system. We provide both measurement and simulation results to show their performance.

2.4 Conclusion

In this section we have provided brief descriptions of data acquisition and data conversion systems. In particular, we provided some general descriptions of integrated capacitive and resistive sensors. This was followed by descriptions of two of the most common data converter topologies used in sensor interface systems, namely successive approximation and sigma-delta. Finally, these were followed by detailed descriptions of two complete acquisition systems. The first system was based on a piezoelectric acoustic emission sensor interfaced to a charge amplifier and data converter. The second system was a smart temperature sensor. As feature sizes continue to decrease and integrated sensor technologies progress, it is likely that extremely smart and high-performance systems will be integrated on single chips. Additionally, significant

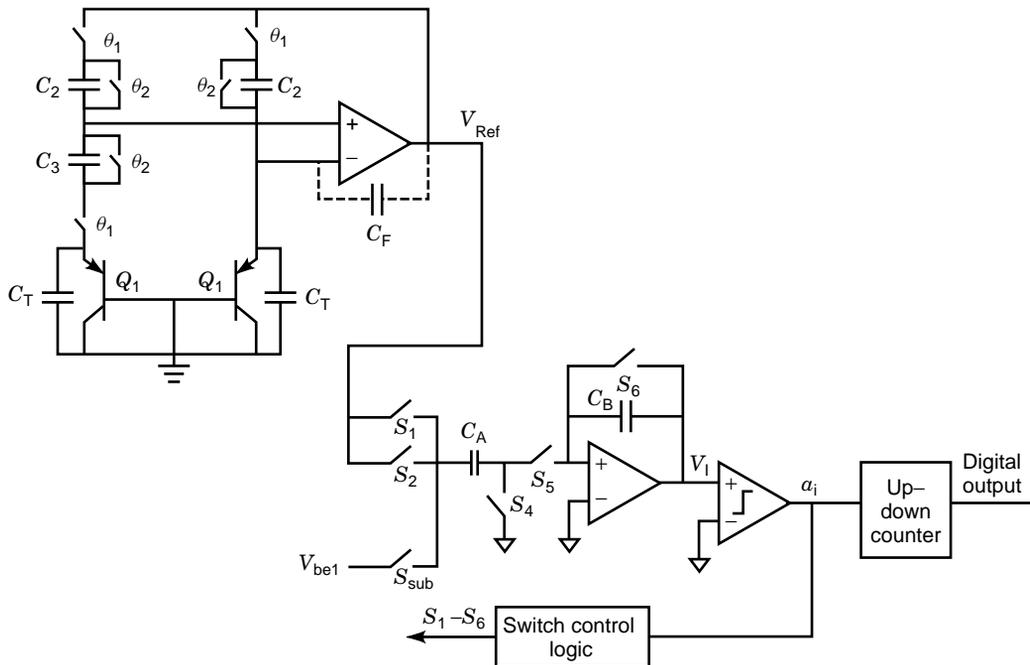

Fig. 53 Smart temperature sensor circuit.

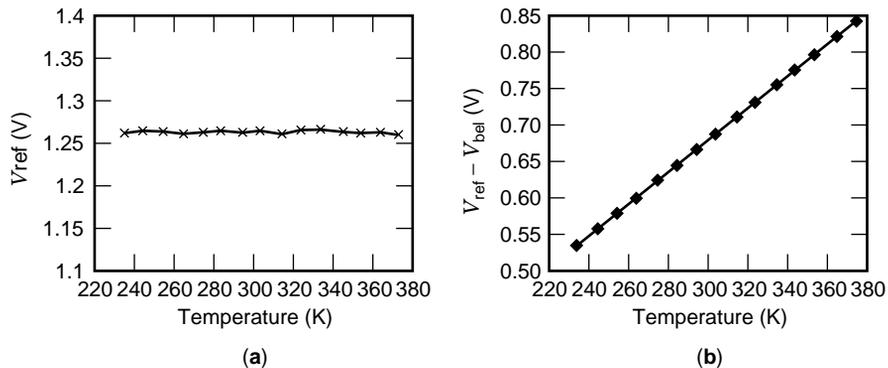

Fig. 54 Measurement results for the (a) voltage reference and (b) temperature sensor.

reduction in power and area as a result of smaller feature sizes will make such systems ubiquitous.

3 DATA ANALYSIS

Arbee L. P. Chen and Yi-Hung Wu

What is data analysis? Nolan⁵⁰ gives a definition that is a way of making sense of the patterns that are in, or can be imposed on, sets of figure. In concrete terms, data analysis consists of an observation and an investigation

of the given data, and the derivation of characteristics from the data. Such characteristics, or features as they are sometimes called, contribute to the insight of the nature of data. Mathematically, the features can be regarded as some variables, and the data are modeled as a realization of these variables with some appropriate sets of values. In traditional data analysis,⁵¹ the values of the variables are usually numerical and may be transformed into symbolic representation. There are two general types of variables: discrete and continuous.

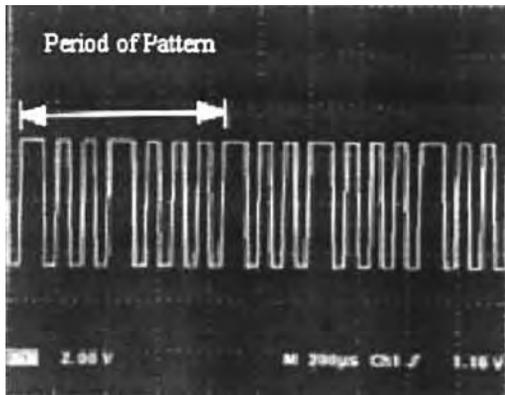

Fig. 55 Measurement results for analog-to-digital converter.

Discrete variables vary in units, such as the number of words in a document or the population in a region. In contrast, continuous variables can vary in less than a unit to a certain degree of accuracy. The stock price and the height of people are examples of this type. The suitable method for collecting values of discrete variables is counting, and for continuous ones it is measurement.

The task of data analysis is required among various application fields, such as agriculture, biology, economics, government, industry, medicine, military, psychology, and science. The source data provided for different purposes may be in various forms, such as text, image, or wave form. There are several basic types of purposes for data analysis:

1. Obtain the implicit structure of data
2. Derive the classification of data
3. Search particular objects in data

For example, the stockbroker would like to get the future trend of the stock price, the biologist needs to divide animals into taxonomies, and the physician tries to find the related symptoms of a given disease. The techniques to accomplish these purposes are generally drawn from statistics that provide well-defined mathematical models and probability laws. In addition, some theories, such as fuzzy-set theory, are also useful for data analysis in particular. This section is an attempt to give a brief description of these techniques and concepts of data analysis. In Section 3.1, a variety of data analysis methods are introduced and illustrated by examples. We first give two categories of data analysis according to its initial conditions and resultant uses. Next, we show two well-known methods based on different mathematical models. In Section 3.2, an approach to data analysis for Internet applications is proposed. Some improvements of the data analysis methods are discussed in Section 3.3. Finally, we give a brief summary.

3.1 Data Analysis Methods

In data analysis, the goals are to find significant patterns in the data and apply this knowledge to some applications. Analysis is generally performed in the following stages:

1. Feature selection
2. Data classification
3. Conclusion evaluation

The first stage consists of the selection of the features in the data according to some criteria. For instance, features of people may include their height, skin color, and fingerprints. Considering the effectiveness of human recognition, the fingerprint, which is the least ambiguous, may get the highest priority for selection. In the second stage, the data are classified according to the selected features. If the data consist of at least two features, for example, the height and the weight of people, which can be plotted in a suitable coordinate system, we can inspect so-called scatter plots and detect clusters or contours for data grouping. Furthermore, we can investigate ways to express data similarity. In the final stage, the conclusions drawn from the data would be compared with the actual demands. A set of mathematical models has been developed for this evaluation. In the following sections, we first divide the study of data analysis into two categories according to different initial conditions and resultant uses. Then, we introduce two famous models for data analysis. Each method will be discussed first, followed by examples. Because the feature selection depends on the actual representations of data, we postpone the discussion about this stage until the next section. In this section, we focus on the classification procedure based on the given features.

Categorization of Data Analysis There are a variety of ways to categorize the methods of data analysis. According to the initial conditions and the resultant uses, there are two categories, supervised data analysis and unsupervised data analysis. The term *supervised* means that human knowledge has to be provided for the process. In supervised data analysis, we specify a set of classes called a *classification template* and select some samples from the data for each class. These samples are then labeled by the names of the associated classes. Based on this initial condition, we can automatically classify the other data termed *to-be-classified* data. In *unsupervised* data analysis, there is no classification template, and the resultant classes depend on the samples. Following are descriptions of supervised and unsupervised data analysis with an emphasis on their differences.

Supervised Data Analysis. The classification template and the well-chosen samples are given as an initial state and contribute to the high accuracy of

data classification. Consider the K nearest-neighbor classifier which is a typical example of supervised data analysis. The input to the classifier includes a set of labeled samples S , a constant value K , and a to-be-classified datum X . The output after the classification is a label denoting a class to which X belongs. The classification procedure is as follows.

1. Find the K nearest neighbors (K NNs) of X from S .
2. Choose the dominant classes by K NNs.
3. If there exists only one dominant class, label X by this class; otherwise, label X by any dominant class.
4. Add X to S , and the process terminates.

The first step selects K samples from S such that the values of the selected features (also called patterns) of these K samples are closest to those of X . Such a similarity may be expressed in a variety of ways. The measurement of distances among the patterns is one of the suitable instruments, for example, the Euclidean distance as shown in Eq. (60). Suppose the K samples belong to a set of classes; the second step is to find the set of dominant classes C' . A dominant class is a class that contains the majority of the K samples. If there is only one element in C' , say class C_i , we assign X to C_i . On the other hand, if C' contains more than one element, X is assigned to an arbitrary class in C' . After deciding on the class of X , we label it and add it into the set S .

$$\delta(X, Y) = \sqrt{\sum_{k=1}^m (X_k - Y_k)^2} \quad (60)$$

where each datum is represented by m features.

Example. Suppose there is a data set about the salaries and ages of people. Table 1 gives such a set of samples S and the corresponding labels. There are three labels that denote three classes: rich, fair, and poor. These classes are determined based on the assumption that richness depends on the values of the salary and age. In Table 1, we also append the rules for assigning labels for each age. From the above, we can get the set membership of each class.

$$C_{\text{rich}} = \{Y_1, Y_4, Y_8\} \quad C_{\text{fair}} = \{Y_2, Y_5, Y_6, Y_{10}\}$$

$$C_{\text{poor}} = \{Y_3, Y_7, Y_9\}$$

If there is a to-be-classified datum X with age 26 and salary \$35,000 (35k), we apply the classification procedure to classify it. Here we let the value of K be 4 and use the Euclidean distance as the similarity measure.

1. The set of 4 NNs is $\{Y_4, Y_5, Y_6, Y_9\}$.

Table 1 Set of Samples with Salary and Age Data

Sample	Age	Salary	Label	Assumed Rules to Assign Labels
Y_1	20	25k	Rich	rich, >20k; poor, <10k
Y_2	22	15k	Fair	rich, >26k; poor, <13k
Y_3	24	15k	Poor	rich, >35k; poor, <16k
Y_4	24	40k	Rich	
Y_5	28	25k	Fair	rich, >44k; poor, <22k
Y_6	30	40k	Fair	rich, >50k; poor, <25k
Y_7	30	20k	Poor	
Y_8	32	60k	Rich	rich, >56k; poor, <28k
Y_9	36	30k	Poor	rich, >68k; poor, <34k
Y_{10}	40	70k	Fair	rich, >80k; poor, <40k
X	26	35k	Fair	rich, >38k; poor, <19k

2. The dominant class is the class C_{fair} because $Y_6, Y_5 \in C_{\text{fair}}, Y_4 \in C_{\text{rich}}$, and $Y_9 \in C_{\text{poor}}$.
3. Label X by C_{fair} .
4. New sample S contains an updated class $C_{\text{fair}} = \{Y_2, Y_5, Y_6, Y_{10}, X\}$.

We can also give an assumed rule to decide the corresponding label for the age of X as shown in Table 1. Obviously, the conclusion drawn from the above classification coincides with such an assumption from human knowledge.

Unsupervised Data Analysis. Under some circumstances, data analysis consists of a partition of the whole data set into a number of subsets. Moreover, the data within each subset have to be similar to a high degree, whereas the data between different subsets have to be similar to a very low degree. Such subsets are called clusters, and the way to find a good partition is sometimes also called cluster analysis. There are a variety of methods developed to handle this problem. A common characteristic among them is the iterative nature of the algorithms.

The C -mean clustering algorithm is representative in this field. The input contains the sample set S and a given value C , which denotes the number of clusters in the final partition. Notice that no labels are assigned to the samples in S in advance. Before classification we must specify an initial partition W_0 with C clusters. The algorithm terminates when it converges to a stable situation in which the current partition remains the same as the previous one. Different initial partitions can lead to different final results. One way to get the best partition is to apply this algorithm with all different W_0 's. To simplify the illustration, we only consider a given W_0 and a fixed C . The classification procedure is as follows.

1. Let W be W_0 on S .
2. Compute the mean of each cluster in W .
3. Evaluate the nearest mean of each sample and move a sample if its current cluster is not the one corresponding to its nearest mean.

- If any movement occurs, go to step 2; otherwise, the process terminates.

The first step sets the current partition W to be W_0 . Then we compute a set of means M in W . In general, a mean is a virtual sample representing the whole cluster. It is straightforward to use averaging as the way to find M . Next, we measure the similarities between each sample in S and every mean M . Suppose a sample Y_j belongs to a cluster C_i in the previous partition W , while another cluster C_k has a mean nearest to Y_j . Then we move Y_j from C_i to C_k . Finally, if there exists such a sample movement, the partition W would become a new one and requires more iterations. On the other hand, if no such movement occurs during an iteration, the partition would become stable and produce the final clustering.

Example. Consider the data in Table 1 again. Suppose there is no label on each sample and only the salary and the age data are used as the features for analysis. For clarity, we use a pair of values on the two features to represent a sample, for instance, the pair (20, 25k) refers to the sample Y_1 . Suppose there is an initial partition containing two clusters C_1 and C_2 . Let the means of these clusters be M_1 and M_2 , respectively. The following shows the iterations for the clustering.

- For the initial partition W : $C_1 = \{Y_1, Y_2, Y_3, Y_4, Y_5\}$, $C_2 = \{Y_6, Y_7, Y_8, Y_9, Y_{10}\}$.

First iteration

- $M_1 = (23.6, 24k)$, $M_2 = (33.6, 44k)$.
- Move Y_4 from C_1 to C_2 ; move Y_7 and Y_9 from C_2 to C_1 .
- For the new partition W : $C_1 = \{Y_1, Y_2, Y_3, Y_5, Y_7, Y_9\}$, $C_2 = \{Y_4, Y_6, Y_8, Y_{10}\}$.

Second iteration

- $M_1 = (26.6, 21.6k)$, $M_2 = (31.5, 52.5k)$.
- There is no sample movement; the process terminates.

We can easily find a simple discriminant rule behind this final partition. All the samples with salaries lower than 40k belong to C_1 , and the others belong to C_2 . Hence we may conclude with a discriminant rule that divides S into two clusters by checking the salary data. If we use another initial partition, say W' , where $C_1 = \{Y_1, Y_3, Y_5, Y_7, Y_9\}$ and $C_2 = \{Y_2, Y_4, Y_6, Y_8, Y_{10}\}$, the conclusion is the same. The following process yields another partition with three clusters.

- For the initial partition W : $C_1 = \{Y_1, Y_4, Y_7\}$, $C_2 = \{Y_2, Y_5, Y_8\}$, $C_3 = \{Y_3, Y_6, Y_9, Y_{10}\}$.

First iteration

- $M_1 = (24.6, 28.3k)$, $M_2 = (27.3, 33.3k)$, $M_3 = (32.5, 38.7k)$.
- Move Y_4 from C_1 to C_2 , move Y_2 and Y_5 from C_2 to C_1 , move Y_8 from C_2 to C_3 , move Y_3 from C_3 to C_1 , move Y_9 from C_3 to C_2 .
- For the new partition W : $C_1 = \{Y_1, Y_2, Y_3, Y_5, Y_7\}$, $C_2 = \{Y_4, Y_9\}$, $C_3 = \{Y_6, Y_8, Y_{10}\}$.

Second iteration

- $M_1 = (24.8, 20k)$, $M_2 = (30, 35k)$, $M_3 = (34, 56.6k)$.
- Move Y_6 from C_3 to C_2 .
- For the new partition W : $C_1 = \{Y_1, Y_2, Y_3, Y_5, Y_7\}$, $C_2 = \{Y_4, Y_6, Y_9\}$, $C_3 = \{Y_8, Y_{10}\}$.

Third iteration

- $M_1 = (24.8, 20k)$, $M_2 = (30, 36.6k)$, $M_3 = (36, 65k)$.
- There is no sample movement; the process terminates.

After three iterations, we have a stable partition and also conclude with the discriminant rule that all the samples with salaries lower than 30k belong to C_1 , the other samples with salaries lower than 60k belong to C_2 , and the remainder belongs to C_3 . The total number of iterations depends on the initial partition, the number of clusters, the given features, and the similarity measure.

Methods for Data Analysis In the following, we introduce two famous techniques for data analysis. One is Bayesian data analysis based on probability theory, and the other is fuzzy data analysis based on fuzzy-set theory.

Bayesian Data Analysis. Bayesian inference, as defined in Ref. 52, is the process of fitting a probability model to a set of samples, which results in a probability distribution to make predictions for to-be-classified data. In this environment, a set of samples is given in advance and labeled by their associated classes. Observing the patterns contained in these samples, we can obtain not only the distributions of samples for the classes but also the distributions of samples for the patterns. Therefore, we can compute a distribution of classes for these patterns and use this distribution to predict the classes for the to-be-classified data based on their patterns. A typical process of Bayesian data analysis contains the following stages:

- Compute the distributions from the set of labeled samples.

2. Derive the distribution of classes for the patterns.
3. Evaluate the effectiveness of these distributions.

Suppose a sample containing the pattern a on some features is labeled class C_i . First, we compute a set of probabilities $P(C_i)$ that denote a distribution of samples for different classes and let each $P(a|C_i)$ denote the conditional probability of a sample containing the pattern a , given that the sample belongs to the class C_i . In the second stage, the conditional probability of a sample belonging to class C_i , given that the sample contains the pattern a , can be formulated as follows:

$$P(C_i|a) = \frac{P(a|C_i)P(C_i)}{P(a)} \quad (61)$$

where

$$P(a) = \sum_i P(a|C_i)P(C_i)$$

From Eq. (62), we can derive the probabilities of a sample belonging to classes according to the patterns contained in the sample. Finally, we can find a way to determine the class by using these probabilities. The following is a simple illustration of data analysis based on this probabilistic technique.

Example. Consider the data in Table 1. We first gather the statistics and transform the continuous values into discrete ones as in Table 2. Here we have two discrete levels, young and old, representing the age data, and three levels, low, median, and high, referring to the salary data. We collect all the probabilities and derive the ones for prediction based on Eq. (62):

$$\begin{aligned} P(\text{young, low}|C_{\text{rich}}) &= \frac{1}{3} & P(\text{young, low}|C_{\text{fair}}) &= \frac{1}{2} \\ P(\text{young, low}|C_{\text{poor}}) &= \frac{1}{3}, \\ P(\text{young, median}|C_{\text{rich}}) &= \frac{1}{3} & P(\text{young, median}|C_{\text{fair}}) &= 0 \\ P(\text{young, median}|C_{\text{poor}}) &= 0, \dots \\ P(\text{young, low}) &= \frac{4}{10} & P(\text{young, median}) &= \frac{1}{10} \\ P(\text{young, high}) &= 0, \dots \\ P(C_{\text{rich}}) &= \frac{3}{10} & P(C_{\text{fair}}) &= \frac{2}{5} & P(C_{\text{poor}}) &= \frac{3}{10} \\ P(C_{\text{rich}}|\text{young, low}) &= \frac{1}{4} & P(C_{\text{fair}}|\text{young, low}) &= \frac{1}{2} \\ P(C_{\text{poor}}|\text{young, low}) &= \frac{1}{4} \\ P(C_{\text{rich}}|\text{young, median}) &= 1 & P(C_{\text{fair}}|\text{young, median}) &= 0 \\ P(C_{\text{poor}}|\text{young, median}) &= 0, \dots \end{aligned}$$

Because there are two features representing the data, we compute the joint probabilities instead of the individual probabilities. Here we assume that the two features have the same degree of significance. At this

Table 2 Summary of Probability Distribution for Data in Table 1

Sample	Rich	Fair	Poor	Expressions of New Condensed Features
Young	2	2	1	Age is lower than 30
Old	1	2	2	Other ages
Low	1	2	3	Salary is lower than 36k
Median	1	1	0	Other salaries
High	1	1	0	Salary is higher than 50k

point, we have constructed a model to express the data with their two features. The derived probabilities can be regarded as a set of rules to decide the class of any to-be-classified datum.

If there is a to-be-classified datum X whose age is 26 and salary is 35k, we apply the derived rules to label X . We transform the pattern of X to indicate that the age is young and the salary is low. To find the suitable rules, we can define a penalty function $\lambda(C_i|C_j)$, which denotes the payment when a datum belonging to C_j is classified into C_i . Let the value of this function be 1 if C_j is not equal to C_i and 0 if two classes are the same. Furthermore, we can define a distance measure $\iota(X, C_i)$ as in Eq. (64), which represents the total amount of payments when we classify X into C_i . We conclude that the lower the value of $\iota(X, C_i)$, the higher the probability that X belongs to C_i . In this example, we label X by C_{fair} because $\iota(X, C_{\text{fair}})$ is the lowest.

$$\iota(X, C_i) = \sum_j \lambda(C_i|C_j)P(C_j|X) \quad (62)$$

$$\iota(X, C_{\text{rich}}) = 0 \times \frac{1}{4} + 1 \times \frac{1}{2} + 1 \times \frac{1}{4} = \frac{2}{4}$$

$$\iota(X, C_{\text{fair}}) = \frac{1}{2} \quad \iota(X, C_{\text{poor}}) = \frac{3}{4}$$

Fuzzy Data Analysis. Fuzzy-set theory, established by Zadeh,⁵³ allows a gradual membership $MF_A(X)$ for any datum X on a specific set A . Such an approach more adequately models the data uncertainty than using the common notion of set membership. Take cluster analysis as an example. Each datum belongs to exactly one cluster after the classification procedure. Often, however, the data cannot be assigned exactly to one cluster in the real world, such as the jobs of a busy person, the interests of a researcher, or the conditions of the weather. In the following, we replace the previous example for supervised data analysis with the fuzzy-set notion to show its characteristic.

Consider a universe of data U and a subset A of U . Set theory allows to express the membership of A on U by the characteristic function $F_A(X) : U \rightarrow \{0, 1\}$.

$$F_A(X) = \begin{cases} 1 & X \in A \\ 0 & X \notin A \end{cases} \quad (63)$$

From the above, it can be clearly determined whether X is an element of A or not. However, many real-world

phenomena make such a unique decision impossible. In this case, expressing membership is more suitable. A fuzzy set A on U can be represented by the set of pairs that describe the membership function $MF_A(X) : U \rightarrow [0, 1]$ as define in Ref. 54:

$$A = \{(X, MF_A(X)) | X \in U, MF_A(X) \in [0, 1]\} \quad (64)$$

Example. Table 3 contains a fuzzy-set representation of the data set in Table 1. The membership function of each sample is expressed in a form of possibility that stands for the degree of the acceptance that a sample belongs to a class. Under the case of supervised data analysis, the to-be-classified datum X needs to be labeled using an appropriate classification procedure. All the distances between each sample and X are calculated using the two features and Euclidean distance.

1. Find the K NNs of X from S .
2. Compute the membership function of X for each class.
3. Label X by the class with a maximal membership.
4. Add X to S and stop the process.

The first stage in finding K samples with minimal distances is the same, so we have the same set of four nearest neighbors $\{Y_4, Y_5, Y_6, Y_9\}$ when the value of $K = 4$. Let $\delta(X, Y_j)$ denote the distance between X and the sample Y_j . In the next stage, we calculate the membership function $MF_{C_i}(X)$ of X for each class C_i as follows:

$$MF_{C_i}(X) = \frac{\sum_j MF_{C_i}(Y_j)\delta(X, Y_j)}{\sum_j \delta(X, Y_j)} \quad \forall Y_j \in k \text{ NNs of } X \quad (65)$$

Table 3 Fuzzy-Set Membership Functions for Data in Table 1

Sample	Rich	Fair	Poor	Estimated Distances between the Sample and X
Y_1	0.5	0.2	0.3	11.66
Y_2	0.1	0.5	0.4	20.39
Y_3	0	0.2	0.8	20.09
Y_4	0.6	0.3	0.1	5.38
Y_5	0.2	0.5	0.3	10.19
Y_6	0.2	0.5	0.2	6.4
Y_7	0	0	1	15.52
Y_8	0.9	0.1	0	25.7
Y_9	0	0.3	0.7	11.18
Y_{10}	0.4	0.6	0	37.69
X	0.2	0.42	0.38	

$$MF_{C_{rich}}(X) = \frac{0.6 \times 5.38 + 0.2 \times 10.19 + 0.2 \times 6.4 + 0 \times 11.18}{5.38 + 10.19 + 6.4 + 11.18} \approx 0.2$$

$$MF_{C_{fair}}(X) = \frac{0.3 \times 5.38 + 0.5 \times 10.19 + 0.6 \times 6.4 + 0.3 \times 11.18}{5.38 + 10.19 + 6.4 + 11.18} \approx 0.42$$

$$MF_{C_{poor}}(X) = \frac{0.1 \times 5.38 + 0.3 \times 10.19 + 0.2 \times 6.4 + 0.7 \times 11.18}{5.38 + 10.19 + 6.4 + 11.18} \approx 0.38$$

Because the membership of X for class C_{fair} is higher than all others, we label X by C_{fair} . The resultant membership directly gives a confidence measure of the classification

3.2 Data Analysis on Internet Data

The dramatic growth of information systems over the past years has brought about the rapid accumulation of data and an increasing need for information sharing. The World Wide Web (WWW) combines the technologies of the uniform resource locator (URL) and hypertext to organize the resources on the Internet into a distributed hypertext system.⁵⁴ As more and more users and servers register on the WWW, data analysis on its rich content is expected to produce useful results for various applications. Many research communities such as network management, information retrieval, and database management have been working in this field⁵⁴

Many tools for Internet resource discovery⁵⁵ use the results of data analysis on the WWW to help users find the correct positions of the desired resources. However, many of these tools essentially keep a keyword-based index of the available resources (Web pages). Owing to the imprecise relationship between the semantics of keywords and the Web pages,⁵⁶ this approach clearly does not fit the user requests well.

The goal of Internet data analysis is to derive a classification of a large amount of data, which can provide a valuable guide for the WWW users. Here the data are the Web pages produced by the information providers of the WWW. In some cases, data about the browsing behaviors of the WWW users are also interesting to the data analyzers, such as the most popular sites browsed or the relations among the sites in a sequence of browsing. Johnson and Fotouhi⁵⁷ propose a technique to aid users to roam through the hypertext environment. They gather and analyze all the browsing paths of some users to generate a summary as a guide for other users. Many efforts have been made to apply the results of such data analysis.⁵⁷ In this section, we focus on the Web pages that are the core data of the WWW. First, we present a study on the nature of Internet data. Then we show the feature selection stage and enforce a classification procedure to group the data at the end.

Each site within the Web environment contains one or more Web pages. Under this environment, any WWW user can make a request to any site for any Web page in it. Moreover, the user can also roam through the Web by means of the anchor information provided in each Web page. Such an approach has resulted in several essential difficulties for data analysis.

1. Huge amounts of data
2. Frequent changes
3. Heterogeneous presentations

Basically, Internet data originate from all over the world, and the amount of data is huge. As any WWW user can create, delete, and update the data, and change the locations of the data at any time, it is difficult to get a precise view of the data. Furthermore, the various forms of expressing the same data also reveal the status of the chaos on the WWW. As a whole, Internet data analysis should be able to handle the large amount of data and control the uncertainty factors in a practical way. The data analysis procedure consists of the following stages:

1. Observe the data.
2. Collect the samples.
3. Select the features.
4. Classify the data.
5. Evaluate the results.

In the first stage, we observe the data and conclude with a set of features that may be effective for classifying the data. Next, we collect a set of samples based on a given scope. In the third stage, we estimate the fitness of each feature for the collected samples to determine a set of effective features. Then, we classify the to-be-classified data according to the similarity measure on the selected features. At last, we evaluate the classification results and find a way for further improvement.

Data Observation In the following, we provide two directions for observing the data.

Semantic Analysis. We may consider the semantics of a Web page as potential features. Keywords contained in a Web page can be analyzed to determine the semantics such as which field it belongs to or what concepts it provides. There have been many efforts at developing techniques to derive the semantics of a Web page. The research results of information retrieval^{58,59} can also be applied for this purpose.

Observing the data formats of Web pages, we can find several parts expressing the semantics of the Web pages to some extent. For example, the title of a Web page usually refers to a general concept of the Web page. An anchor, which is constructed by the home-page designer, provides a URL of another Web page and makes a connection between the two Web

pages. As far as the home-page designer is concerned, the anchor texts must sufficiently express the semantics of the whole Web page to which the anchor points. As to the viewpoint of a WWW user, the motivation to follow an anchor is based on the fact that this anchor expresses desired semantics for the user. Therefore, we can make a proper connection between the user's interests and those truly relevant Web pages. We can group the anchor texts to generate a corresponding classification of the Web pages pointed to by these anchor texts. Through this classification we can relieve the WWW users of the difficulties on Internet resource discovery through a query facility.

Syntactic Analysis. Syntactic analysis is based on the syntax of the Web pages to derive a rough classification. Because the data formats of Web pages follow the standards provided on the WWW, for example, hypertext markup language (HTML) we can find potential features among the Web pages. Consider the features shown in Table 4. The white pages, which mean the Web pages with a list of URLs, can be distinguished from the ordinary Web pages by a large number of anchors and the short distances between two adjacent anchors within a Web page. Note that here the distance between two anchors means the number of characters between them. For publication, the set of the headings has to contain some specific keywords, such as "bibliography" or "Publications." The average distance between two adjacent anchors has to be lower than a given threshold and the placement of anchors has to center to the bottom of the Web page.

According to these features, some conclusions may be drawn in the form of classification rules. For instance, the Web page is designed for publication if it satisfies the requirements of the corresponding features. Obviously, this approach is effective only when the degree of support for such rules is high enough. Selection of effective features is a way to improve the precision of syntactic analysis.

Sample Collection It is impossible to collect all the Web pages, and thus choosing a set of representative samples becomes a very important task. On the Internet, we have two approaches to gather these samples.

Table 4 Potential Features for Some Kinds of Web Pages

Kind of Home Page	Potential Feature
White page	Number of anchors, average distance between two adjacent anchors
Publication	Headings, average distance between two adjacent anchors, anchor position
Person Resource	Title, URL directory Title, URL filename

1. Supervised sampling
2. Unsupervised sampling

Supervised sampling means the sampling process is based on human knowledge that specifies the scope of the samples. In supervised data analysis, there exists a classification template that consists of a set of classes. The sampling scope can be set based on the template. The sampling is more effective when all classes of the template contain at least one sample. On the other hand, we consider unsupervised sampling if there is not enough knowledge about the scope, as in the case of unsupervised data analysis. The most trivial way to get samples is to choose any subset of Web pages. However, this arbitrary sampling may not fit the requirement of random sampling well. We recommend the use of search engines that provide different kinds of Web pages in a form of directory.

Feature Selection In addition to collecting enough samples, we have to select suitable features for the subsequent classification. No matter how good the classification scheme is, the accuracy of the results would not be satisfactory without effective features. A measure for the effectiveness of a feature is to estimate the degree of class separability. A better feature implies a higher class separability. This measure can be formulated as a criterion to select effective features.

Example. Consider the samples shown in Table 5. From Table 4, there are two potential features for white pages, the number of anchors (F_0) and the average distance between two adjacent anchors (F_1). We assume that $F_0 \geq 30$ and $F_1 \leq 3$ when the sample is a white page. However, a sample may actually belong to the class of white pages although it does not satisfy the assumed conditions. For example, Y_6 is a white page although its $F_0 < 30$. Therefore, we need to find a way to select effective features.

From the labels, the set membership of the two classes is as follows, where the class C_1 refers to the

class of white pages.

$$C_0 = \{Y_1, Y_2, Y_3, Y_4, Y_5\} \quad C_1 = \{Y_6, Y_7, Y_8, Y_9, Y_{10}\}$$

We can begin to formulate the class separability. In the following formula, we assume that the number of classes is c , the number of samples within class C_j is n_j , and Y_k^i denotes the k th sample in class C_i . First, we define the interclass separability D_b , which represents the ability of a feature to distinguish the data between two classes. Next, we define the intraclass separability D_w , which expresses the power of a feature to separate the data within the same class. The two measures are formulated in Eqs. (69) and (67) based on the Euclidean distance defined in Eq. (60). Since a feature with larger D_b and smaller D_w implies a better class separability, we define a simple criterion function D_{F_j} [Eq. (71)] as a composition of D_b and D_w to evaluate the effectiveness of a feature F_j . Based on this criterion function, we get $D_{F_0} = 1.98$ and $D_{F_1} = 8.78$. Therefore, F_1 is more effective than F_0 due to its higher class separability.

$$D_b = \frac{1}{2} \sum_{i=1}^c P_i \sum_{j \neq i} P_j \frac{1}{n_i n_j} \sum_{k=1}^{n_i} \sum_{m=1}^{n_j} \delta(Y_k^i, Y_m^j) \quad (66)$$

where

$$P_i = \frac{n_i}{\sum_{j=1}^c n_j}$$

$$D_w = \frac{1}{2} \sum_{i=1}^c P_i \sum_{j=i} P_j \frac{1}{n_i n_j} \sum_{k=1}^{n_i} \sum_{m=1}^{n_j} \delta(Y_k^i, Y_m^j) \quad (67)$$

where

$$P_i = \frac{n_i}{\sum_{j=1}^c n_j}$$

and

$$D_{F_j} = D_b - D_w \quad (68)$$

Table 5 Set of Samples with Two Features. The Labels Come from Human Knowledge

Sample	F_0^a	F_1^b	White Page
Y_1	8	5	No
Y_2	15	3.5	No
Y_3	25	2.5	No
Y_4	35	4	No
Y_5	50	10	No
Y_6	20	2	Yes
Y_7	25	1	Yes
Y_8	40	2	Yes
Y_9	50	2	Yes
Y_{10}	80	8	Yes

^a F_0 denotes the number of anchors.

^b F_1 denotes the average distance for two adjacent anchors.

We have several ways to choose the most effective set of features:

1. Ranking approach
2. Top-down approach
3. Bottom-up approach
4. Mixture approach

Ranking approach selects the features one by one according to the rank of their effectiveness. Each time we include a new feature from the rank, we compute the joint effectiveness of the features selected so far by Eqs. (69)–(71). When the effectiveness degenerates,

the process terminates. Using a top-down approach, we consider all the features as the initial selection and drop the features one by one until the effectiveness degenerates. On the contrary, the bottom-up approach adds a feature at each iteration. The worse case of the above two approaches occurs if we choose the bad features earlier in the bottom-up approach or the good features earlier in the top-down approach. The last approach allows us to add and drop the features at each iteration by combining the above two approaches. After determining the set of effective features, we can start the classification process.

Data Classification In the following, we only consider the anchor semantics as the feature, which is based on the dependency between an anchor and the Web page to which the anchor points. As mentioned previously, the semantics expressed by the anchor implies the semantics of the Web page to which the anchor points, and also describes the desired Web pages for the users. Therefore, grouping the semantics of the anchors is equivalent to classifying the Web pages into different classes. The classification procedure consists of the following stages:

1. Label all sample pages.
2. For each labeled pages, group the texts of the anchors pointing to it.
3. Record the texts of the anchors pointing to the to-be-classified page.
4. Classify the to-be-classified page based on the anchor information.
5. Refine the classification process.

In the beginning, we label all the samples and record all the anchors pointing to them. Then we group together the anchor texts contained in the anchors pointing to the same sample. In the third stage, we group the anchor texts contained in the anchors pointing to the to-be-classified page. After the grouping, we determine the class of the to-be-classified page according to the corresponding anchor texts. At last, we can further improve the effectiveness of the classification process. There are two important measures during the classification process. One is the similarity measure of two data, and the other is the criterion for relevance feedback.

Similarity Measure. After the grouping of samples, we have to measure the degree of membership between the to-be-classified page and each class. Considering the Euclidean distance again, there are three kinds of approaches for such measurement:

1. Nearest-neighbor approach
2. Farthest-neighbor approach
3. Mean approach

The first approach finds the sample in each class nearest to the to-be-classified page. Among these representative samples, we can choose the class containing the one with a minimal distance and assign the page to it. On the other hand, we can also find the farthest sample in each class from the page. Then we assign the page to the class that contains the representative sample with a minimal distance. The last approach is to take the mean of each class into consideration. As in the previous approaches, the mean of each class represents a whole class, and the one with a minimal distance from the page would be chosen. An example follows by using the mean approach.

Example. Inspect the data shown in Table 6. There are several Web pages and anchor texts contained in some anchors pointing to the Web pages. Here we consider six types of anchor texts, T_1, T_2, \dots, T_6 . The value of an anchor text for a Web page stands for the number of the anchors pointing to the Web page, which contain the anchor text. The labeling is the same as in the previous example. We can calculate the means of the two classes:

$$M_0 = (0, 4, 1, 1, 1, 0.2, 1)$$

$$M_1 = (4.2, 3.4, 2.6, 1.4, 2, 1.4)$$

Suppose there is a Web page X to be classified as shown in Table 6. We can compute the distances between X and the two means. They are $\delta(X, M_0) = 6.94$ and $\delta(X, M_1) = 4.72$. Thus we assign X to class C_1 .

Relevance Feedback. The set of samples may be enlarged after a successful classification by including the classified Web pages. However, the distance

Table 6 Set of Web Pages with Corresponding Anchor Texts and Labels. The Labels Come from Human Knowledge

between a to-be-classified page and the nearest mean may be very large, which means that the current classification process does not work well on this Web page. In this case, we reject the classification of such a Web page and wait until more anchor texts for this Web page are accumulated. This kind of rejection not only expresses the extent of the current ability to classify Web pages, but also promotes the precision of the classification results. Furthermore, by the concept of class separability formulated in Eqs. (69)–(71), we can define a similar criterion function D_S to evaluate the performance of the current set of samples.

$$D_S = D_F(S) \quad (69)$$

where F is the set of all effective features and S is the current set of samples.

Example. Reconsider the data shown in Table 6. Before we assign X to C_1 , the initial $D_S = 0.75$. When C_1 contains X , $D_{S \cup \{X\}}$ yields a smaller value 0.16. On the other hand, $D_{S \cup \{X\}}$ becomes 1.26 if we assign X to C_0 . Hence, although X is labeled C_1 , it is not suitable to become a new sample for the subsequent classification. The set of samples can be enlarged only when such an addition of new samples gains a larger D_S value, which means the class separability is improved.

3.3 Improvement of Data Analysis Methods

Although the previous procedures are able to fit the requirements of data analysis well, there are still problems, such as speed or memory requirements and the complex nature of real-world data. We have to use some heuristic techniques to improve the classification performance. For example, the number of clusters given in unsupervised data analysis has significant impact on the time spent at each iteration and the quality of the final partition. Notice that the initial partition may contribute to a specific sequence of adjustments and then a particular solution. Therefore, we have to find an ideal number of clusters during the analysis according to the given initial partition. The bottom-up approach for decreasing the number of clusters at each iteration is a way to determine the final partition. Given a threshold of similarity among the clusters, we can merge two clusters that are similar enough to become a new single cluster at each iteration. We can find a suitable number of clusters when there are no more similar clusters to be merged. In the following sections, we introduce two more techniques to improve the work of data analysis.

Rough-Set-Based Data Analysis The approach to classifying Internet data by anchor semantics requires a large amount of anchor texts. These anchor texts may be contained in the anchors pointing to the Web pages in different classes. An anchor text is said to be indiscernible when it cannot be used to distinguish

the Web pages in different classes. We employ the rough-set theory^{60,61} to find the indiscernible anchor texts, which will then be removed. The remaining anchor texts will contribute to a higher degree of accuracy for the subsequent classification. In addition, the cost of distance computation can also be reduced. In the following, we introduce the basic idea of the rough-set theory and an example for the reduction of anchor texts.

Rough-Set Theory. By the rough-set theory, an information system is modeled in the form of a 4-tuple (U, A, V, F) , where U represents a finite set of objects, A refers to a finite set of attributes, V is the union of all the domains of the attributes in A , and F is a binary function $(U \times A: \rightarrow V)$. The attribute set A often consists of two subsets, one refers to condition attributes \bar{C} and the other stands for decision attributes \bar{D} . In the approach of classification on Internet data, U stands for all the Web pages, A is the union of the anchor texts (\bar{C}) and the class of Web pages (\bar{D}). V is the union of all the domains of the attributes in A , and F handles the mappings. Let B be a subset of A . A binary relation called indiscernibility relation is defined as

$$\text{IND}_B = \{(X_i, X_j) \in U \times U \mid \forall p \in B, p(X_i) = p(X_j)\} \quad (70)$$

That is, X_i and X_j are indiscernible by the set of attributes B if $p(X_i)$ is equal to $p(X_j)$ for every attribute p in B . IND_B is an equivalence relation that produces an equivalence class denoted $[X_i]_B$ for each sample X_i . With regard to the Internet data, two Web pages X_i and X_j , which have the same statistics for each anchor text in \bar{C} belong to the same equivalence class $[X_i]_{\bar{C}}$ (or $[X_j]_{\bar{C}}$). Let U' be a subset of U . A lower approximation $\text{LOW}_{B, U'}$, which contains all the samples in each equivalence class $[X_i]_B$ contained in U' , is defined as

$$\text{LOW}_{B, U'} = \{X_i \in U \mid [X_i]_B \subset U'\} \quad (71)$$

Based on Eq. (75), $\text{LOW}_{\bar{C}, [X_i]_{\bar{D}}}$ contains the Web pages in the equivalence classes produced by $\text{IND}_{\bar{C}}$, and these equivalence classes are contained in $[X_i]_{\bar{D}}$ for a given X_i . A positive region $\text{POS}_{\bar{C}, \bar{D}}$ is defined as the union of $\text{LOW}_{\bar{C}, [X_i]_{\bar{D}}}$ for each equivalence class produced by $\text{IND}_{\bar{D}}$. $\text{POS}_{\bar{C}, \bar{D}}$ refers to the samples that belong to the same class when they have the same anchor texts. As defined in Ref. 62, \bar{C} is independent of \bar{D} if each subset \bar{C}_i in \bar{C} satisfies the criterion that $\text{POS}_{\bar{C}_i, \bar{D}} \neq \text{POS}_{\bar{C}_i, \bar{D}}$; otherwise, \bar{C} is said to be dependent on \bar{D} . The degree of dependency $\gamma_{\bar{C}, \bar{D}}$ is defined as

$$\gamma_{\bar{C}, \bar{D}} = \frac{\text{card}(\text{POS}_{\bar{C}, \bar{D}})}{\text{card}(U)} \quad (72)$$

where card denotes set cardinality;

$$\text{CON}_{p,\gamma\overline{C},\overline{D}} = \gamma\overline{C},\overline{D} - \gamma\overline{C}-|p|,\overline{D} \quad (73)$$

From these equations, we define the contribution $\text{CON}_{p,\gamma\overline{C},\overline{D}}$ of an anchor text p in \overline{C} to the degree of dependency $\gamma\overline{C},\overline{D}$, CIDbar; by using Eq. (73). According to Eq. (73), we say an anchor text p is dispensable if $\gamma\overline{C}-\{p\},\overline{D} = \gamma\overline{C},\overline{D}$. That is, the anchor text p makes no contribution to $\gamma\overline{C},\overline{D}$ and the value of $\text{CON}_{p,\gamma\overline{C},\overline{D}}$ equals 0. The set of indispensable anchor texts is the core of the reduced set of anchor texts. The remaining task is to find a minimal subset of \overline{C} called a reduct of \overline{C} that satisfies Eq. (74) and the condition that the minimal subset is independent of \overline{D} .

$$\text{POS}_{\overline{C},\overline{D}} = \text{POS}_{\text{minimal subset of } \overline{C},\overline{D}} \quad (74)$$

Reduction of Anchor Texts. To employ the concepts of the rough-set theory for the reduction of anchor texts, we transform the data shown in Table 6 into those in Table 7. The numerical value of each anchor text is transformed into a symbol according to the range in which the value falls. For instance, a value in the range between 0 and 2 is transformed into the symbol L. This process is a generalization technique usually used for a large database.

By Eq. (73), we can compute $\text{CON}_{p,\gamma\overline{C},\overline{D}}$ for each anchor text p and sort them in ascending order. In

this case, all $\text{CON}_{p,\gamma\overline{C},\overline{D}}$ are 0 except $\text{CON}_{T_1,\gamma\overline{C},\overline{D}}$. That is, only the anchor text T_1 is indispensable, which becomes the unique core of \overline{C} . Next, we use a heuristic method to find a reduct of \overline{C} because such a task has been proved to be NP-complete in Ref. 63. Based on an arbitrary ordering of the dispensable anchor texts, we check the first anchor text to see whether it is dispensable. If it is, then remove it and continue to check the second anchor text. This process continues until no more anchor texts can be removed.

Example. Suppose we sort the dispensable anchor texts as the sequence $\{T_2, T_3, T_4, T_5, T_6\}$, we then check one at a time to see whether it is dispensable. At last, we obtain the reduct $\{T_1, T_6\}$. During the classification process, we only consider these two anchor texts for similarity measure. Let the symbols used in each anchor text be transformed into three discrete values, 0, 1, and 2. The means of the two classes are $M_0 = (0, 0)$ and $M_1 = (1, 0.8)$. Therefore, we classify X into the class C_1 due to its minimum distance. When we use the reduct $\{T_1, T_6\}$ to classify data, the class separability $D_{\{T_1, T_6\}}$ is 0.22. Different reducts may result in different values of class separability. For instance, the class separability becomes 0.27 if we choose the reduct $\{T_1, T_2\}$.

Hierarchical Data Analysis Consider the 1-nearest-neighbor classifier for supervised data analysis. We may not want to compute all the distances each time a to-be-classified datum X arrives. We can organize the set of samples into a hierarchy of subsets and record a mean M_i for each subset S_i and the farthest distance d_i from M_i to any sample in S_i . If there exists a nearest neighbor of X in a subset other than S_i , we do not need to compute the distances between X and all the samples in S_i as the triangular inequality [Eq. (75)] holds. Such techniques can reduce the computation time to find the nearest neighbor.

$$\delta(X, M_i) - d_i \geq \delta(X, Y) \quad (75)$$

where Y is the nearest neighbor of X .

3.4 Summary

In this section, we describe the techniques and concepts of data analysis. A variety of data analysis methods are introduced and illustrated by examples. Two categories, supervised data analysis and unsupervised data analysis, are presented according to their different initial conditions and resultant uses. Two methods for data analysis are also described, which are based on probability theory and fuzzy-set theory, respectively. An approach of data analysis Internet data is presented. Improvements for the data analysis methods are also discussed.

4 DIODES

Konstantinos Misiakos

The word *diode* originates from the Greek word $\Delta\iota\omicron\delta\omicron\varsigma$ meaning passage or way through. In electronics terminology, in fact, diode refers to a two-terminal device that allows current to flow in one direction while it blocks the flow of current in the opposite direction. Such devices usually employ semiconductor junctions or metal–semiconductor junctions. There are also diodes made of vacuum tubes or metal—purely ionic crystal contacts. This section deals with semiconductor p – n junction diodes because they are the most widely used in practice due to their versatility, reproducibility, stability, and compatibility with integrated circuit technology. Additionally, an insight into the operation of the p – n junction diode is the basis for understanding the device physics of other semiconductor devices, the majority of which use the p – n junction as the building block. The semiconductor of our choice will be silicon because almost all diodes, discrete or integrated, are made of this element. Extensions to other semiconductors will be made to generalize theoretical results or to set limits to the validity of certain equations.

Figure 56 shows the electrical symbol of a diode. The arrow-type symbol indicates the conduction direction. For a diode to conduct an appreciable electric current, the voltage on the left side of the symbol must be a little higher than the voltage on the right side. If this polarity is reversed, the current drops to negligible values even for a large bias. The two previous polarity modes are known as forward and reverse bias, respectively. In Fig. 56*b* the very basic material structure of a diode is shown. The starting material is a high-purity silicon crystal, the properties of which are properly modified by selectively introducing dopants (elements) from either the third or the fifth column of the periodic table. The third-column elements, when introduced into the silicon lattice, behave as acceptors: They trap electrons from the valence band, thereby creating positively charged holes in the valence band and negatively charged immobile acceptor ions. The acceptor-doped part of the diode is called the p side. On the other hand, fifth-column elements behave as donors: They give up their fifth electron, creating a population of conduction band electrons and positively charged immobile donor ions. The donor-doped part of the device is the n side. The introduction of acceptor and donor dopants into silicon creates the two polarity sides of the diode, as shown in Fig. 56*a*. Schematically speaking, when applying a forward bias, the higher voltage on the n side makes the electron and hole gases move into each other. Thus, an electric current is created through electron–hole pair recombination. On the contrary, a lower voltage on the p side moves the charge carriers away, thus preventing recombination and eliminating the current. In terms of dopants, the previous account of how the p – n diode is formed also holds for germanium diodes, which also is a fourth-column elemental

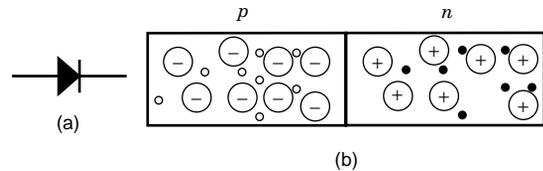

Fig. 56 Electrical symbol of a diode (a) and illustration of a semiconductor p – n junction (b). In (b) the large circles with the minus and the plus signs are the acceptor and the donor ions, whereas the small circles are the holes (empty) and the electrons (dark).

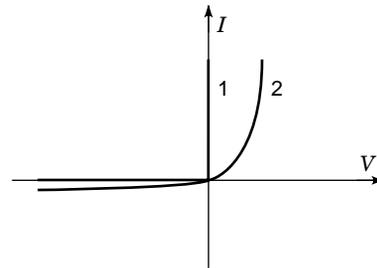

Fig. 57 Current–voltage characteristics of an ideal diode, curve 1, and a realistic one, curve 2.

semiconductor. For compound semiconductors (e.g., GaAs, InP, CdTe), the chemical origin of donor and acceptor dopants is more complex in relation to the semiconductor elements themselves.

In Fig. 57 the current–voltage (I – V) characteristic of an ideal diode as well as of a realistic one is shown. The ideal diode would behave as a perfect switch when forward biased: Unlimited current flow without any voltage drop across the device. The same ideal diode would allow no current in the reverse direction, no matter what the magnitude of the reverse bias is. Now, a realistic semiconductor diode would exhibit a resistance to current flow in the forward direction, whereas in reverse bias a small current would always be present due to leakage mechanisms. The disagreement between the ideal and the actual electrical behavior is not restricted only to the static I – V characteristics shown in Fig. 57. It extends to the transient response obtained when applying a time-dependent terminal excitation. The response of a realistic diode cannot follow at exactly the same speed as the terminal excitation of an ideal diode would. When designing a diode to be used as a switching device, care is taken to bring the device electrical characteristics as close to the ideal ones as possible. This is done by choosing both the geometrical features and the fabrication process steps in a way to suppress the parasitic components of the diode. As a result of the semiconductor electronic band structure as well as technological constraints,

material limitations impose certain basic restrictions on the device performance and create the subsequent deviation from the ideal performance. In the following sections, these restrictions will be investigated, and the deviation from the ideal performance will be analyzed in terms of the basic device physics, material constants, and geometry considerations.

Before considering the device physics of the diode, we will briefly discuss the steps in the basic fabrication process employed when making a silicon diode. These steps determine its basic geometrical and technological characteristics, which in turn determine the device electrical behavior. Today, almost all silicon diodes are made through the standard planar process of the silicon integrated circuit technology. A silicon wafer is first oxidized at temperatures in the vicinity of 1000°C. Such oxidation creates a silicon dioxide (SiO₂) cover layer with a thickness on the order of a micron. This layer is used as a mask for the subsequent technological steps. The SiO₂ film is then patterned by lithographic techniques and through etching, which allows windows of exposed silicon to be opened. Then, either by diffusion or by ion implantation, dopants are introduced into the exposed areas. The dopants are of a type opposite to the one already existing in the original wafer. In this way, *p-n* junctions are created in the exposed areas. In the rest of the wafer, the SiO₂ layer stops the ions and prevents diffusion into the silicon bulk. On the back surface, another diffusion or implantation of the same dopants as in the bulk is usually applied for reasons that will become clear in the next sections. At the end, metal contacts are evaporated on the front and the back. Lithography, again, on the front side defines the contacts of the individual diodes. The metal contacts are required for the diodes to interact with the external world in terms of terminal excitation (voltage or current) and terminal response (current or voltage, respectively). Similar methods are used for germanium diodes, whereas the compound semiconductor devices are usually made by epitaxial growth on proper substrates and by *in situ* doping.

4.1 Fundamentals of *p-n* Junctions

The basic *p-n* junction device physics was proposed by Shockley.⁶⁴ He derived the current–voltage characteristics, considering the electron and hole current continuity equations and the relationship between the carrier quasi-Fermi levels and the externally applied potentials. Here, we rederive the general current–voltage relation of a *p-n* junction based on Shockley's classic work⁶⁴ and its later extension.⁶⁵

Basic Equations and Assumptions To formulate the electron and hole transport in a semiconductor device mathematically, we can always start by expressing the carrier densities and currents in terms of the

carrier quasi-Fermi potentials under uniform temperature conditions:

$$J_n = \begin{cases} -e\mu_n n \nabla F_n & (76a) \\ e\mu_n n E + eD_n \nabla n & (76b) \end{cases}$$

$$n = n_i \exp\left(\frac{-eF_n - E_i}{kT}\right) \quad (76c)$$

$$J_p = \begin{cases} -e\mu_p p \nabla F_p & (77a) \\ e\mu_p p E - eD_p \nabla p & (77b) \end{cases}$$

$$p = n_i \exp\left[\frac{-(-eF_p) + E_i}{LT}\right] \quad (77c)$$

In Eqs. (76a) and (77a), J_n and J_p are the electric current densities of electrons and holes, respectively. Equations (76b) and (77b) express the currents in terms of drift and diffusion, where μ_n , D_n , n and μ_p , D_p , p are the mobilities, diffusivities, and volume densities of electrons and holes, respectively. Finally, F_n and F_p are the electron and hole quasi-Fermi potentials, E_i is the intrinsic energy level, and E the electric field density. Figure 58 shows the energy band diagram of a *p-n* junction under forward bias and illustrates the space dependence of the quasi-Fermi potentials, of the bottom of the conduction band E_c , and of the top of the valence band E_v . Equations (76c) and (77c) hold provided that the differences $E_c - (eF_n)$ and $(eF_p) - E_v$ are positive and at least several times the thermal energy kT . Equations (76a) and (77a) are borrowed from thermodynamics and hold provided that the bias is such that perturbations from equilibrium are small. Small, here, implies that the energy distribution of electrons and holes in the conduction and the valence band, respectively, continue (within a good approximation) to follow the Boltzmann statistics. Additionally, we assume that the mean free paths of the carriers are negligible compared to the physical dimensions of the device. Finally, Eqs. (76) and (77) hold provided quantum mechanical tunneling of carriers across potential barriers is not important. Such a constraint is relaxed in the last section of nonconventional transport diodes.

The second set of equations to be considered is the electron and hole continuity equations:

$$\frac{\partial n}{\partial t} = \frac{1}{e} \nabla J_n - U(n, p) + G \quad (78)$$

$$\frac{\partial p}{\partial t} = -\frac{1}{e} \nabla J_p - U(n, p) + G \quad (79)$$

where U is the electron–hole net recombination rate either by band-to-band transitions or through traps, whereas G is the band-to-band generation rate resulting from ionizing radiation or impact ionization processes. For the sake of simplicity, we assume that U

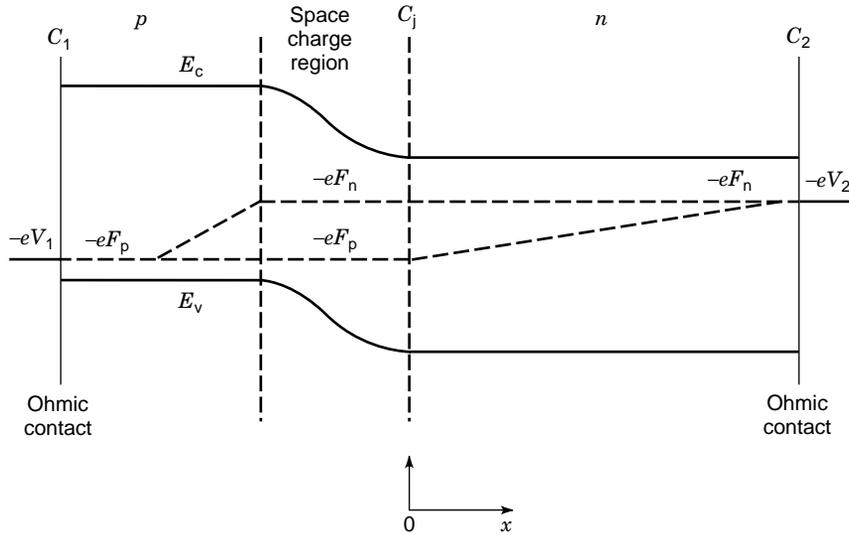

Fig. 58 Band diagram of forward-biased p - n junction. Boundaries C_1 and C_2 are the ohmic contacts, whereas C_j is the base-injecting boundary.

and G are the same for both carriers. Equations (78) and (79) are more general than the previous ones because they do the “bookkeeping” by equating the increase in the rate of carrier density to minus the carrier losses resulting from carrier out-fluxin ($\nabla J_p/e$ and $-\nabla J_n/e$) and recombination.

Next is the Poisson equation, which relates the electric field to the charge density caused by both mobile and immobile charges:

$$\nabla E = \frac{e}{\epsilon}[-n + p + N_D - N_A] \quad (80)$$

where ϵ is the semiconductor dielectric constant and N_D and N_A are the donor and acceptor densities, respectively. The charge density resulting from donors and acceptors is not carrier density dependent, unless the temperature drops to the cryogenic region.

The final equation to be considered is the one that equates the electric field to the gradient of the electrostatic potential:

$$E = \frac{1}{e}\nabla E_c = \frac{1}{e}\nabla E_v = \frac{1}{e}\nabla E_i \quad (81)$$

Equation (81) implies that the electrostatic potential is determined by conduction and the valence band edges because the carriers there have only potential energy. The last equation assumes that the separation in the energy scale of the three levels (E_c , E_v , and E_i) is space independent. So, in Eq. (81), as well as in eqs. (76b), (76c), (77b), and (77c), we neglect band distortion resulting from heavy doping or other effects

(e.g., mechanical stain). This is discussed in a later section on heavy doping effects.

Boundary Conditions. Equations (76)–(81) form a system of six relations with six unknown variables: F_n , F_p , E_i , J_n , J_p , and E . They apply, within the range of their validity, to any semiconductor device. In this sense, any semiconductor device understanding, design, operation, and performance is based on this set of six equations. What distinguishes a device of a particular kind is its boundary conditions, as well as the doping and trap density and type.

Ohmic Contacts. For a diode, a two-terminal device, the boundary conditions necessarily include two ohmic contacts that will supply the charge to be transported through the device. The voltage across and the current through the two ohmic contacts are, interchangeably, the excitation or the response of the device. The ohmic contacts are realized by depositing metals (e.g., Ti or Al) on heavily doped regions of the semiconductor. An ideal ohmic contact should, by definition, establish thermodynamic equilibrium between the metal and the semiconductor at all the contact points. In analytical terms, this is expressed by equating the carrier quasi-Fermi potentials to the metal Fermi potential:

$$F_n(C_1) = F_p(C_1) = V_1 \quad (82a)$$

$$F_n(C_2) = F_p(C_2) = V_2 \quad (82b)$$

where V_1 and V_2 are the voltages of the metal contacts ($V_1 - V_2$ is the terminal voltage), whereas C_1

and C_2 are the contact areas of the first and the second ohmic contact, respectively. The pinning of the Fermi potentials at the externally applied voltages is illustrated in Fig. 58. If $V_1 = V_2$ and G in Eqs. (78) and (79) were zero, the device would be in equilibrium. Then the solution of the previous system of six equations would be zero currents and equal and flat Fermi potentials throughout the diode. When an external voltage is applied, the splitting of the Fermi potential values between the two ohmic contacts drives the device out of equilibrium. Such a boundary value split enforces a separation of the electron and hole quasi-Fermi potentials through the device, as shown in Fig. 58. The separation of the two potentials implies that the nonequilibrium conditions mainly refer to the interaction between electrons and holes. At any point, excluding ohmic contacts, electrons are out of equilibrium with respect to holes because the relaxation time of interband transitions (recombination and generation mechanisms) required to bring them into equilibrium are too slow (milliseconds or microseconds for germanium and silicon and nanoseconds for most compound semiconductors). On the contrary, the intraband transitions resulting from scattering have short relaxation times (picoseconds) so that electrons or holes are nearly in equilibrium within their band. This is required for the carrier Fermi potentials to have a meaning, as mentioned in the discussion following Eqs. (76) and (77).

Semiconductor–Insulator Interfaces. The surface that bounds the device includes, in addition to the ohmic contact, the semiconductor–vacuum or semiconductor–insulator interface. The exposed semiconductor surface is usually covered by an insulating film (SiO_2 in silicon) to reduce recombination. If we assume that there is no injection in the insulator, then at the interface the boundary conditions for Eqs. (78) and (79) are

$$\frac{\partial n_s}{\partial t} = -\frac{1}{e} J_n^n - U_s \quad (83)$$

$$\frac{\partial p_s}{\partial t} = \frac{1}{e} J_p^n - U_s \quad (84)$$

where the subscript s refers to surface densities and the superscript n refers to the normal component looking into the insulator. The boundary conditions for Eq. (80) are dictated by the laws of electrostatics. The discontinuity of the normal component of the dielectric displacement vector must be equal to the surface-charge density, whereas the tangential component of the electric field must be continuous.

Because the boundary conditions have been set, the system of six equations [Eqs. (76)–(81)] can be solved, in principle. As it turns out, the solution of such a nonlinear system of coupled equations can be found only numerically even for one-dimensional p – n junctions with uniform acceptor and donor densities. To

derive analytical approximations, we need to make certain assumptions regarding the physical makeup of the device and the degree of bias. These analytical expressions help predict the device response under reasonable bias, whereas the appreciation of their validity range provides an insight into the diode device physics.

4.2 Doping Carrier Profiles in Equilibrium and Quasi-Neutral Approximation

As mentioned earlier, a p – n junction diode consists of an acceptor-doped p region in contact with a donor-doped n region. The two-dimensional area where the donor and acceptor densities are equal is called the metallurgical junction. Let us assume, for the moment, equilibrium conditions. In such a case, the currents are zero and the quasi-Fermi potentials are equal and spatially independent, $F_n = F_p = F$. Therefore, from Eqs. (76) and (77), $pn = n_i^2$, where n_i is the intrinsic-carrier density. Now, the six equations reduce to the Poisson equation, which, with the help of Eqs. (76c), (77c), and (81), takes the form

$$\Delta^2[E_i - (-eE)] = \frac{e^2}{\epsilon} \left[-n_i \exp\left(\frac{(-eF) - E_i}{kT}\right) + n_i \exp\left(\frac{E_i - (-eF)}{kT}\right) + N_D - N_A \right] \quad (85)$$

The last equation is known as the Boltzmann–Poisson equation. Approximate analytical solutions are possible when the donor and acceptor densities are uniform in the n and p regions, respectively. In this case, the field is zero, and the bands are flat everywhere except at and near the metallurgical junction. The finite-size region around the metallurgical junction is called the space-charge region, whereas the zero-field regions are called quasi-neutral regions, for reasons to be explained shortly. In the n and p quasi-neutral regions, electrons and holes are the majority carriers, respectively. The majority-carrier densities are equal to the respective doping densities. With reference to the metallurgical junction, the space-charge region extends W_A and W_D within the p and the n regions. At zero bias, and in one dimension, an approximate solution of Eq. (85) gives

$$W_A = \sqrt{\frac{2\epsilon}{e} V_{bi} \frac{N_D}{N_A(N_A + N_D)}} \quad (86a)$$

$$W_D = \sqrt{\frac{2\epsilon}{e} V_{bi} \frac{N_A}{N_D(N_A + N_D)}} \quad (86b)$$

$$V_{bi} = \frac{kT}{e} \ln\left(\frac{N_A N_D}{n_i^2}\right) \quad (86c)$$

In Eq. (86c) V_{bi} is the zero bias electrical potential difference, or barrier, between the p and the n side

reflects in the level differences of the fat bands of each side. Such a barrier prevents majority carriers from diffusing into the other side. These approximations result by assuming that the electron and hole densities are zero in the space-charge region. This is the depletion approximation, which reduces Eq. (85) to a linear second-order differential equation with constant terms and coefficients.

The zero-field condition for the rest of the n and p sides, outside the space-charge region, apparently justifies the term quasi-neutral regions. This term also applies when the n and p regions have gradually changing dopant profiles in the sense that the net space charge is much less than the majority-carrier charge. Here, by gradually changing we mean that the doping profile $N(x)$ in the quasi-neutral region is such that⁶⁶

$$\frac{\epsilon kT}{e^2} \left| \nabla^2 \left[\ln \frac{N(x)}{n_i} \right] \right| \ll N(x) \quad (87)$$

In such regions, the zero-bias majority-carrier density continues to be nearly the same as the net dopant density, but the electric field is not zero as in the uniform doping case.

4.3 Forward- and Reverse-Bias Conditions

The quasi-neutrality condition of the n and p regions is preserved even under bias, but now the boundaries with the space-charge region move appropriately to accommodate the new boundary conditions. This neutrality condition can be expressed as

$$n \approx p + N_D - N_A \quad (88)$$

Under a small forward bias, the applied voltage changes the electric field preferentially at the space-charge region, because it is the region with the fewest carriers, has the highest resistance, and is in series with more conductive n and p regions. The equilibrium barrier height V_{bi} lowers under forward bias, and the majority electrons overcoming the repulsive field diffuse from the n side to the p side, whereas the holes are doing the opposite. The carrier quasi-Fermi potentials are no longer equal, as shown in Fig. 58. The diffusion process, through the space-charge region and inside the quasi-neutral regions, increases dramatically the minority-carrier population on either side and gives rise to an appreciable electric current.

For forward voltages, the degree of bias defines three injection-level regimes distinguished by how the minority-carrier density compares to the majority one in the quasi-neutral regions. These regimes are the low-level, the moderate-level, and the high-level injection condition. In the low-level injection regime, the minority-carrier density is well below the majority-carrier density, and the electric field in the quasi-neutral regions is practically unaffected by the bias. As a result, the applied voltage drops across the space-charge region and reduces the barrier height from V_{bi}

to $V_b = V_{bi} - V$. Provided the depletion approximation still holds, Eq. (86) still applies with V_{bi} being replaced by V_b . In low-level injection, the majority-carrier density is the same as at zero bias, as Eq. (88) points out, and is nearly equal to the net doping density. In the high-level injection regime, the minority-carrier injection is so intense that the injected carriers have densities far exceeding the dopant densities. Now, both carrier densities are about the same, $n = p$, to preserve neutrality in the quasi-neutral region. In other words, there is no real distinction between minority and majority carriers in terms of concentrations, but we obtain an electron-hole plasma having densities well above that of the dopant densities instead. In the moderate injection, the minority-carrier density approaches the order of magnitude of the majority-carrier density causing the majority-carrier density to start to increase, as Eq. (88) implies.

Under reverse bias, the built-in barrier increases in the space-charge region, the repulsive forces on the majority carriers coming from the quasi-neutral regions increase, and injection of minority carriers is not possible. The space-charge region is now totally depleted from both carriers, and a small leakage current exists as a result of thermal generation of electron and hole pairs in the depletion region.

Recombination Currents in the Steady State

Here, we will introduce the base and emitter terms as well as a general expression for the terminal current as the sum of recombination components. Between the two quasi-neutral regions, emitter is the one that is heavily doped, usually by diffusion or implantation, whereas the base is more lightly doped and occupies most of the substrate on which the device is made, at least in silicon. The heavy doping of the emitter excludes the possibility of moderate- or high-level injection conditions in this region. At forward bias, majority carriers from the emitter diffuse as minority carriers to the base where they recombine. Simultaneously, recombination occurs in the emitter because minority carriers are back-injected from the base, as well as in the space-charge region. At steady state, $\partial n/\partial t = \partial p/\partial t = 0$, and in the dark $G = 0$. Now, the continuity equations [Eqs. (78) and (79)] become after volume integration:

$$I_D = I_e + I_b + I_{SCR} \quad (89)$$

where I_D is the terminal current and I_e , I_b , and I_{SCR} are the net recombination currents in the emitter, the base, and the space-charge region, respectively. Equation (89) expresses the total current as the sum of the recombination currents in the three regions of the device. Therefore, excess carrier recombination along with diffusion are the two basic transport mechanisms that determine the diode current at a given bias. The carrier recombination occurs either at the ohmic contacts, at the surface, or in the bulk. The minority carriers that arrive at the ohmic contact are supposed

to recombine simultaneously there, to preserve the boundary condition, Eq. (82b). The bulk recombination occurs either through traps or through band-to-band transitions. In terms of trap-mediated recombination, the Shockley–Read–Hall mechanism^{67,68} is the most common:

$$U_{\text{SRH}} = \frac{(pn - n_i^2)N_t}{\frac{1}{\sigma_p v_{\text{th}}} \left[n + n_i \exp\left(\frac{E_t - E_i}{kt}\right) \right]} + \frac{1}{\sigma_n v_{\text{th}}} \left[p + n_i \exp\left(-\frac{E_t - E_i}{kt}\right) \right] \quad (90)$$

where N_t is the trap density, σ_n and σ_p are the electron and hole capture cross sections, respectively, E_t , is the trap energy level in the gap, and v_{th} is the carrier thermal velocity. The band-to-band recombination is discussed in the heavy-doping effects section.

4.4 Approximate Analytical Expressions in Steady State

As previously mentioned, the set of Eqs. (76)–(81) has no analytical solution in the general case. Approximate closed-form expressions, though, are possible when low-level injection conditions dominate in the quasi-neutral base region. Without loss of generality, we assume that we are dealing with a p – n diode with a heavily doped p emitter and an n base. The steady-state situation results when a terminal bias, say a terminal voltage V , is steadily applied on the terminals, and we wait long enough for the initial transient to disappear. The steady-state version of the continuity equations [Eqs. (78) and (79)] is simplified because the time derivatives are set equal to zero. First, we will derive the expressions for the base current, and then extensions will be made for the recombination current in the emitter and the space-charge regions. If low-level injection conditions prevail in the base, then, to a good approximation, the original system of equations [Eqs. (76)–(81)] reduces to the minority-carrier equations [Eqs. (77) and (79)], which are now decoupled from Eq. (80) (the Poisson equation). This decoupling results because, as previously mentioned, at low-level injection the electric field is practically bias independent. Any small field variations would affect only the drift current of the majority carriers because of their high density; the minority carriers would not be influenced. That is why we focus on the minority-carrier transport to exploit the Poisson equation decoupling. Another reason for focusing on the minority carriers is the fact that the recombination in low-level injection, where $p \ll n$, can always be written as a linear function of their density:

$$U = \frac{p - p_0}{\tau} \quad (91)$$

where p_0 is the equilibrium carrier density, whereas the variable τ , called minority-carrier lifetime, is the

inverse of the derivative of the recombination rate with respect to the minority-carrier density. In the case of Shockley–Read–Hall recombination, $\tau = 1/\sigma_p v_{\text{th}} N_t$. Therefore, from Eqs. (77b), (79), and (91), we end up at

$$-\nabla(E\mu_p p' - D_p \nabla p') - \frac{p'}{\tau} + G = 0 \quad (92)$$

where $p' = p - p_0$ is the excess minority-carrier density. Because of the field independence on p' , Eq. (92) is linear and becomes homogenous if $G = 0$. In the later case, the solution is proportional to $p'(C_j)$, the excess minority-carrier density at the injecting boundary (Fig. 58).

Forward Bias and Low-Level Injection Under forward bias, a basic assumption will be made. This assumption allows the coupling of the minority-carrier density to the externally applied terminal voltage: the Fermi levels are flat in the regions where the carriers are a majority and also in the space-charge region. Under this condition and from Eqs. (76c), (77c), and (82),

$$p(C_j)n(C_j) = n_i^2 \exp\left(\frac{eV}{kT}\right) \quad (93)$$

$$p'(C_j) = \frac{n_i^2 [eV/kT - 1]}{N_D(C_j)} \quad (94)$$

Equation (93) holds under any injection level, provided that the flat Fermi potential assumption holds, whereas Eq. (94) for the excess minority-carrier density holds only in low-level injection. The proportionality of the solution with respect to $p'(C_j)$ forces all carrier densities and currents to become proportional to the term $\exp(eV/kT) - 1$. Here, we note that the surface recombination is also a linear function of the excess minority-carrier density when $p \ll n$. More analytically, Eq. (84) becomes

$$J_p^n = eS_p p' \quad (95)$$

where S_p is called surface recombination velocity. Therefore, the total base recombination current in Eq. (89) is proportional to the term $\exp(eV/kT) - 1$. The same is true for the quasi-neutral emitter recombination. Thus, Eq. (89) becomes

$$I_D = (I_{0e} + I_{0b}) \left[\exp\left(\frac{eV}{kT}\right) - 1 \right] + I_{\text{SCR}} \quad (96)$$

where the preexponential factors I_{0b} and I_{0e} are called base and emitter saturation currents, respectively. Equation (94) points out that the saturation currents are proportional to n_i^2 .

The space-charge region recombination is a current component that is hard to express in analytical terms. This difficulty arises because in this region the field depends on the bias and there is no such entity as a minority carrier. Consequently, the linearity conditions that allowed us to derive Eq. (96) no longer hold. To derive an approximate expression for the bias dependence of I_{SCR} , certain simplification must be made throughout the space-charge region regarding the integral of Eq. (90). These simplifications result in a bias dependence of the form $\exp(eV/nkT) - 1$, where n , the ideality or slope factor, takes values from 1 to 2.⁶⁵ The specific value depends on the trap position in the energy gap, the doping profiles and the cross section for hole capture relative to the cross section for electron capture. This range for n holds provided that the capture coefficients do not depend on the electric field. Now the preexponential factor I'_{SCR} is proportional to n_i . Finally, the expression for the forward current of a diode in the base of which low-level injection conditions prevail becomes

$$I_D = (I_{0e} + I_{0b}) \left[\exp\left(\frac{eV}{kT}\right) - 1 \right] + I'_{SCR} \left[\exp\left(\frac{eV}{nkT}\right) - 1 \right] \quad (97)$$

For voltages higher than $3nkT/e$, the unity can be dropped from Eqs. (96) and (97). Because of a better slope factor, the emitter and base recombination will dominate the diode current for voltages above a certain level. Below this level, the space-charge region recombination must be considered too. Such trends are seen in Fig. 59. Curve 1 is the I - V characteristic of a diode with a base doping of $5.5 \times 10^{14} \text{ cm}^{-3}$ and has an ideality factor of 1 in the bias range from 0.2 up to 0.4 V. For lower voltages, the space-charge region recombination slightly increases the ideality factor and makes the measured current deviate from the $\exp(eV/kT) - 1$ dependence. The ideality factor also increases for voltages above 0.4 V because of high-injection effects, which are discussed in the next subsection. The device of curve 2 has a very light doping density in the base, $4.5 \times 10^{11} \text{ cm}^{-3}$ and is driven in high injection at even smaller bias. As discussed in the next subsection, curve 2 exhibits unity slope factor even at very low voltages.

Curve 3 shows what happens if the temperature is reduced to 78 K. The sharp reduction of the intrinsic-carrier density due to its $\cong \exp(-E_g/2kT)$ dependence requires much higher voltages to reach the same current as at 300 K. In fact, to reach a current density of 10 mA/cm^2 , a voltage in excess of 1 V is required. The reduction of n_i reduces the recombination in the base and the emitter is much faster than in the space-charge region because the proportionality constants are n_i^2 and n_i , respectively. Therefore, at low temperatures, the bias regions with higher than 1 ideality factor are

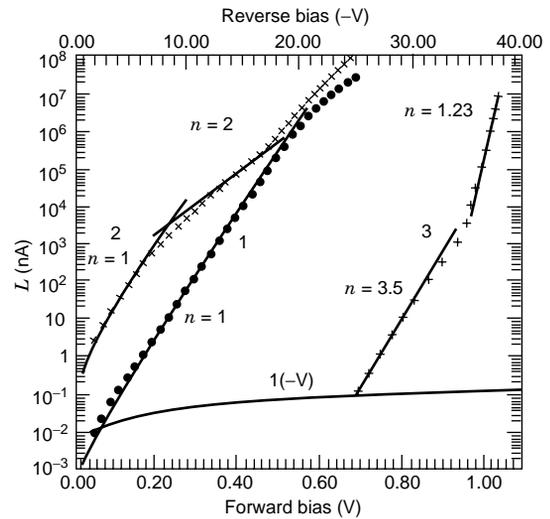

Fig. 59 Experimental I - V characteristics of two different diodes. Diode 1 has a base thickness of $250 \mu\text{m}$, a base-doping density of $5.5 \times 10^{14} \text{ cm}^{-3}$, and an area of $2.9 \times 2.9 \text{ mm}^2$. Diode 2 has a base thickness of $300 \mu\text{m}$, a base-doping density of $4.5 \times 10^{11} \text{ cm}^{-3}$, and an area of $5 \times 5 \text{ mm}^2$. The base in both devices is of n type. Plot 3 is the I - V characteristic of diode 2 at 78 K. The other plots are at 300 K. Curve 1(- V) is the reverse bias characteristic, with reversed sign, of diode 1 (top axis). The straight lines in curves 1, 2, and 3 are the exponential $\exp(eV/nkT) - 1$ fits to the experimental points. The slope factor n is also shown.

expected to be wider. This is evidenced in curve 3 of Fig. 59, where the ideality factor is 3.5 for voltages below 950 mV. The increase of the ideality factor above 2 is a result of the Poole-Frenkel effect, which reduces the effective energy separation of the traps from the bands.⁶⁹ The influence of small values of n_i on the ideality factor is evident not only when the temperature drops but also when the bandgap increases. In several compound semiconductor devices, their large bandgap, compared to 1.1 eV of silicon, results in an intrinsic-carrier density, which is several orders of magnitude smaller than the 10^{10} cm^{-3} value for silicon at 300 K.^{70,71} Consequently, their I - V characteristics show slope factors substantially larger than 1 for the entire range of bias. On the contrary, germanium diodes have slope factors of 1 even at reduced temperatures because of the smaller gap, 0.66 eV, of the semiconductor.

One-Dimensional Case. Equation (97) holds for any three-dimensional geometry and doping profile because no assumption, except for low-level injection, was made so far regarding doping profile and device topology. If, however, we want to express in close

form the saturation values of the emitter and base recombination currents, then one-dimensional devices with uniform doping profile must be considered. In such a case, the one-dimensional, homogenous, and constant-coefficient version of Eq. (92) becomes

$$\frac{d^2 p'}{dx^2} = \frac{p'}{L_p^2} \quad (98)$$

where $L_p = \sqrt{D_p \tau}$ is the minority-carrier diffusion length. The first boundary condition for Eq. (98) is Eq. (94) applied at the injecting boundary. The other one refers to the ohmic contact. If it is an ideal ohmic contact deposited directly on the uniformly doped base, then the second boundary condition becomes, from Eq. (82), $p'(l) = 0$. Here, l is the base length and the coordinate origin is at the injecting boundary, as shown in Fig. 58. In many cases, between the ohmic contact and the uniformly doped base, a thin and heavily doped region intervenes.

This region has thickness on the order of a micrometer and a doping of the same type as the rest of the base. The purpose of such a layer, called back-surface field is to provide a better ohmic contact and to isolate the contact from the lightly doped base so that carrier recombination generation is reduced.⁷² Such a back-surface field terminates the lightly doped base of diode 2 in Fig. 59 making it a $p-i-n$ diode, where i stands for intrinsic. Therefore, in the presence of this contact layer, the base ends at a "low/high" $n-n^+$ junction. In terms of minority-carrier recombination, this interface is characterized by an effective recombination velocity S_{pe} , experienced by the minority carriers at the low side of the junction. The expression for S_{pe} is

$$S_{pe} = \frac{I_{0c} N_D}{en_i^2 S} \quad (99)$$

where I_{0c} is the saturation value of the recombination current in the back-surface field and S is the device cross section. Equation (99) can be derived from Eq. (95), by applying Eq. (94) at the $n-n^+$ junction and by equating the minority current at the low/high junction to the recombination in the heavily doped region.

Under the previous boundary conditions, the solution of Eq. (98) yields for the base saturation current:

$$I_{0b} = S \frac{en_i^2 D_p}{N_D L_p} \frac{1 + [D_p / (S_{pe} L_p)] \tanh(\ell / L_p)}{\tanh(\ell / L_p) + D_p / (S_{pe} L_p)} \quad (100)$$

Equation (100) shows that, in terms of the one-dimensional geometry, the quantity that matters is the ratio ℓ / L_p . Values of this ratio much less than one define the short base, whereas values above 3 define the long base. In the long base case, Eq. (100) becomes $I_{0b} = S en_i^2 D_p / (N_D L_p)$. Similar equations hold for a uniform

emitter, too, but now the heavy doping effects could modify the value of n_i^2 , as will be discussed in the section on heavy doping effects. If the base doping is very light, as in a $p-i-n$ diode, then the increased value of I_{0b} will make the base recombination dominate the current components in Eq. (97). Accordingly, the influence of space-charge region recombination current on the slope factor will be suppressed even for voltages as low as a few kT/e , as shown in Fig. 59, curve 2. Also, by extrapolating the $\exp(eV/kT)$ of curve 2 at zero voltage, a base recombination current of 0.7 nA is obtained. This corresponds to a 300-K saturation current density of 2.8 nA/cm² compared to emitter saturation current densities on the order of pA/cm². On the other hand, diode 1, with a base-doping density three orders of magnitude higher than that in diode 2, exhibits a saturation current of 24 pA/cm². This saturation current comes mainly from the base recombination as a result of its relatively light doping density and the absence of a back-surface field which gives S_{pe} very high values.

Equation (100) applies to uniformly doped regions. If the doping is nonuniform, close form expressions are not possible, in the general case. This is the case because the one-dimensional version of Eq. (92) is still an ordinary differential equation with nonconstant coefficients. However, analytical approximations can be derived based on iterative techniques.⁷³

Diffusion in Three Dimensions. Equation (98) holds provided the cross-sectional dimensions of the diode are much larger than the diffusion length. Otherwise, lateral diffusion of minority carriers in the base becomes important. In such a case, the three-dimensional version of Eq. (98) takes the form

$$\nabla_{p'}^2 = \frac{p'}{L_p^2} \quad (101)$$

The last equation can be solved very accurately by semianalytical techniques based on the two-dimensional Fourier transform.⁷⁴ Simulation results are as shown in Fig. 60. As illustrated, in the case of a point contact diode having emitter dimensions of $0.1 L_p$, the base recombination is expected to increase by a factor of 25 as a result of the lateral carrier diffusion.

High-Level Injection So far, our analytical approaches were based on the low-level injection assumption. In high-level injection, where $n = p$, an equation similar to Eq. (98) can be derived where now the hole diffusion length is replaced by the ambipolar diffusion length.⁷⁵ The boundary conditions, however, are not linear and depend on the electric field, which, now, is a function of bias. If the quasi-Fermi potentials are flat in the quasi-neutral base, then the electron-hole plasma density p is space independent and equals $n_i \exp(eV/2kT)$, as can be derived from Eq. (93). In such

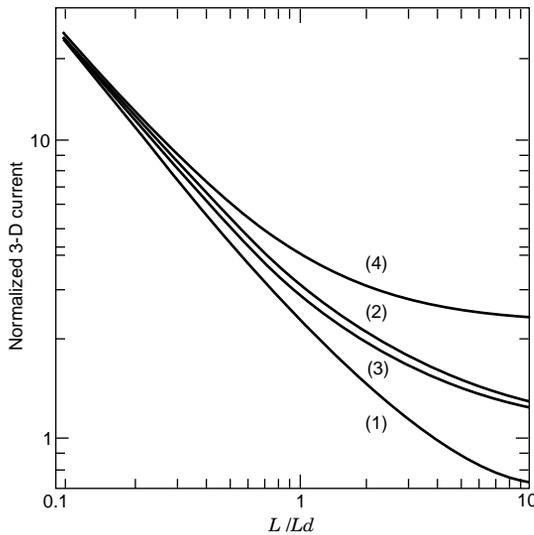

Fig. 60 Three-dimensional diffusion base saturation current of a planar p - n junction with a square emitter having a side length L . The top surface of the base is supposed to have zero recombination velocity. The current is normalized with respect to the one-dimensional diffusion current $I_{0b} = en_i^2 L^2 D_p / N_D L_p$. In curve 2, $S_{pe} = 0$ and $l = L_p/2$. In curve 2, l is assumed to be infinite. In curve 3, $S_{pe} = D_p/L_p$ and $l = L_p/2$, whereas in curve 4, S_{pe} is assumed to be infinite and $l = L_p/2$.

a case, by integrating the recombination current in the emitter, the base, and the back-surface field we obtain

$$I_D = (I_{0e} + I_{0c}) \exp\left(\frac{eV}{kT}\right) + \left(\frac{eSl}{\tau'}\right) \exp\left(\frac{eV}{2kT}\right) n_i \quad (102)$$

where τ' is the high-injection lifetime defined as the ratio of the recombination rate divided by the plasma density. The flat Fermi level condition can easily be satisfied in p - i - n diodes where the light base doping density makes the high-level injection possible even at a bias of 0.4 V. In Fig. 59, curve 2 shows the $\exp(eV/2kT)$ dependence, or slope factor of 2, for voltages of about 0.4 V, which drive the p - i - n device to high-level injection. For even higher voltages, the emitter and back-surface field recombination in Eq. (102) starts dominating the current, and the slope factor drops again. For higher base doping densities, as in curve 1 of diode 1, the required voltage for high-level injection conditions could exceed 0.5 V at 300 K. Now, the heavily doped region recombination in Eq. (102) competes with the bulk recombination, and the slope factor of 2 does not appear. The bent of both curves 1 and 2 at voltages near 0.6 V is a result of series resistance effects, which invalidate the assumption of flat Fermi levels across the base. In

such a case, the simulation is possible only by device simulators that solve the complete system of the transport equations.

Reverse Bias Under reverse bias where $V < 0$, the assumption of flat Fermi levels across the space-charge region that led to Eq. (97) no longer hold. On the other hand, however, the space-charge region can be considered to be fully depleted from free carriers. In such a case, Eq. (86) holds with V_{bi} replaced by $V_{bi} + |V|$. Therefore, the depleted space-charge region will expand toward the base according to the square root of the bias for $|V| > 5$ V. In this region, the Shockley-Read-Hall Eq. (90) predicts a negative recombination or generation of electron-hole pairs. This generation current is the basic component of the leakage current in reverse bias. The contribution of the diffusion components from the base and the emitter, $-I_{0b} - I_{0e}$, is usually negligible unless the base is very lightly doped. The bottom line in Fig. 59 shows the reverse-bias current for diode 1. The square-root dependence on voltage is not exactly obeyed because of the Poole-Frenkel effect, which increases the generation rate at higher fields.

4.5 Transient Response of Diodes

If a diode is subjected to a transient terminal bias, then in addition to currents due to carrier diffusion and recombination, we also have the dielectric displacement current resulting from the time dependence of the electric field. If low-level injection is observed in the quasi-neutral regions, the displacement current is restricted in the space-charge region. At the same time, low-level injection ensures that linearity holds in the base and the emitter, and Eq. (92) still applies with $\partial p'/\partial t$ replacing zero in the right-hand side of the relation. The solution of the time-dependent edition of Eq. (92) provides the minority-carrier currents at the injecting boundaries of the base and the emitter, $I_b(t)$ and $I_e(t)$, respectively. These currents have now two components: the minority-carrier recombination and the minority-carrier storage current $\partial Q'/\partial t$, where Q' is the total excess minority-carrier charge. To calculate the total transient current, reconsider Eq. (89) in its transient version. Therefore, in addition to $I_b(t)$ and $I_e(t)$, the transient space-charge region current is required. Unlike the base and the emitter, this current in addition to the recombination and storage component also includes the displacement current.⁷⁶ Insofar as the displacement current is concerned, the space-charge region behaves as a parallel plate capacitor with a plate distance $W = W_A + W_D$, Eq. (86), a dielectric constant ϵ and a capacitance $C_{SCR} = \epsilon S/W$. During transit, the dielectric displacement current is supplied by the majority carriers from either side of the junction.

To calculate the transient currents in the base and the emitter, the boundary conditions must be defined. Boundary condition Eq. (95) holds because of

linearity. The other condition at the injecting boundary depends on the kind of transient to be considered (89). Here we will assume that the device is in equilibrium for $t < 0$, whereas at $t = 0$ a constant voltage V is applied. We can now assume that Eq. (94) applies with $p'(C_j)$ replaced by $p'(C_j, t)$ for $t > 0$. This assumption has a validity range depending on how fast the f at quasi-Fermi potential condition can be established across the space-charge region. As a matter of fact, even in the absence of series resistance effects, it takes a short time for this condition to be established. This short time relates to the dielectric response time of the majority carriers and the minority-carrier diffusion time across the space-charge region.⁷⁷ For almost all practical cases, the delay in establishing a fixed minority-carrier density at the edge of the quasi-neutral region will not exceed the limit of a few tens of a picosecond⁷⁷ in the absence of series resistance effects. Therefore, if the time granularity used in solving the time-dependent version of Eq. (92) is restricted to about a nanosecond, then the solutions will be accurate. In practical cases, however, the very first part of the transient current, following the sudden application of a voltage, will be determined by charging C_{CSR} through the series resistance of the majority carriers in the base and the emitter. The respective time constant could be on the order of a nanosecond. In such a case, the minority-carrier transport in the base will determine the transient only after several nanoseconds have elapsed since the application of the voltage. The transient base transport can be expressed in semianalytical forms using Laplace transform techniques,⁷⁷ especially in the case of uniform and one-dimensional quasi-neutral regions. In a long-base diode, the transition will last for about a minority-carrier lifetime. In a short-base device with an ohmic contact at the base end, the transient will last approximately $L^2/2D_p$, which is the minority-carrier diffusion time through the base.

Small-Signal Response In many cases, the device operates under sinusoidal small-signal excitation superimposed on a steady-state excitation. In such cases, Eq. (92) still holds, but now $1/\tau$ will have to be replaced by $1/\tau + j\omega$, where j is the imaginary unit and ω is the angular frequency of the excitation. This is the case because the time derivative of the small-signal carrier density is the carrier density amplitude times $j\omega$. Having done the complex lifetime replacement, the analysis that followed Eq. (92) still holds. Now, however, the small-signal value of the excess minority-carrier density at the injecting boundary will be the steady-state value in Eq. (94) times ev/kT . Here, v is the small-signal terminal voltage, which is supposed to be much less than kT/e . Under low-level injection and in view of the previous transient response discussion, the small-signal version of Eq. (97) will refer to a terminal current I_D^* having a real and an imaginary

component:

$$I_D^* = (I_{0e}^* + I_{0b}^*) \frac{ev}{kT} \left[\exp\left(\frac{eV}{kT}\right) - 1 \right] + I_{SCR}^* \frac{ev}{nkT} \left[\exp\frac{eV}{nkT} - 1 \right] + j\omega C_{SCR} v = v(G + j\omega C) \quad (103)$$

The star exponents denote the complex values of the saturation currents as a result of the complex lifetime. In Eq. (103), G and C are the diode small-signal parallel conductance and capacitance, respectively. These two components are of great importance because their frequency dependence can reveal minority-carrier properties, such as diffusivity and lifetime⁷⁸ and allow the device circuit representation when the diode is part of a greater small-signal circuit. For uniformly doped quasi-neutral regions, I_{0e}^* and I_{0b}^* can be obtained from Eq. (100) by replacing the diffusion length $L = (D\tau)^{1/2}$ with the complex diffusion length $L^* = L/(1 + j\omega\tau)^{1/2}$. For frequencies sufficiently high, the magnitude of the complex diffusion length will become much shorter than the base thickness. Then, the complex version of Eq. (100) predicts that the base current would change as $1/L^*$. If the base component in Eq. (103) were to dominate, then beyond a certain frequency, C would change as $\omega^{-1/2}$ while G would change as $\omega^{1/2}$.

This frequency dependence is confirmed in Fig. 61, which shows the frequency response of diode 1, from

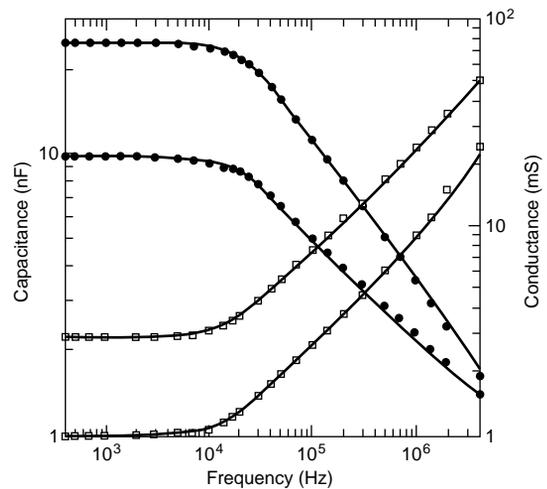

Fig. 61 Experimentally measured capacitance (dots) and conductance (squares) at 300 K for diode 1. The bottom and the top curves correspond to two different bias points: 420 and 450 mV, respectively. The solid curves are the theoretical fits from the equivalent circuit of Fig. 62.

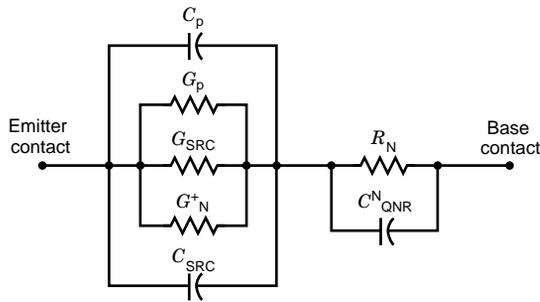

Fig. 62 The equivalent circuit model of a diode. The base injection currents in Eq. (103) corresponds to C_p , imaginary part, and G_p , real part. The injection in the emitter is represented by G_N^+ . The space-charge region recombination is represented by G_{SRC} , whereas C_{SRC} is the space-charge region capacitance. The rest of the components are accounted for in the text.

Fig. 59, at two bias points. The theoretical fit to the experimental results was obtained on the basis of the diode equivalent circuit shown in Fig. 62. This circuit includes all the components relating to carrier injection and storage in the device's three regions in accordance with Eq. (103). It also includes the base resistance R_N , which has been ignored in Eq. (103). In Fig. 61, the square root law is better obeyed at the higher bias point and for frequencies less than 1 MHz, especially for the capacitance. This is a combined result of the space-charge region capacitance, the relative contribution of which increases at lower bias, and the series resistance, the influence of which is stronger at high frequencies. The corner frequencies of the conductance and the capacitance depend on the base thickness and the lifetime. The fit shown in Fig. 61 gave a minority-hole lifetime in the n -type base of about $30 \mu\text{s}$. Such a lifetime and Eq. (100) imply that the saturation current density of 24 pA/cm^2 at 300 K, as shown in Fig. 59, is 90% due to base recombination. The emitter contribution of 10% is discussed in the section on heavy doping effects.

The series resistance R_N becomes the bulk majority-carrier resistance under reverse bias or even under forward bias, provided that the frequency is high ($|L^*| \ll l$). The capacitance C_{QNR}^N in parallel with R_N , as shown in Fig. 62, is the geometrical capacitance of the quasi-neutral base.^{79,80} For ordinary resistivity devices, it can be ignored unless the frequency is in the gigahertz range. However, for diodes made on high resistivity substrates, this capacitance must be considered especially at reverse bias and high frequencies.⁸⁰ From Fig. 62 and in the limit of very high frequencies under forward bias, the parallel conductance saturates at $1/R_N$ whereas the parallel capacitance does so at C_{QNR}^N . This is because of the combination of the increasing injection conductances and

the space-charge region capacitance. Then, the product $R_N C_{QNR}^N$ becomes the dielectric response time of the majority carriers in a uniform base. At high injection, the parallel conductance will saturate at the sum of the two carrier conductances.⁸¹ Under reverse bias, the circuit of Fig. 62 reduces to the space-charge region capacitance in series with the parallel combination of C_{QNR}^N and R_N . Unlike the forward-bias case, where the circuit parameters depend roughly exponentially on the terminal voltage V , in reverse bias the voltage dependence would be restricted to $V^{-1/2}$. In the sense of the voltage dependence, the circuit of Fig. 62 is the circuit of a varactor.

4.6 Heavy Doping Effects in Emitter

In the previous subsection, the emitter saturation current density was estimated to be about 2 pA/cm^2 . From Eq. (100) and by assuming microsecond lifetimes, we would expect saturation currents on the order of a fA/cm^2 from an emitter doped in the range 10^{19} – 10^{20} cm^{-3} . Such a discrepancy by three orders of magnitude is due to the heavy doping effects, namely the short lifetime resulting from Auger recombination and the effective increase of n_i due to bandgap narrowing. In the Auger recombination process, a minority carrier recombines directly with a majority one, and the energy is transferred to another majority carrier. Because of such kinetics, the Auger minority-carrier lifetime is inversely proportional to the square of the majority-carrier density. The proportionality constant is $\sim 10^{-31} \text{ cm}^6/\text{s}$ for minority electrons in p^+ emitters and $3 \times 10^{-31} \text{ cm}^6/\text{s}$ for minority holes in n^+ emitters.⁸² In heavily doped regions, the Auger recombination rate is by far higher than the Shockley–Read–Hall rate and determines the lifetime. Therefore, nanosecond lifetimes are expected, especially for holes, in emitters doped in the vicinity of 10^{20} cm^{-3} .

In a heavily doped region, every minority carrier interacts strongly with the majority carriers because of their high density. The minority-majority carrier attraction along with the carrier-dopant interaction and the semiconductor lattice random disruption by the dopant atoms reduces the bandgap and changes the density of states in both bands.^{83,84} The net result is an effective shrinkage of the gap depending on the doping type and density.^{85–87} This shrinkage changes the intrinsic-carrier density n_i to a much higher effective n_{ie} . The result of the band distortion is that the original system of transport equations [Eqs. (76)–(81)] no longer holds. More specifically Eqs. (76b), (76c), (77b), and (77c) are not valid for the majority carriers even if n_{ie} substitutes n_i because Boltzmann statistics must be replaced by Fermi–Dirac statistics. Also, Eq. (81) no longer holds in a nonuniform region because the band edges are not parallel any more and each carrier experiences a different field. However, the minority carriers still

follow the Boltzmann statistics, and Eq. (92) holds for the minority carriers. Now E is the minority-carrier field ($1/e\nabla E_c$ for electrons), and the boundary condition Eq. (94) is valid with n_i replaced by n_{ie} . Therefore, Eq. (100) still applies for the minority-carrier recombination in a uniformly doped emitter. For an emitter doped at about 10^{20} cm^{-3} , a gap narrowing of about 100 meV is expected,^{15–87} which makes n_{ie} several tens higher than n_i . If such an n_{ie} as well as nanosecond lifetimes replace n_i and microsecond lifetimes in Eq. (100), an emitter saturation current on the order of pA/cm^2 is predicted, in accordance with the experimental results of the previous section.

4.7 Diodes of Nonconventional Transport

So far in this section, devices based on the drift and diffusion model of Eqs. (76) and (77) were studied. Charge carriers can be transported from one region to another by tunneling. Also, they can be temporarily trapped in energy-gap states, atom clusters, or crystallites imbedded in insulating films, thereby affecting the tunneling or the conventional transport of the free carriers.

In this respect, the first device to be examined is the $p-i-n$ diode 2 of Fig. 59, operating at cryogenic temperatures. Around 4.2 K, the equilibrium Fermi level in the lightly doped n^- region is pinned at the donor level. These levels, now, are not ionized except for a fraction to compensate the charge of the unintentionally introduced acceptor ions. At such low temperatures, there are no free carriers in the base, and no measurable conduction is possible unless the voltage is raised enough to achieve the fat-band condition.^{88,89} For silicon, this voltage V_0 would be about 1.1 V. For even higher voltages, conduction is possible only if electrons and holes can be injected in the frozen substrate from the n and p regions, respectively. In this sense, Eq. (99) based on the assumption of flat majority-carrier Fermi levels no longer holds. For $T < 10 \text{ K}$, injection is possible by carrier tunneling through the small potential barrier existing at each of the $p-i$ and $i-n$ interfaces.⁵⁹ These barriers exist because of the band distortion in the heavily doped regions and the smaller gap there, as outlined in the previous section. For $V > V_0$, electrons tunnel in the i layer, and the higher the forward bias, the higher the current due to a field-induced effective lowering of the barriers.

As shown in Fig. 63, for temperatures below 10 K it takes at least several volts to establish a current of few nanoamps. The injected electrons in the i layer are trapped by the ionized donors and build a space charge and a subsequent potential barrier. For even higher voltages approaching 10 V, the barrier at the $i-p$ interface lowers, holes now enter the i layer in large numbers. Their charge neutralizes the trapped electron charge and causes the voltage breakdown and the negative differential resistance that appears in Fig. 63 for $T < 10 \text{ K}$. The negative resistance persists

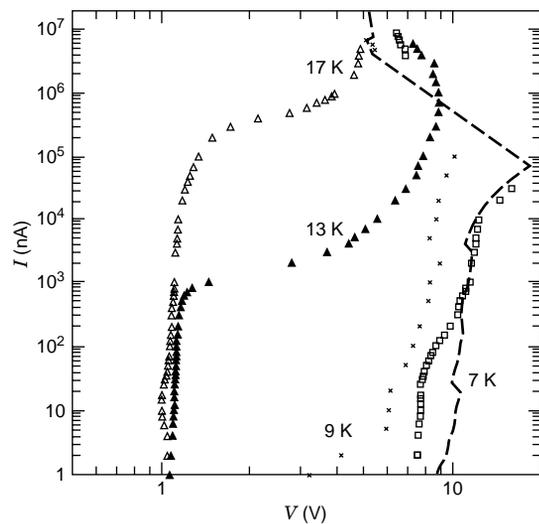

Fig. 63 Measured I - V characteristics of diode 2 at cryogenic temperatures. The square points correspond to 4.2 K. The $T < 10 \text{ K}$ plots exhibit a distinct voltage breakdown. Reprinted from K. Misiakos, D. Tsamakias, and E. Tsoi, Measurement and modeling of the anomalous dynamic response of high resistivity diodes at cryogenic temperatures, *Solid State Electronics*, **41**: 1099–1103, 1997, with kind permission from Elsevier Science Ltd., The Boulevard, Langford Lane, Kidlington OX5 1 GB, UK.

and beyond breakdown as a result of new carrier generation by the impact ionization of occupied shallow donors by the injected carriers. The interaction of free and trapped carriers through impact ionization gives rise to a negative dynamic conductance and capacitance which for frequencies high enough change as ω^{-2} .⁹⁰ For $T > 10 \text{ K}$ the injection mechanism changes to thermion emission over the interface potential barriers, whereas the space-charge effects are now less pronounced.

Another example of tunneling injection mechanism is the breakdown effect in zener diodes. Here, the base is quite heavily doped ($\approx 10^{18} \text{ cm}^{-3}$), and the strong electric field in the space-charge region increases even further by applying a reverse bias. For field approaching 10^6 V/cm , a valence band electron can tunnel to a conduction band state of the same energy. This way, electron-hole pairs are created, and the reverse current sharply increases. Another diode structure based on tunneling is a new metal-insulator-semiconductor device having silicon nanocrystals imbedded in the thin insulating film.⁹¹ One way to realize such diodes is by depositing an aluminum electrode on a thin (on the order of 10 nm) SiO_2 layer containing silicon nanocrystals. The substrate is n -type crystalline silicon. The silicon nanocrystals can be created either by oxidizing deposited amorphous silicon layers⁹¹ or by

low-energy silicon ion implantation in the SiO_2 film⁹² In the absence of the nanocrystals, by applying a negative voltage of a few volts on the aluminum electrode relative to the n -type silicon substrate, only a small tunneling current would be present.

When the nanocrystals are introduced, much higher currents are observed while the conductance curve exhibits characteristic peaks. Such peaks are shown in Fig. 64 showing the reverse current and conductance of a quantum dot diode formed by low-energy implantation of silicon in a 10-nm SiO_2 layer.⁹² The conductance peaks appear when the metal Fermi level is swept across the discrete energy states of the nanocrystals, thus enabling resonant tunneling from the metal to the semiconductor.⁹¹ The three-dimensional confinement of electrons in the quantum-dot crystallites creates a large separation between energy states, which along with the Coulomb blockade effect of the occupied states explains the large voltage separation of the three first conductance peaks in Fig. 64.^{91,92} Such quantum dot devices hold the

promise of single-electron transistors⁹³ and silicon-based light-emitting diodes.⁹⁴

As we end this section, we would like to mention the basic uses of the diode as a device. The most frequent use of the diode is the protection of CMOS integrated circuits from electrostatic discharges by clamping the output pads to the power-supply voltages through reverse-biased p - n junctions. In analog integrated circuits, forward-biased diodes are used for voltage shifting. Such diodes usually come from properly wired bipolar transistors (e.g., emitter-base diodes with base-collector short circuited). Diodes, as discrete devices, find applications mainly as rectifying elements in power circuits. The breakdown effect of zener diodes makes these devices useful as voltage reference sources in power supplies. Photodiodes are widely used for detecting photons or charge particles. Finally, large area diodes with exposed front surface and proper design and engineering can efficiently convert solar light into electricity and are used as solar cells.⁹⁵

Normand et al., Silicon nanocrystal formation in thin thermal-oxide films by very low energy Si^+ ion implantation, *Microelectronic Engineering*, **36**(1-4): 79-82, 1997, with kind permission of Elsevier Science-NL, Sara Burgerharstraat 25, 1055 KV Amsterdam, The Netherlands.

5 ELECTRONIC COMPONENTS

Clarence W. de Silva

5.1 Materials and Passive Components

Conductive Material and Components

Conductance and Resistance. When a voltage is applied across a conductor, a current will flow through the conductor. For a given voltage v (volts), the current i (amperes) will increase with the conductance G of the conductor. In the linear range of operation, this characteristic is expressed by Ohm's law:

$$i = Gv$$

Resistance $R(\Omega)$ is the inverse of conductance:

$$R = \frac{1}{G}$$

Silver, copper, gold, and aluminum are good conductors of electricity.

Resistivity. For a conductor, resistance increases with the length (L) and decreases with the area of cross section (A). The corresponding relationship is

$$R = \frac{\rho L}{A}$$

The constant of proportionality ρ is the resistivity of the conducting material. Hence, resistivity may be defined as the resistance of a conductor of unity length and unity cross-sectional area. It may be expressed in the units $\Omega \cdot \text{cm}^2/\text{cm}$ or $\Omega \cdot \text{cm}$. A larger unit would be $\Omega \text{ m}^2/\text{m}$ or $\Omega \cdot \text{m}$.

Alternatively, resistivity may be defined as the resistance of a conductor of unity length and unity diameter. According to this definition

$$R = \frac{\rho L}{d^2}$$

where d represents the wire diameter. If the wire diameter is 1 mil (or 1/1000 in), the wire area would be 1 circular mil (or cmil). Furthermore, if the wire length is 1 foot, the units of ρ would be $\Omega \cdot \text{cmil}/\text{ft}$. Resistivities of several common materials are given in Table 8.

Effect of Temperature. Electrical resistance of a material can change with many factors. For example, the resistance of a typical metal increases with temperature, and the resistance decreases with temperature for many nonmetals and semiconductors. Typically, temperature effects on hardware have to be minimized in precision equipment, and temperature compensation or calibration would be necessary. On the other hand, high-temperature sensitivity of resistance in

Table 8 Resistivities of Some Materials

Copper	1.7×10^{-8}
Ferrite (manganese-zinc)	20.0
Gold	2.4×10^{-8}
Graphite carbon	775.0×10^{-8}
Lead	9.6×10^{-8}
Magnesium	45.8×10^{-8}
Mercury	20.4×10^{-8}
Nichrome	112.0×10^{-8}
Polyester	1×10^{10}
Polystyrene	1×10^{16}
Porcelain	1×10^{16}
Silver	1.6×10^{-8}
Steel	15.9×10^{-8}
Tin	11.5×10^{-8}
Tungsten	5.5×10^{-8}

Note: Multiply by 6.0×10^8 to obtain the resistivity in $\Omega \cdot \text{mil}/\text{ft}$.

some materials is exploited in temperature sensors such as RTDs and thermistors. The sensing element of an RTD is made of a metal such as nickel, copper, platinum, or silver. For not too large variations in temperature, the following linear relationship could be used:

$$R = R_0(1 + \alpha \Delta t)$$

where R is the final resistance, R_0 is the initial resistance, ΔT is the change in temperature, and α is the temperature coefficient of resistance.

Values of α for several common materials are given in Table 9. These values can be expressed in ppm/°C (parts per million per degree centigrade) by multiplying each value by 10^6 . Note that graphite has a negative temperature coefficient and nichrome has

Table 9 Temperature Coefficients of Resistance for Several Materials

Material	Temp. Coeff. Resistance α (per °C) at 20°C (68°F)
Aluminum	0.0040
Brass	0.0015
Copper	0.0039
Gold	0.0034
Graphite carbon	-0.0005
Iron	0.0055
Lead	0.0039
Nichrome	0.0002
Silver	0.0038
Steel	0.0016
Tin	0.0042
Tungsten	0.0050

a very low temperature coefficient of resistance. A platinum RTD can operate accurately over a wide temperature range and possesses a high sensitivity (typically $0.4 \Omega/^\circ\text{C}$).

Thermistors are made of semiconductor material such as oxides of cobalt, copper, manganese, and nickel. Their resistance decreases with temperature. The relationship is nonlinear and is given approximately by

$$R = R_0 e^{-\beta(1/T_0 - 1/T)}$$

where the temperatures T and T_0 are in absolute degrees (kelvins or rankines), and R and R_0 are the corresponding resistances. The parameter β is a material constant.

Effect of Strain. The property of resistance change with strain in materials, or piezoresistivity, is used in strain gauges. The foil strain gauges use metallic foils (e.g., a copper–nickel alloy called constantan) as their sensing elements. The semiconductor strain gauges use semiconductor elements (e.g., silicon with the trace impurity boron) in place of metal foils. An approximate relationship for a strain gauge is

$$\frac{\Delta R}{R} = S_s \varepsilon$$

where ΔR is the change in resistance due to strain ε , R is initial resistance, and S_s is the sensitivity (gauge factor) of the strain gauge.

The gauge factor is of the order of 4.0 for a metal-foil strain gauge and can range from 40.0 to 200.0 for a semiconductor strain gauge.⁹⁶

Temperature effects have to be compensated for in high-precision measurements of strains. Compensation circuitry may be employed for this purpose. In semiconductor strain gauges, self-compensation for temperature effects can be achieved due to the fact that the temperature coefficient of resistance varies nonlinearly with the concentration of the dope material.⁹⁶ The temperature coefficient curve of a p -type semiconductor strain gauge is shown in Fig. 65.

Superconductivity. The resistivity of some materials drops virtually to zero when the temperature is decreased close to absolute zero, provided that the magnetic field strength of the environment is less than some critical value. Such materials are called superconducting materials. The superconducting temperature T (absolute) and the corresponding critical magnetic field strength H are related through

$$H = H_0 \left(1 - \frac{T}{T_c}\right)^2$$

where H_0 is the critical magnetic field strength for a superconducting temperature of absolute zero, and T_c

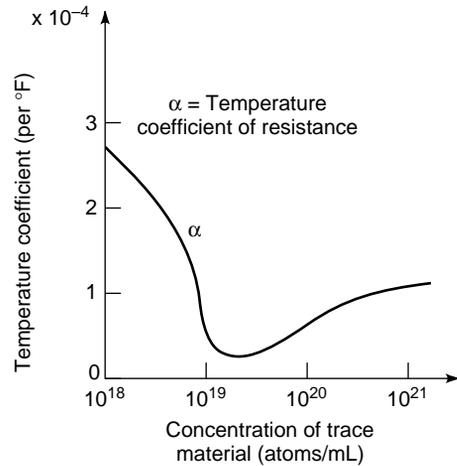

Fig. 65 Temperature coefficient of resistance of p -type semiconductor strain gauge.

is the superconducting temperature at zero magnetic field. The constants H_0 and T_c for several materials are listed in Table 10.

Superconducting elements can be used to produce high-frequency (e.g., 1×10^{11} Hz) switching elements (e.g., Josephson junctions) that can generate two stable states (e.g., zero voltage and a finite voltage, or zero magnetic field and a finite magnetic field). Hence, they are useful as computer memory elements. Other applications of superconductivity include powerful magnets with low dissipation (for medical imaging, magnetohydrodynamics, fusion reactors, particle accelerators, etc.), actuators (for motors, magnetically levitated vehicles, magnetic bearings, etc.), sensors, and in power systems.

Color Code for Fixed Resistors. Carbon, wound metallic wire, and conductive plastics are commonly used as commercial resistors. A wire-wound resistor element is usually encapsulated in a casing made of an insulating material such as porcelain or bakelite. Axial

Table 10 Superconductivity Constants for Some Materials

Material	T_c (K)	H_0 (A/m)
Aluminum	1.2	0.8×10^4
Gallium	1.1	0.4×10^4
Indium	3.4	2.3×10^4
Lead	7.2	6.5×10^4

Gray	8	8	10^8	
White	9	9	10^9	

or radial leads are provided for external connection. The outer surface of a fixed resistor is color coded for the purpose of its specification. Four stripes are used for coding. The first stripe gives the first digit of a two-digit number, and the second stripe gives the second digit. The third stripe specifies a multiplier, which should be included with the two-digit number to give the resistance value in ohms. The fourth stripe gives the percentage tolerance of the resistance value. This color code is given in Table 11.

Dielectric Material and Components

Dielectrics and Capacitors. Dielectric materials are insulators, having resistivities larger than $1 \times 10^{12} \Omega \cdot \text{m}$ and containing less than 1×10^6 mobile electrons per cubic meter. When a voltage is applied across a medium of dielectric material sandwiched between two electrode plates, a charge polarization takes place at the two electrodes. The resulting charge depends on the capacitance of the capacitor formed in this manner. In the linear range, the following relationship holds:

$$q = Cv$$

where v is applied voltage (in volts), q is stored charge (in coulombs), and C is capacitance (farads). Since current (i) is the rate of change of charge (dq/dt), we can write

$$i = C \frac{dv}{dt}$$

Hence, in the frequency domain (substitute $j\omega$ for the rate of change operator), we have

$$i = Cj\omega v$$

and the electrical impedance (v/i in the frequency domain) of a capacitor is given by

$$\frac{1}{j\omega C}$$

where ω is the frequency variable, and $j = \sqrt{-1}$.

Permittivity. Consider a capacitor made of a dielectric plate of thickness d sandwiched between two conducting plates (electrodes) of common (facing) area A . Neglecting the fringe effect, its capacitance is given by

$$C = \frac{\epsilon A}{d}$$

where ϵ is the permittivity of the dielectric material. The relative permittivity (or dielectric constant) ϵ_r is defined as

$$\epsilon_r = \frac{\epsilon}{\epsilon_0}$$

where ϵ_0 = permittivity of vacuum (approx. 8.85×10^{-12} F/m). Relative permittivities of some materials are given in Table 12.

Capacitor Types. The capacitance of a capacitor is increased by increasing the common surface area of the electrode plates. This increase can be achieved, without excessively increasing the size of the capacitor, by employing a rolled-tube construction. Here, a dielectric sheet (e.g., paper or a polyester film) is placed between two metal foils, and the composite is rolled into a tube. Axial or radial leads are provided

Table 12 Dielectric Constants of Some Materials

Material	Relative Permittivity ϵ_r

for external connection. If the dielectric material is not flexible (e.g., mica), a stacked-plate construction may be employed in place of the rolled construction to obtain compact capacitors having high capacitance. High-permittivity ceramic disks are used as the dielectric plates in miniature, single-plate, high-capacitance capacitors. Electrolytic capacitors can be constructed using the rolled-tube method, using a paper soaked in an electrolyte in place of the dielectric sheet. When a voltage is applied across the capacitor, the paper becomes coated with a deposit of dielectric oxide that is formed through electrolysis. This becomes the dielectric medium of the capacitor. Capacitors having low capacitances of the order of 1×10^{-12} F (1 pF), and high capacitances of the order of 4×10^{-3} F are commercially available.

An important specification for a capacitor is the breakdown voltage, which is the voltage at which discharge will occur through the dielectric medium (i.e., the dielectric medium ceases to function as an insulator). This is measured in terms of the dielectric strength, which is defined as the breakdown voltage for a dielectric element of thickness 1 mil (1×10^{-3} in). Approximate dielectric strengths of several useful materials are given in Table 13.

Color Code for Fixed Capacitors. Color codes are used to indicate the specification of a paper or ceramic capacitor. The code consists of a colored end followed by a series of four dots printed on the outer surface of the capacitor. The end color gives the temperature coefficient of the capacitance in parts per million per degree centigrade (ppm/°C). The first two dots specify a two-digit number. The third dot specifies a multiplier which, together with the two-digit number, gives the capacitance value of the capacitor in picofarads. The fourth dot gives the tolerance of the capacitance. This code is shown in Table 14.

Piezoelectricity. Some materials, when subjected to a stress (strain), produce an electric charge. These are termed piezoelectric materials, and the effect is called piezoelectricity. Most materials that possess a nonsymmetric crystal structure are known to exhibit the piezoelectric effect. Examples are barium titanate, cadmium sulfide, lead zirconate titanate, quartz, and Rochelle salt. The reverse piezoelectric effect (the

Table 14 Color Code for Ceramic and Paper Capacitors

Color	End Color, Temp.	First Dot, Coeff. (ppm/°C)	Second Dot, Digit	Third Dot, Multiplier	Fourth Dot Tolerance	
					For ≤ 10 pF	For > 10 pF

material deforms in an electric field) is also useful in practice.

The piezoelectric characteristic of a material may be represented by its piezoelectric coefficient k_p , which is defined as

$$k_p = \frac{\text{change in strain (m/m)}}{\text{change in electric field strength (V/m)}}$$

with no applied stress. Piezoelectric coefficients of some common materials are given in Table 15.

Applications of piezoelectric materials include actuators for ink-jet printers, miniature step motors, force sensors, precision shakers, high-frequency oscillators, and acoustic amplifiers. Note that large k_p values are desirable in piezoelectric actuators. For instance, PZT is used in microminiature step motors.⁹⁶ On the other hand, small k_p values are desirable in piezoelectric sensors (e.g., quartz accelerometers).

Magnetic Material and Components

Magnetism and Permeability. When electrons move (or spin), a magnetic field is generated. The combined effect of such electron movements is the cause of magnetic properties of material.

Table 13 Approximate Dielectric Strengths of Several Materials

Material	Dielectric Strength (V/mil)
Air	25
Ceramics	1000
Glass	2000
Mica	3000
Oil	400
Paper	1500

Table 15 Piezoelectric Coefficients of Some Materials

Material	Piezoelectric Coefficient k_p (m/V)
Barium titanate	2.5×10^{-10}
PZT	6.0×10^{-10}
Quartz	0.02×10^{-10}
Rochelle salt	3.5×10^{-10}

In the linear range of operation of a magnetic element, we can write

$$B = \mu H$$

where B is the magnetic flux density (webers per meter squared or teslas), H is magnetic field strength (amperes per meter), and μ is the permeability of the magnetic material. The relative permeability μ_r of a magnetic material is defined as

$$\mu = \frac{\mu}{\mu_0}$$

where μ_0 is the permeability of a vacuum (approx. $4\pi \times 10^{-7}$ H/m). (Note: 1 T = 1 Wb/m²; 1 H = 1 Wb/A.)

Hysteresis Loop. The B versus H curve of a magnetic material is not linear and exhibits a hysteresis loop as shown in Fig. 66. It follows that μ is not a constant. Initial values (when magnetization is started at the demagnetized state of $H = 0$ and $B = 0$) are usually specified. Some representative values are given in Table 16.

Properties of magnetic materials can be specified in terms of parameters of the hysteresis curve. Some important parameters are shown in Fig. 66:

H_c = coercive field or coercive force (A/m)

B_r = remnant flux density (Wb/m² or T)

B_{sat} = saturation flux density (T)

Magnetic parameters of a few permanent-magnetic materials are given in Table 17. Note that high values

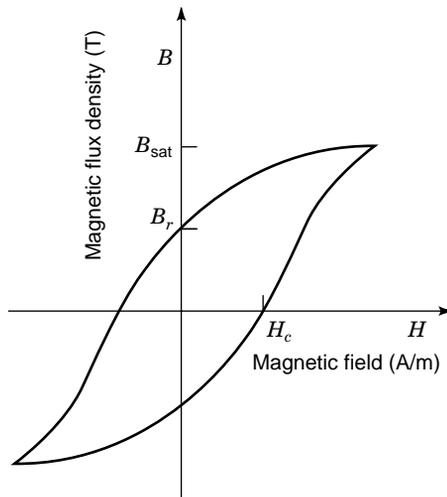

Fig. 66 Hysteresis curve (magnetization curve) of magnetic material.

Table 16 Initial Relative Permeability (Approximate) of Some Materials

Material	Relative Permeability μ_r
Alnico (Fe ₂ Ni Al)	6.5
Carbon steel	20
Cobalt steel (35% Co)	12
Ferrite (manganese-zinc)	800–10,000
Iron	200
Permalloy (78% Ni, 22% Fe)	3000
Silicon iron (grain oriented)	500–1500

Table 17 Parameters of Some Magnetic Materials

Material	H_c (A/m)	B_r (Wb/m ²)
Alnico	4.6×10^4	1.25
Ferrites	14.0×10^4	0.65
Steel (carbon)	0.4×10^4	0.9
Steel (35% Co)	2.0×10^4	1.4

of H_c and B_r are desirable for high-strength permanent magnets. Furthermore, high values of μ are desirable for core materials that are used to concentrate magnetic flux

Magnetic Materials. Magnetic characteristics of a material can be imagined as if contributed by a matrix of microminiature magnetic dipoles. Paramagnetic materials (e.g., platinum and tungsten) have their magnetic dipoles arranged in a somewhat random manner. These materials have a μ_r value approximately equal to 1 (i.e., no magnetization). Ferromagnetic materials (e.g., iron, cobalt, nickel, and some manganese alloys) have their magnetic dipoles aligned in one direction (parallel) with virtually no cancellation of polarity. These materials have a high μ_r (of the order of 1000) in general. At low H values, μ_r will be correspondingly low. Antiferromagnetic materials (e.g., chromium and manganese) have their magnetic dipoles arranged in parallel, but in an alternately opposing manner thereby virtually canceling the magnetization ($\mu_r = 1$). Ferrites have parallel magnetic dipoles arranged alternately opposing, as in antiferromagnetic materials, but the adjacent dipoles have unequal strengths. Hence, there is a resultant magnetization (μ_r is of the order of 1000).

Applications of magnets and magnetic materials include actuators (e.g., motors, magnetically levitated vehicles, tools, magnetic bearings), sensors and transducers, relays, resonators, and cores of inductors and transformers. Also, see the applications of superconductivity.

Piezomagnetism. When a stress (strain) is applied to a piezomagnetic material, the degree of magnetization of the material changes. Conversely, a piezomagnetic material undergoes deformation when the magnetic field in which the material is situated is changed.

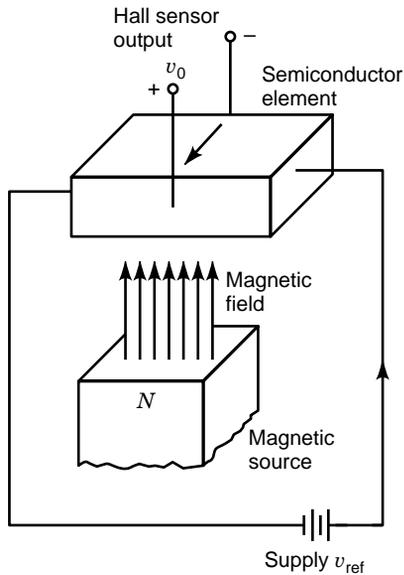

Fig. 67 Hall effect sensor.

Hall Effect Sensors. Suppose that a dc voltage v_{ref} is applied to a semiconductor element that is placed in a magnetic field in an orthogonal direction, as shown in Fig. 67. A voltage v_0 is generated in the third orthogonal direction, as indicated in the figure.⁹⁶ This is known as the Hall effect. Hall effect sensors use this phenomenon. For example, the motion of a ferromagnetic element can be detected in this manner since the magnetic field in which the sensor is mounted would vary as a result of the motion of the ferromagnetic element. Hall effect sensors are useful as position sensors, speed sensors, commutation devices for motors, and instrument transformers for power transmission systems.

Magnetic Bubble Memories. Consider a film of magnetic material such as gadolinium gallium oxide ($Gd_3Ga_5O_{12}$) deposited on a nonmagnetic garnet layer (substrate). The direction of magnetization will be perpendicular to the surface of the film. Initially, some regions of the film will be N poles, and the remaining regions will be S poles. An external magnetic field can shrink either the N regions or the S regions, depending on the direction of the field. The size of the individual magnetic regions can be reduced to the order of $1 \mu\text{m}$ in this manner. These tiny magnetic bubbles are the means with which information is stored in a magnetic bubble memory.

Inductance. Suppose that a conducting coil having n turns is placed in a magnetic field of flux ϕ (in webers). The resulting flux linkage is $n\phi$. If the flux linkage is changed, a voltage is induced in the coil.

This induced voltage (v) is given by

$$v = \frac{d(n\phi)}{dt} = n \frac{d\phi}{dt}$$

If the change in magnetic flux is brought about by a change in current (i), we can write

$$v = L \frac{di}{dt}$$

where L is the inductance of the coil (in henries).

In the frequency domain, we have

$$v = Lj\omega i$$

where ω = frequency and $j = \sqrt{-1}$.

It follows that the electrical impedance of an inductor is given by $j\omega L$.

5.2 Active Components

Active components made of semiconductor junctions and field effect components are considered in this section. Junction diodes, bipolar junction transistors, and field-effect transistors are of particular interest here. Active components are widely used in the monolithic (integrated-circuit) form as well as in the form of discrete elements.

pn Junctions A pure semiconductor can be doped to form either a p -type semiconductor or an n -type semiconductor. A pn junction is formed by joining a p -type semiconductor element and an n -type semiconductor element.

Semiconductors. Semiconductor materials have resistivities that are several million times larger than those of conductors and several billion times smaller than those of insulators. Crystalline materials such as silicon and germanium are semiconductors. For example, the resistivity of pure silicon is about 5×10^{10} times that of silver. Similarly, the resistivity of pure germanium is about 5×10^7 times that of silver. Typically, semiconductors have resistivities ranging from 10^{-4} to $10^7 \Omega \cdot \text{m}$. Other examples of semiconductor materials are gallium arsenide, cadmium sulfide and selenium.

A pure (intrinsic) semiconductor material has some free electrons (negative charge carriers) and holes (positive charge carriers). Note that a hole is formed in an atom when an electron is removed. Strictly, the holes cannot move. But suppose that an electron shared by two atoms (a covalent electron) enters an existing hole in an atom, leaving behind a hole at the point of origin. The resulting movement of the electron is interpreted as a movement of a hole in the direction opposite to the actual movement of the covalent electron.

The number of free electrons in a pure semiconductor is roughly equal to the number of holes.

The number of free electrons or holes in a pure semiconductor can be drastically increased by adding traces of impurities in a controlled manner (doping) into the semiconductor during crystal growth (e.g., by alloying in a molten form, and by solid or gaseous diffusion of the trace). An atom of a pure semiconductor that has four electrons in its outer shell will need four more atoms to share in order to form a stable covalent bond. These covalent bonds are necessary to form a crystalline lattice structure of atoms that is typical of semiconductor materials. If the trace impurity is a material such as arsenic, phosphorus, or antimony whose atoms have five electrons in the outer shell (a donor impurity), a free electron will be left over after the formation of a bond with an impurity atom. The result will be an *n*-type semiconductor having a very large number of free electrons. If, on the other hand, the trace impurity is a material such as boron, gallium, aluminum, or indium whose atoms have only three electrons in the outer shell (an acceptor impurity), a hole will result on formation of a bond. In this case, a *p*-type semiconductor, consisting of a very large number of holes, will result. Doped semiconductors are termed extrinsic.

Depletion Region. When a *p*-type semiconductor is joined with an *n*-type semiconductor, a *pn* junction is formed. A *pn* junction exhibits the diode effect, much larger resistance to current flow in one direction than in the opposite direction across the junction. As a *pn* junction is formed, electrons in the *n*-type material in the neighborhood of the common layer will diffuse across into the *p*-type material. Similarly, the holes in the *p*-type material near the junction will diffuse into the opposite side (strictly, the covalent electrons will diffuse in the opposite direction). The diffusion will proceed until an equilibrium state is reached. But, as a result of the loss of electrons and the gain of holes on the *n* side and the opposite process on the *p* side, a potential difference is generated across the *pn* junction, with a negative potential on the *p* side and a positive potential on the *n* side. Due to the diffusion of carriers across the junction, the small region surrounding the common area will be virtually free of carriers (free electrons and holes). Hence, this region is called the depletion region. The potential difference that exists in the depletion region is mainly responsible for the diode effect of a *pn* junction.

Biasing. The forward biasing and the reverse biasing of a *pn* junction are shown in Fig. 68. In the case of forward biasing, a positive potential is connected to the *p* side of the junction, and a negative potential is connected to the *n* side. The polarities are reversed for reverse biasing. Note that in forward biasing, the external voltage (bias voltage v) complements the potential difference of the depletion region (Fig. 68a). The free electrons that crossed over to the *p* side from the *n* side will continue to flow toward the positive terminal of

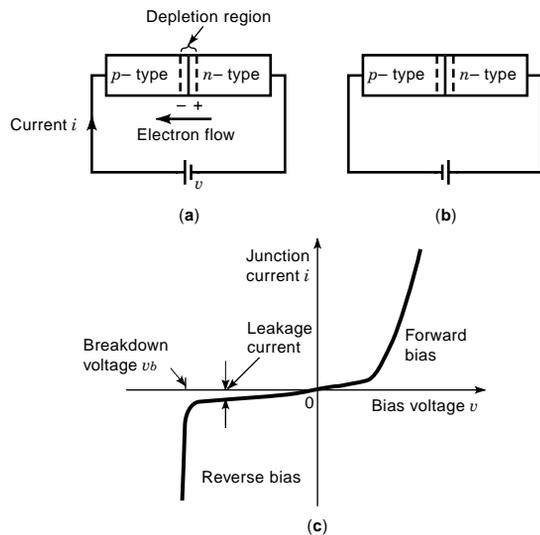

Fig. 68 A *pn* junction diode: (a) forward biasing; (b) reverse biasing; (c) characteristic curve.

the external supply, thereby generating a current (junction current i). The junction current increases with the bias voltage, as shown in Fig. 68c.

In reverse biasing, the potential in the depletion region is opposed by the bias voltage (Fig. 68b). Hence, the diffusion of free electrons from the *n* side into the *p* side is resisted. Since there are some (very few) free electrons in the *p* side and some holes in the *n* side, the reverse bias will reinforce the flow of these minority electrons and holes. This will create a very small current (about 10^{-9} A for silicon and 10^{-6} A for germanium at room temperature), known as the *leakage current*, in the opposite direction to the forward-bias current. If the reverse bias is increased, at some voltage (breakdown voltage v_b in Fig. 68c) the junction will break down, generating a sudden increase in the reverse current. There are two main causes of this breakdown. First, the intense electric field of the external voltage can cause electrons to break away from neutral atoms in large numbers. This is known as Zener breakdown. Second, the external voltage will accelerate the minority free electrons on the *p* side (and minority holes on the *n* side), creating collisions that will cause electrons on the outer shells of neutral atoms to break away in large numbers. This is known as the avalanche breakdown. In some applications (e.g., rectifier circuits), junction breakdown is detrimental. In some other types of applications (e.g., as constant voltage sources and in some digital circuits), the breakdown state of specially designed diodes is practically utilized. Typical breakdown voltages of *pn* junctions made of three common semiconductor materials are given in Table 18. Note that the breakdown voltage decreases with the concentration of the trace material.

Table 18 Typical Breakdown Voltage of pn Junction at Room Temperature

Semiconductor	Breakdown Voltage (V)	
	Dope Concentration $= 10^{15}$ atoms/cm ³	Dope Concentration $= 10^{17}$ atoms/cm ³
Germanium	400	5.0
Silicon	300	11.0
Gallium arsenide	150	16.0

The current through a reverse-biased pn junction will increase exponentially with temperature. For a forward-biased pn junction, current will increase with temperature at low to moderate voltages and will decrease with temperature at high levels of voltage.

Diodes A semiconductor diode is formed by joining a p -type semiconductor with an n -type semiconductor. A diode offers much less resistance to current flow in one direction (forward) than in the opposite direction (reverse). There are many varieties of diodes. Zener diodes, voltage variable capacitor (VVC) diodes, tunnel diodes, microwave power diodes, pin diodes, photodiodes, and light-emitting diodes (LED) are examples. The last two varieties will be discussed in separate sections.

Zener Diodes. Zener diodes are a particular type of diodes that are designed to operate in the neighborhood of the reverse breakdown (both Zener and avalanche breakdowns). In this manner, a somewhat constant voltage output (the breakdown voltage) can be generated. This voltage depends on the concentration of the trace impurity. By varying the impurity concentration, output voltages in the range of 2–200 V may be realized from a Zener diode. Special circuits would be needed to divert large currents that are generated at the breakdown point of the diode. The rated power dissipation of a Zener diode should take into consideration the current levels that are possible in the breakdown region. Applications of Zener diodes include constant voltage sources, voltage clipper circuits, filter circuits for voltage transients, digital circuits, and two-state devices.

VVC Diodes. VVC diodes use the property of a diode that, in reverse bias, the capacitance decreases (nonlinearly) with the bias voltage. The depletion region of a pn junction is practically free of carriers (free electrons and holes) and, hence, behaves like the dielectric medium of a capacitor. The adjoining p region and n region serve as the two plates of the capacitor. The width of the depletion region increases with the bias voltage. Consequently, the capacitance of a reverse-biased pn junction decreases as the bias voltage is increased. The obtainable range of capacitance can be varied by changing the dope concentration and also by distributing the dope concentration

nonuniformly along the diode. For example, a capacitance variation of 5–500 pF may be obtained in this manner (note: $1 \text{ pF} = 1 \times 10^{-12} \text{ F}$). VVC diodes are also known as varactor diodes and varicaps and are useful in voltage-controlled tuners and oscillators.

Tunnel Diodes. The depletion of a pn junction can be made very thin by using very high dope concentrations (in both the p and n sides). The result is a tunnel diode. Since the depletion region is very narrow, charge carriers (free electrons and holes) in the n and p sides of the diode can tunnel through the region into the opposite side on application of a relatively small voltage. The voltage–current characteristic of a tunnel diode is quite linear at low (forward and reverse) voltages. When the forward bias is further increased, however, the behavior will become very nonlinear; the junction current will peak, then drop (a negative conductance) to a minimum (valley), and finally rise again, as the voltage is increased. Due to the linear behavior of the tunnel diode at low voltages, almost instantaneous current reversal (i.e., very low reverse recovery time) can be achieved by switching the bias voltage. Tunnel diodes are useful in high-frequency switching devices, sensors, and signal conditioning circuits.

pin Diodes. The width of the depletion region of a conventional pn junction varies with many factors, primarily the applied (bias) voltage. The capacitance of a junction depends on this width and will vary due to such factors. A diode with practically a constant capacitance is obtained by adding a layer of silicon between the p and n elements. The sandwiched silicon layer is called the intrinsic layer, and the diode is called a pin diode. The resistance of a pin diode varies inversely with junction current. Pin diodes are useful as current-controlled resistors at constant capacitance.

Schottky Barrier Diodes. Most diodes consist of semiconductor–semiconductor junctions. An exception is a Schottky barrier diode, which consists of a metal–semiconductor (n -type) junction. A metal such as gold, silver, platinum, or palladium and a semiconductor such as silicon or gallium arsenide may be used in the construction. Since no holes exist in the metal, a depletion region cannot be formed at the metal–semiconductor junction. Instead, an electron barrier is formed by the free electrons from the n -type semiconductor. Consequently, the junction capacitance will be negligible, and the reverse recovery time will be very small. For this reason, Schottky diodes can handle very high switching frequencies (10^9 Hz range). Since the electron barrier is easier to penetrate than a depletion region, by using a reverse bias, Schottky diodes exhibit much lower breakdown voltages. Operating noise is also lower than for semiconductor–semiconductor diodes.

Thyristors. A thyristor, also known as a silicon-controlled rectifier or a solid-state controlled rectifier, is

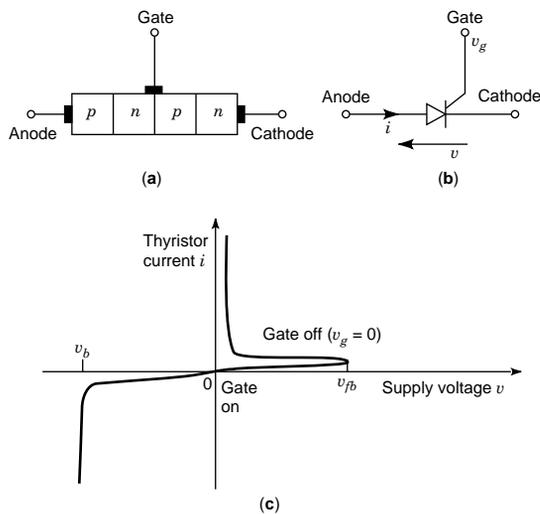

Fig. 69 Thyristor: (a) schematic representation; (b) circuit symbol; (c) characteristic curve.

semiconductor-controlled rectifier or simply an SCR, possesses some of the characteristics of a semiconductor diode. It consists of four layers ($pnpn$) of semiconductor and has three terminals—the anode, the cathode, and the gate—as shown in Fig. 69a. The circuit symbol for a thyristor is shown in Fig. 69b. The thyristor current is denoted by i , the external voltage is v , and the gate potential is v_g . The characteristic curve of a thyristor is shown in Fig. 69c. Note that a thyristor cannot conduct in either direction (i almost zero) until either the reverse voltage reaches the reverse breakdown voltage (v_b) or the forward voltage reaches the forward breakover voltage (v_{fb}). The forward breakover is a bistable state, and once this voltage is reached, the voltage drops significantly and the thyristor begins to conduct like a forward-biased diode. When v_g is less than or equal to zero with respect to the cathode, v_{fb} becomes quite high. When v_g is made positive, v_{fb} becomes small, and v_{fb} will decrease as the gate current (i_g) is increased. A small positive v_g can make v_{fb} very small, and then the thyristor will conduct from anode to cathode but not in the opposite direction (i.e., it behaves like a diode). It follows that a thyristor behaves like a voltage-triggered switch; a positive firing signal (a positive v_g) will close the switch. The switch will be opened when both i and v_g are made zero. When the supply voltage v is dc and nonzero, the thyristor will not be able to turn itself off. In this case a commutating circuit that can make the trigger voltage v_g slightly negative has to be employed. Thyristors are commonly used in control circuits for dc and ac motors.

Parameter values for diodes are given in data sheets provided by the manufacturer. Commonly used variables and characteristic parameters in association with

Table 19 Characteristic Variables and Parameters for Diodes

Diode Variable/Parameter	Description
Forward bias (v_f)	Positive external voltage at p with respect to n
Reverse bias (v_r)	Positive external voltage at n with respect to p
Breakdown voltage (v_b)	Minimum reverse bias that will break down the junction resistance
Junction current (i_f)	Forward current through a forward-biased diode
Leakage current (i_r)	Reverse current through a reverse-biased diode
Transition capacitance (C_t)	Capacitance (in the depletion region) of a reverse-biased diode
Diffusion capacitance (C_d)	Capacitance exhibited while a forward-biased diode is switched off
Forward resistance (R_f)	Resistance of a forward-biased diode
Reverse recovery time (t_{rr})	Time needed for the reverse current to reach a specified level when the diode is switched from forward to reverse
Operating temperature range (T_A)	Allowable temperature range for a diode during operation
Storage temperature range (T_{srg})	Temperature that should be maintained during storage of a diode
Power dissipation (P)	Maximum power dissipation allowed for a diode at a specified temperature

diodes are described in Table 19. For thyristors, as mentioned before, several other quantities such as v_{fb} , v_g , and i_g should be included. The time required for a thyristor to be turned on by the trigger signal (turn-on time) and the time for it to be turned off through commutation (turn-off time) determine the maximum switching frequency (bandwidth) for a thyristor. Another variable that is important is the holding current or latching current, which denotes the small forward current that exists at the breakover voltage.

Bipolar Junction Transistors A bipolar junction transistor (BJT) has two junctions that are formed by joining p regions and n regions. Two types of transistors, npn and pnp , are possible with this structure. A BJT has three terminals, as indicated in Fig. 70a. The middle (sandwiched) region of a BJT is thinner than the end regions, and this region is known as the base. The end regions are termed the emitter and the collector. Under normal conditions, the emitter–base junction is forward biased, and the collector–base junction is reverse biased, as shown in Fig. 70b.

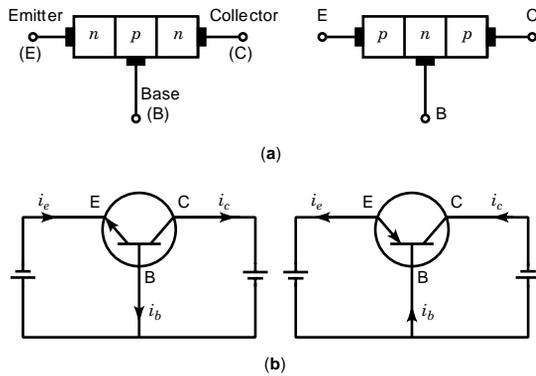

Fig. 70 Bipolar junction transistors: (a) *npn* and *pnp* transistors; (b) circuit symbols and biasing.

To explain the behavior of a BJT, consider an *npn* transistor under normal biasing. The forward bias at the emitter–base junction will cause free electrons in the emitter to flow into the base region, thereby creating the emitter current (i_e). The reverse bias at the collector–base junction will increase the depletion region there. The associated potential difference at the collector–base junction will accelerate the free electrons in the base into the collector and will form the collector current (i_c). Holes that are created in the base, for recombination with some free electrons that entered the base, will form the base current (i_b). Usually, i_c is slightly smaller than i_e . Furthermore, i_b is much smaller than i_c .

Transistor Characteristics. The common-emitter connection is widely used for transistors in amplification applications. In this configuration the emitter terminal will be common to the input side and the output side of the circuit. Transistor characteristics are usually specific for this configuration. Figure 71 shows typical characteristic curves for a junction transistor in the common-emitter connection. In this configuration both voltage gain (output voltage/input voltage) and current gain (collector current/base current) will be greater than unity, thereby providing a voltage amplification as well as a current amplification. Note from Fig. 71 that the control signal is the base current (i_b), and the characteristic of the transistor depends on i_b . This is generally true for any bipolar junction transistor; a BJT is a current-controlled transistor. In the common-base configuration the base terminal is common to both input and output.

Maximum frequency of operation and allowable switching rate for a transistor are determined by parameters such as rise time, storage time, and fall time. These and some other useful ratings and characteristic parameters for bipolar junction transistors are defined in Table 20. Values for these parameters are normally given in the manufacturer's data sheet for a particular transistor.

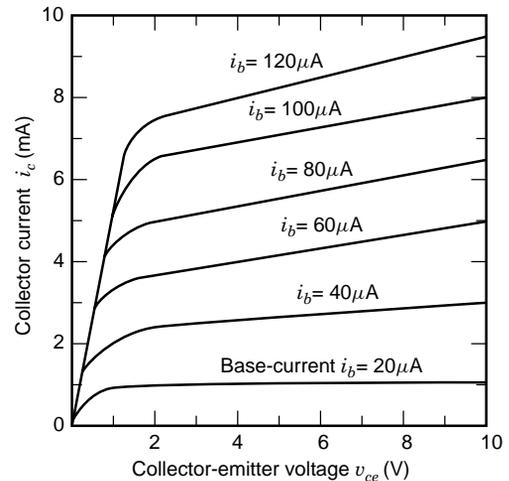

Fig. 71 Characteristic curves of common emitter BJT.

Table 20 Rating Parameters for Transistors

Transistor Parameter	Description
Collector-to-base voltage (v_{cb})	Voltage limit across collector and base with emitter open
Collector-to-emitter voltage (v_{ce})	Voltage limit across collector and emitter with base connected to emitter
Emitter-to-base voltage (v_{eb})	Voltage limit across emitter and base with collector open
Collector cutoff current (i_{co})	Reverse saturation current at collector with either emitter open (i_{cbo}) or base open (i_{cbo})
Transistor dissipation (P_T)	Power dissipated by the transistor at rated conditions
Input impedance (h_i)	Input voltage/input current with output voltage = 0 (Defined for both common emitter and common base configurations, h_{ie} , h_{ib})
Output admittance (h_o)	Output current/output voltage with input current = 0 (h_{oe} , h_{ob} are defined)
Forward current transfer ratio (h_f)	Output current/input current with output voltage = 0 (h_{fe} , h_{fb} are defined)
Reverse voltage transfer ratio (h_r)	Input voltage/output voltage with input current = 0 (h_{re} , h_{rb} are defined)
Rise time (t_r)	Time taken to reach the full current level for the first time when turned on
Storage time (t_s)	Time taken to reach the steady current level when turned on
Fall time (t_f)	Time taken for the current to reach zero when turned off

Fabrication Process. The actual manufacturing process for a transistor is complex and delicate. For example, an *npn* transistor can be fabricated by starting with a crystal of *n*-type silicon. This starting element is called the wafer or substrate. The *npn* transistor is formed, by using the planar diffusion method, in the top half of the substrate as follows: The substrate is heated to about 1000°C . A gas stream containing a donor-type impurity (which forms *n*-type regions) is impinged on the crystal surface. This produces an *n*-type layer on the crystal. The substrate is oxidized by heating to a high temperature. The resulting layer of silicon dioxide acts as an insulating surface. A small area of this layer is then dissolved off using hydrofluoric acid. The crystal is again heated to 1000°C , and a gas stream containing acceptor-type impurity (which forms *p*-type regions) is impinged on the window thus formed. This produces a *p* region under the window on top of the *n* region, which was formed earlier.

Oxidation is repeated to cover the newly formed *p* region. Using hydrofluoric acid, a smaller window is cut on the latest silicon dioxide layer, and a new *n* region is formed, as before, on top of the *p* region. The entire manufacturing process has to be properly controlled so as to control the properties of the resulting transistor. Aluminum contacts have to be deposited on the uppermost *n* region, the second *p* region (in a suitable annular window cut on the silicon dioxide layer), and on the *n* region below it or on the crystal substrate. A pictorial representation of an *npn* transistor fabricated in this manner is shown in Fig. 72.

Field-Effect Transistors An FET, unlike a BJT, is a voltage-controlled transistor. The electrostatic field generated by a voltage applied to the gate terminal of an FET controls the behavior of the FET. Since the device is voltage controlled at very low input current levels, the input impedance is very high, and the input power is very low. Other advantages of an FET over a BJT are that the former is cheaper and requires significantly less space on a chip in the monolithic form. FETs are somewhat slower (in terms of switching rates) and more nonlinear than BJTs, however.

There are two primary types of FETs: metal-oxide-semiconductor field-effect transistor (MOSFET) and junction field-effect transistor (JFET). Even though the

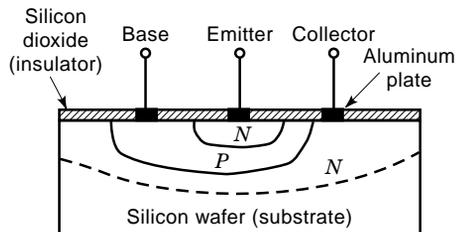

Fig. 72 An *npn* transistor manufactured by the planar diffusion method.

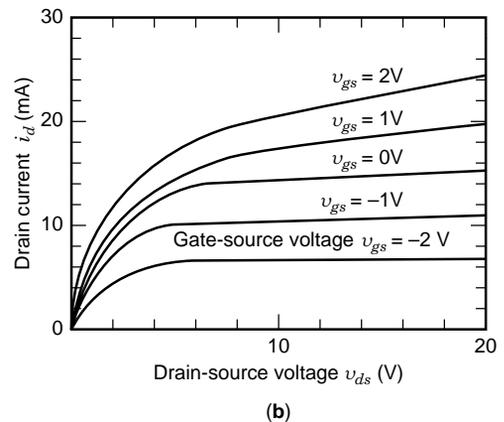

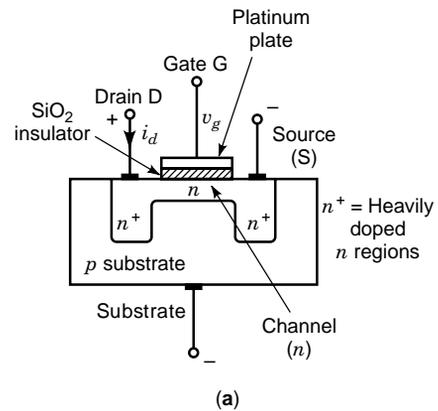

Fig. 73 MOSFET: (a) an *n*-channel depletion-type MOSFET; (b) D-MOSFET characteristics.

physical structure of the two types is somewhat different, their characteristics are quite similar. Insulated-gate FET (or IGFET) is a general name given to MOSFETs.

MOSFET. An *n*-channel MOSFET is produced using a *p*-type silicon substrate, and a *p*-channel MOSFET by an *n*-type substrate. An *n*-channel MOSFET is shown in Fig. 73a. During manufacture, two heavily doped *n*-type regions are formed on the substrate. One region is termed source (S) and the other region drain (D). The two regions are connected by a moderately doped and narrow *n* region called a channel. A metal coating deposited over an insulating layer of silicon dioxide, which is formed on the channel, is the gate (G). The source lead is usually joined with the substrate lead. This is a depletion-type MOSFET (or D-MOSFET). Another type is the enhancement-type MOSFET (or E-MOSFET). In this type, a channel linking the drain and the source is not physically present in the substrate but is induced during operation of the transistor.

Consider the operation of the n -channel D-MOSFET shown in Fig. 73a. Under normal operation, the drain is positively biased with respect to the source. Drain current i_d is considered the output of a MOSFET (analogous to the collector current of a BJT). The control signal of a MOSFET is the gate voltage v_{gs} with respect to the source (analogous to the base current of a BJT). It follows that a MOSFET is a voltage-controlled device. Since the source terminal is used as the reference for both input (gate voltage) and output (drain), this connection is called the common-source configuration. Suppose that the gate voltage is negative with respect to the source. This will induce holes in the channel, thereby decreasing the free electrons there through recombination. This, in turn, will reduce the concentration of free electrons in the drain region and, hence, will reduce the drain current i_d . Clearly, if the magnitude of the negative voltage at the gate is decreased, the drain current will increase, as indicated by the characteristic curves in Fig. 73b. A positive bias at the gate will further increase the drain current of an n -channel MOSFET as shown. The opposite will be true for a p -channel MOSFET.

The JFET. A junction field-effect transistor (JFET) is different in physical structure to a MOSFET but similar in characteristics. The structure of an n -channel JFET is shown in Fig. 74. It consists of two p -type regions formed inside an n -type region. The two p regions are separated by a narrow n region called a

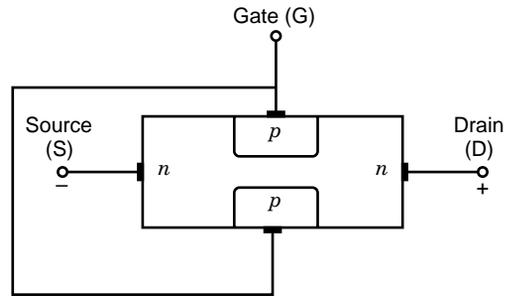

Fig. 74 An n -channel JFET.

channel. The channel links two n -type regions called source (S) and drain (D). The two p regions are linked by a common terminal and form the gate (G). As for a MOSFET, drain current i_d is considered the output of the JFET, and gate voltage v_{gs} , with respect to the source, is considered the control signal. For normal operation, the drain is positively biased with respect to the source, as for an n -channel MOSFET, and the common-source configuration is used.

To explain the operation of a JFET, consider the n -channel JFET shown in Fig. 74. Depletion regions are present at the two pn junctions of the JFET (as

Table 21 Common Transistor Types

Transistor Type		
Abbreviation	Name	Description
BJT	Bipolar junction transistor	Three-layer device (npn or pnp) Current controlled Control = base current Output = collector current
FET	Field-effect transistor	Physical or induced channel (n -channel or p -channel) voltage controlled Control = gate voltage Output = drain current
MOSFET	Metal-oxide-semiconductor FET	n channel or p channel
D-MOSFET	Depletion-type MOSFET	Channel is physically present
E-MOSFET	Enhancement-type MOSFET	Channel is induced
VMOS	V-shaped Gate MOSFET or VFET	An E-MOSFET with increased power-handling capacity
DG-MOS	Dual-gate MOSFET	Secondary gate is present between main gate and drain (lower capacitance)
D-MOS	Double-diffused MOSFET	Channel layer is formed on a high-resistivity substrate and then source and drain are formed (by diffusion). High breakdown voltage
CMOS	Complementary symmetry MOSFET	Uses two E-MOSFETs (n channel and p channel). Symmetry is used to save space on chip. Cheaper and lower power consumption.
GaAs	Gallium arsenide MOSFET	Uses gallium arsenide, aluminum gallium arsenide, (AlGaAs), indium gallium arsenide phosphide (InGaAsP), etc. in place of silicon substrate. Faster operation
JFET	Junction FET	p channel or n channel. Has two (n or p) regions in a (p or n) region linked by a channel (p or n) Control = gate voltage Output = drain current

for a semiconductor diode). If the gate voltage is made negative, the resulting field will weaken the p regions. As a result, the depletion regions will shrink. Some of the free electrons from the drain will diffuse toward the channel to occupy the growing n regions due to the shrinking depletion regions. This will reduce the drain current. It follows that drain current decreases as the magnitude of the negative voltage at the gate is increased. This behavior is similar to that of a MOSFET.

A p -channel JFET has two n regions representing the gate and two p regions forming the source and the drain, which are linked by a p -channel. Its characteristic is the reverse of an n -channel JFET.

Common types of transistor are summarized in Table 21. Semiconductor devices have numerous uses. A common use is as switching devices or as two-state elements. Typical two-state elements are schematically illustrated in Fig. 75.

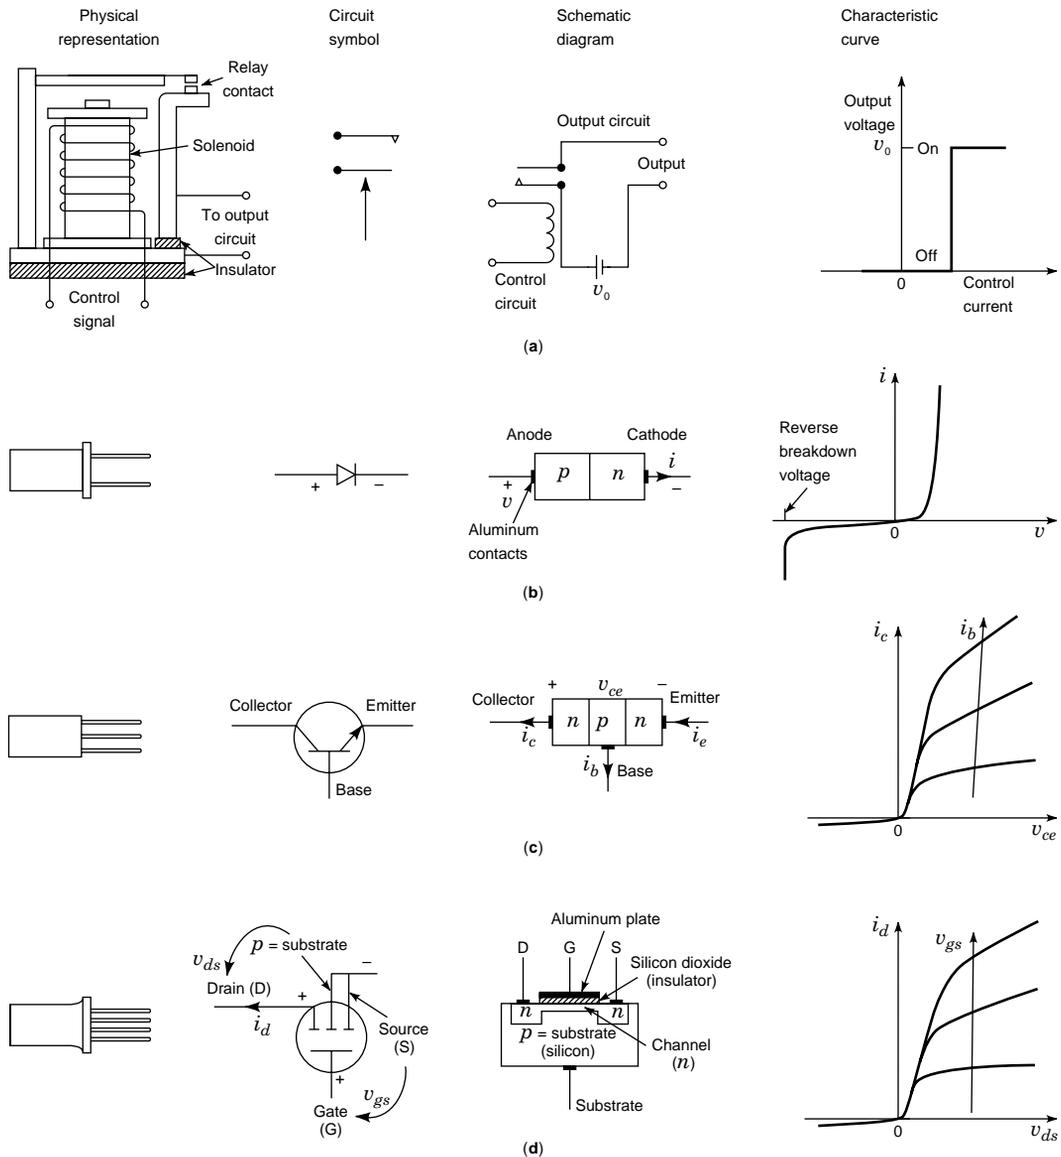

Fig. 75 Discrete switching (two-state) elements: (a) electromagnetic relay; (b) Zener diode; (c) BJT (npn); (d) n -channel MOSFET.

5.3 Light Emitters and Displays

Visible light is part of the electromagnetic spectrum. Electromagnetic waves in the wave length range of 390–770 nm (Note: $1 \text{ nm} = 1 \times 10^{-9} \text{ m}$) form the visible light. Ultraviolet rays and X rays are also electromagnetic waves but have lower wavelengths (higher frequencies). Infrared rays, microwaves, and radio waves are electromagnetic waves having higher wavelengths. Table 22 lists wavelengths of several types of electromagnetic waves. Visible light occupies a broad range of wavelengths. For example, in optical coupling applications, the narrower the wave spectrum, the clearer (noise free) the coupling process. Consequently, it is advantageous to use special light sources in applications of that type. Furthermore, since visible light can be contaminated by environmental light, thereby introducing an error signal into the system, it is also useful to consider electromagnetic waves that are different from what is commonly present in operating environments in applications such as sensing, optical coupling, and processing.

Incandescent Lamps Tungsten-filament incandescent lamps that are commonly used in household illumination emit visible light in a broad spectrum. Furthermore, they are not efficient because they emit more infrared radiation than useful visible light. Ionizing lamps filled with gases such as halogens, sodium vapor, neon, or mercury vapor have much narrower spectra, and they emit very pure visible light (with negligible infrared radiation). Hence, these types of incandescent lamps are more efficient for illumination purposes. Regular fluorescent lamps are known to create a line-frequency (60 or 50 Hz) flicker but are quite efficient and durable. All these types of light sources are usually not suitable in many applications primarily because of the following disadvantages:

1. They are bulky.
2. They cannot be operated at high switching rates (from both time constant and component life points of view).
3. Their spectral bandwidth can be very wide.

Note that a finite time is needed for an incandescent lamp to emit light once it is energized. That is, it has a

Table 22 Wavelengths of Several Selected Components of the Electromagnetic Spectrum

Wave Type	Approximate Wavelength Range (μm)
Radio waves	$1 \times 10^6 - 5 \times 10^6$
Microwaves	$1 \times 10^3 - 1 \times 10^6$
Infrared rays	$0.8 - 1 \times 10^3$
Visible light	0.4 – 0.8
Ultraviolet rays	$1 \times 10^{-2} - 0.4$
X rays	$1 \times 10^{-6} - 5 \times 10^{-2}$

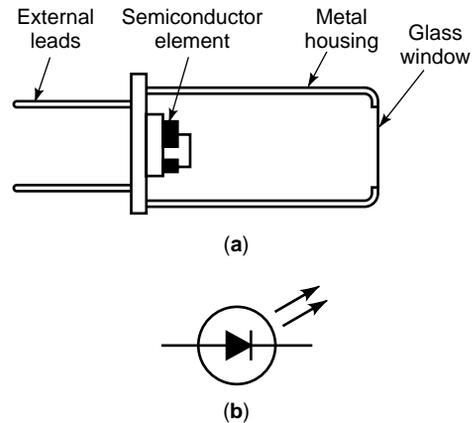

Fig. 76 LED: (a) physical construction; (b) circuit symbol.

large time constant. This limits the switching speed to less than 100 Hz. Furthermore, lamp life will decrease rapidly with increasing switching frequency.

Light-Emitting Diodes The basic components of an LED are shown in Fig. 76a. The element symbol that is commonly used in electrical circuits is shown in Fig. 76b. The main component of an LED is a semiconductor diode element, typically made of gallium compounds (e.g., gallium arsenide or GaAs and gallium arsenide phosphide or GaAsP). When a voltage is applied in the forward-bias direction to this semiconductor element, it emits visible light (and also other electromagnetic wave components, primarily infrared). In the forward-bias configuration electrons are injected into the *p* region of the diode and recombined with holes. Radiation energy (including visible light) is released spontaneously in this process. This is the principle of operation of an LED. Suitable doping with trace elements such as nitrogen will produce the desired effect. The radiation energy generated at the junction of a diode has to be directly transmitted to a window of the diode in order to reduce absorption losses. Two types of construction are commonly used; edge emitters emit radiation along the edges of the *pn* junction, and surface emitters emit radiation normal to the junction surface.

Infrared light-emitting diodes (IRED) are LEDs that emit infrared radiation at a reasonable level of power. Gallium arsenide (GaAs), gallium aluminum arsenide (GaAlAs), and indium gallium arsenide phosphide (InGaAsP) are the commonly used IRED material. Gallium compounds and not silicon or germanium are used in LEDs for reasons of efficiency and intensity characteristics. (Gallium compounds exhibit sharp peaks of spectral output in the desired frequency bands.) Table 23 gives wavelength characteristics of common LED and IRED types ($1 \text{ \AA} = 1 \times 10^{-10} \text{ m} = 0.1 \text{ nm}$). Note that \AA denotes the unit angstrom.

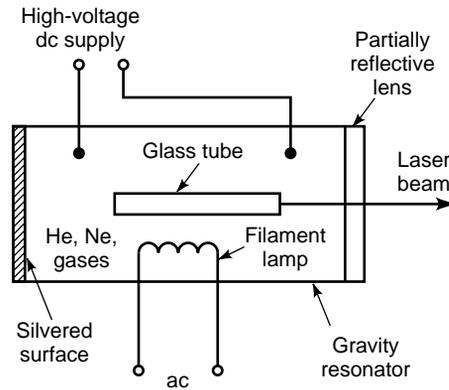

Table 23 Wavelength Characteristics of Common LEDs ($1 \text{ \AA} = 1 \times 10^{-10} \text{ m}$)

LED Type	Wavelength at Peak Intensity	
	(\AA)	Color
Gallium arsenide	5500	Green
	9300	Infrared

Light-emitting diodes are widely used in optical electronics because they can be constructed in miniature sizes, they have small time constants and low impedances, they can provide high switching rates (typically over 1000 Hz), and they have much longer component life than incandescent lamps. They are useful as both light sources and displays.

Lasers Laser (light amplification by stimulated emission of radiation) is a light source that emits a concentrated beam of light that will propagate typically at one or two frequencies (wavelengths) and in phase. Usually, the frequency band is extremely narrow (i.e., monochromatic), and the waves in each frequency are in phase (i.e., coherent). Furthermore, the energy of a laser is highly concentrated (power densities of the order of one billion watts/cm²). Consequently, a laser beam can travel in a straight line over a long distance with very little dispersion. Hence, it is useful in gauging and aligning applications. Lasers can be used in a wide variety of sensors (e.g., motion sensors, tactile sensors, laser-doppler velocity sensors) that employ photosensing and fiber optics. Also, lasers are used in medical applications, microsurgery in particular. Lasers have been used in manufacturing and material removal applications such as precision welding, cutting, and drilling of different types of materials, including metals, glass, plastics, ceramics, leather, and cloth. Lasers are used in inspection (detection of faults and irregularities) and gauging (measurement of dimensions) of parts. Other applications of lasers include heat treatment of alloys, holographic methods of nondestructive testing, communication, information processing, and high-quality printing.

Lasers may be classified as solid, liquid, gas, and semiconductor. In a solid laser (e.g., ruby laser, glass laser), a solid rod with reflective ends is used as the laser medium. The laser medium of a liquid laser (e.g., dye laser, salt-solution laser) is a liquid such as an organic solvent with a dye or an inorganic solvent with dissolved salt compound. Very high peak power levels are possible with liquid lasers. Gas lasers (e.g., helium–neon or He–Ne laser, helium–cadmium or He–Cd laser, carbon dioxide or CO₂ laser) use a gas as

**Fig. 77** Helium–neon (He–Ne) laser.

the laser medium. Semiconductor lasers (e.g., gallium arsenide laser) use a semiconductor diode similar to an edge-emitting LED. Some lasers have their main radiation components outside the visible spectrum of light. For example, a CO₂ laser (wavelength of about 110,000 \AA) primarily emits infrared radiation.

In a conventional laser unit, the laser beam is generated by first originating an excitation to create a light flash. This will initiate a process of emitting photons from molecules within the laser medium. This light is then reflected back and forth between two reflective surfaces before the light beam is finally emitted as a laser. These waves will be limited to a very narrow frequency band (monochromatic) and will be in phase (coherent). For example, consider the He–Ne laser unit schematically shown in Fig. 77. The helium and neon gas mixture in the cavity resonator is heated by a filament lamp and ionized using a high dc voltage (2000 V). Electrons released in the process will be accelerated by the high voltage and will collide with the atoms, thereby releasing photons (light). These photons will collide with other molecules, releasing more photons. This process is known as lasing. The light generated in this manner is reflected back and forth by the silvered surface and the partially reflective lens (beam splitter) in the cavity resonator, thereby stimulating it. This is somewhat similar to a resonant action. The stimulated light is concentrated into a narrow beam by a glass tube and emitted as a laser beam through the partially silvered lens.

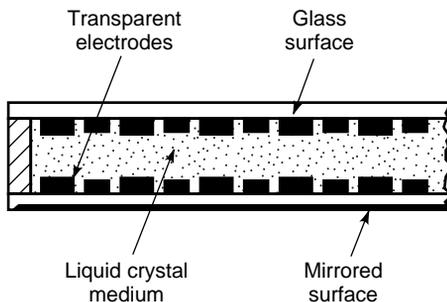

A semiconductor laser is somewhat similar to an LED. The laser element is typically made of a *pn* junction (diode) of semiconductor material such as gallium arsenide (GaAs) or indium gallium arsenide phosphide (InGaAsP). The edges of the junction are reflective (naturally or by depositing a film of silver). As a voltage is applied to the semiconductor laser, the ionic injection and spontaneous recombination that take place near the *pn* junction will emit light as in an LED. This light will be reflected back and forth between the reflective surfaces, passing along

Table 24 Properties of Several Types of Lasers
($1 \text{ \AA} = 1 \times 10^{-10} \text{ m}$)

Laser Type	Wavelength (\AA)	Output Power (W/cm^2)
Solid		
Ruby	7,000	0.1–100
Glass	1,000	0.1–500
Liquid		
Dye	4,000–10,000	0.001–1
Gas		
Helium–neon	6,330	0.001–2
Helium–cadmium	4,000	0.001–1
Carbondioxide	110,000	$1-1 \times 10^4$
Semiconductor:		
GaAs	9,000	0.002–0.01
InGaAsP	13,000	0.001–0.005

the depletion region many times and creating more photons. The stimulated light (laser) beam is emitted through an edge of the *pn* junction. Semiconductor lasers are often maintained at very low temperatures in order to obtain a reasonable component life. Semiconductor lasers can be manufactured in very small sizes. They are lower in cost and require less power in comparison to the conventional lasers. Wave length and power output characteristics of several types of lasers are given in Table 24.

Liquid Crystal Displays A liquid crystal display (LCD) consists of a medium of liquid crystal material (e.g., organic compounds such as cholesteryl nonanote and *p*-azoxyanisole) trapped between a glass sheet and a mirrored surface, as shown in Fig. 78. Pairs of transparent electrodes (e.g., indium tin oxide), arranged in a planar matrix, are deposited on the inner surfaces of the sandwiching plates. In the absence of an electric field across an electrode pair, the atoms of liquid crystal medium in that region will have a parallel orientation. As a result, any light that falls on the glass sheet will first travel through the liquid crystal, then will be reflected back by the mirrored surface, and finally will return unscattered. Once an electrode pair is energized, the molecular alignment of the entrapped

**Fig. 78** LCD element.

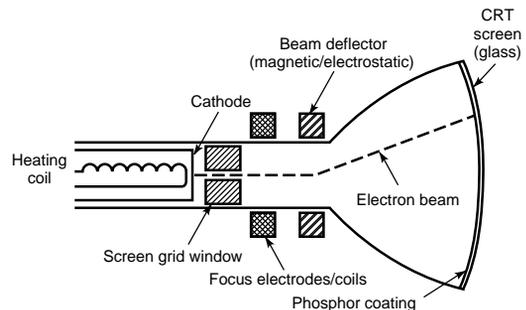

medium will change, causing some scattering. As a result, a dark region in the shape of the electrode will be visible. Alphanumeric characters and other graphic images can be displayed in this manner by energizing a particular pattern of electrodes.

Other types of LCD construction are available. In one type, polarized glass sheets are used to entrap the liquid crystal. In addition, a special coating is applied on the inner surfaces of the two sheets that will polarize the liquid crystal medium in different directions. This polarization structure is altered by an electric field (supplied by an electrode pair), thereby displaying an image element. LCDs require external light to function. But they need significant low currents and power levels to operate. For example, an LED display might need a watt of power, whereas a comparable LCD might require just a small fraction of a milliwatt. Similarly, the current requirement for an LCD will be in the microampere range. LCDs usually need an ac biasing, however. An image resolution on the order of 5 lines/mm is possible with an LCD.

Plasma Displays A plasma display is somewhat similar to an LCD in construction. The medium used in a plasma display is an ionizing gas (e.g., neon with traces of argon or xenon). A planar matrix of electrode pairs is used on the inner surfaces of entrapping glass. When a voltage above the ionizing voltage of the medium is applied to the electrode pair, the gas will break down, and a discharge will result. The electron impacts that are generated at the cathode as a result will cause further release of electrons to sustain the discharge. A characteristic orange glow will result. The pattern of energized electrodes will determine the graphic image.

The electrodes could be either dc coupled or ac coupled. In the case of the latter, the electrodes are coated with a layer of dielectric material to introduce a capacitor at the gas interface. The power efficiency of a plasma display is higher than that of an LED display. A typical image resolution of 2 lines/mm is obtainable.

Cathode Ray Tubes A schematic representation of a cathode ray tube (CRT) is given in Fig. 79. In a CRT,

**Fig. 79** Schematic of CRT.

an electron beam is used to trace lines, characters, and other graphic images on the CRT screen. The electron beam is generated by an electron gun. A cathode made of a metal such as nickel coated with an oxide such as barium strontium calcium oxide forms the electron gun and is heated (say, using a tungsten coil heater) to generate electrons. Electrons are accelerated toward the inner surface of the CRT screen using a series of anodes, biased in increasing steps. The CRT screen is made of glass. Its inner surface is coated with a crystalline phosphor material. The electrons that impinge on the screen will excite the phosphor layer, which will result in the release of additional electrons and radiation. As a result, the point of impingement will be illuminated. The electron beam is focused using either electrostatic (a pair of electrode plates) or magnetic (a coil) means. The position of the luminous spot on the screen is controlled using a similar method. Two pairs of electrodes (or two coils) will be needed to deflect the electron to an arbitrary position on the screen.

Different types of phosphor material will provide different colors (red, green, blue, white, etc.). The color of a monochrome display is determined by this. Color displays employ one of two common techniques. In one method (masking), three guns are used for the three basic colors (red, green, and blue). The three beams pass through a small masking window and fall on the faceplate. The faceplate has a matrix of miniature phosphor spots (e.g., at 0.1-mm spacing). The matrix consists of a regular pattern of R-G-B phosphor elements. The three electron beams fall on three adjacent spots of R-G-B phosphor. A particular color is obtained as a mixture of the three basic colors by properly adjusting the intensity of the three beams. In the second method (penetration), the faceplate has several layers of phosphor. The color emitted will depend on the depth of penetration of the electron beam into the phosphor.

Flicker in a CRT display, at low frequencies, will strain the eye and also can deteriorate dynamic images. Usually, a minimum flicker frequency of 40 Hz will be satisfactory, and even higher frequencies can be achieved with most types of phosphor coatings. Flicker effect worsens with the brightness of an image. The efficiency of a phosphor screen is determined by the light flu density per unit power input (measured in lumens/watt). A typical value is 40 lm/W. Time constant determines the time of decay of an image when power is turned off. Common types of phosphor and their time constants are given in Table 25.

CRTs have numerous uses. Computer display screens, television picture tubes, radar displays, and oscilloscope tubes are common applications. The raster-scan method is a common way of generating an image on a computer or television screen. In this method, the electron beam continuously sweeps the screen (say, starting from the top left corner of the screen and tracing horizontal lines up to the bottom right corner, continuously repeating the process). The spot is turned on or

Table 25 Time Constants of CRT Phosphor

Phosphor	Color	Time Constant (ms)
P1	Green	30.0
P4	White	0.1
P22	Red	2.0
	Green	8.0
	Blue	6.0
RP20	Yellow-green	5.0

off using a controller according to some logic that will determine the image that is generated on the screen. In another method used in computer screens, the beam is directly moved to trace the curves that form the image. In oscilloscopes, the horizontal deflection of the beam can be time sequenced and cycled in order to enable the display of time signals.

5.4 Light Sensors

A light sensor (also known as a photodetector or photosensor) is a device that is sensitive to light. Usually, it is a part of an electrical circuit with associated signal conditioning (amplification filtering etc.) so that an electrical signal representative of the intensity of light falling on the photosensor is obtained. Some photosensors can serve as energy sources (cells) as well. A photosensor may be an integral component of an optoisolator or other optically coupled system. In particular, a commercial optical coupler typically has an LED source and a photosensor in the same package, with a pair of leads for connecting it to other circuits, and perhaps power leads.

By definition the purpose of a photodetector or photosensor is to sense visible light. But there are many applications where sensing of adjoining bands of the electromagnetic spectrum, namely infrared radiation and ultraviolet radiation, would be useful. For instance, since objects emit reasonable levels of infrared radiation even at low temperatures, infrared sensing can be used in applications where imaging of an object in the dark is needed. Applications include infrared photography, security systems, and missile guidance. Also, since infrared radiation is essentially thermal energy, infrared sensing can be effectively used in thermal control systems. Ultraviolet sensing is not as widely applied as infrared sensing.

Typically, a photosensor is a resistor, diode, or transistor element that brings about a change (e.g., generation of a potential or a change in resistance) into an electrical circuit in response to light that is falling on the sensor element. The power of the output signal may be derived primarily from the power source that energizes the electrical circuit. Alternatively, a photocell can be used as a photosensor. In this latter case, the energy of the light falling on the cell is converted into electrical energy of the output signal. Typically, a photosensor is available as a tiny cylindrical element with a sensor head consisting of a circular window (lens). Several types of photosensors are described below.

Photoresistors A photoresistor (or photoconductor) has the property of decreasing resistance (increasing conductivity) as the intensity of light falling on it increases. Typically, the resistance of a photoresistor could change from very high values (megohms) in the dark to reasonably low values (less than $100\ \Omega$) in bright light. As a result, very high sensitivity to light is possible. Some photocells can function as photoresistors because their impedance decreases (output increases) as the light intensity increases. Photocells used in this manner are termed photoconductive cells. The circuit symbol of a photoresistor is given in Fig. 80a.

A photoresistor may be formed by sandwiching a photoconductive crystalline material such as cadmium sulfid (CdS) or cadmium selenide (CdSe) between two electrodes. Lead sulfid (PbS) or lead selenide (PbSe) may be used in infrared photoresistors.

Photodiodes A photodiode is a pn junction of semiconductor material that produces electron-hole

pairs in response to light. The symbol for a photodiode is shown in Fig. 80b. Two types of photodiodes are available. A photovoltaic diode generates a sufficient potential at its junction in response to light (photons) falling on it. Hence, an external bias source is not necessary for a photovoltaic diode. A photoconductive diode undergoes a resistance change at its junction in response to photons. This type of photodiode is usually operated in reverse-biased form; the p lead of the diode is connected to the negative lead of the circuit, and n lead is connected to the positive lead of the circuit. The breakdown condition may occur at about 10 V, and the corresponding current will be nearly proportional to the intensity of light falling on the photodiode. Hence, this current can be used as a measure of the light intensity. Since the current level is usually low (a fraction of a milliamper), amplification might be necessary before using it in the subsequent application (e.g., actuation, control, display). Semiconductor materials such as silicon, germanium, cadmium sulfide and cadmium selenide are commonly used in photodiodes. A diode with an intrinsic layer (a pin diode) can provide faster response than with a regular pn diode.

Phototransistor Any semiconductor photosensor with amplification circuitry built into the same package (chip) is popularly called a phototransistor. Hence, a photodiode with an amplification circuit in a single unit might be called a phototransistor. Strictly, a phototransistor is manufactured in the form of a conventional bipolar junction transistor with base (B), collector (C) and emitter (E) leads.

Symbolic representation of a phototransistor is shown in Fig. 80c. This is an $nnpn$ transistor. The base is the central (p) region of the transistor element. The collector and the emitter are the two end regions (n) of the element. Under operating conditions of the phototransistor, the collector-base junction is reverse biased (i.e., a positive lead of the circuit is connected to the collector, and a negative lead of the circuit is connected to the base of an $nnpn$ transistor). Alternatively, a phototransistor may be connected as a two-terminal device with its base terminal floated and the collector terminal properly biased (positive for an $nnpn$ transistor). For a given level of source voltage (usually applied between the emitter lead of the transistor and load, the negative potential being at the emitter lead), the collector current (current through the collector lead) i_c is nearly proportional to the intensity of the light falling on the collector-base junction of the transistor. Hence, i_c can be used as a measure of the light intensity. Germanium or silicon is the semiconductor material that is commonly used in phototransistors.

Photo-FET A photo-field-effect transistor is similar to a conventional FET. The symbol shown in Fig. 80d is for an n -channel photo-FET. This consists of an n -type semiconductor element (e.g., silicon doped with boron), called channel. A much smaller element of p -type material is attached to the n -type

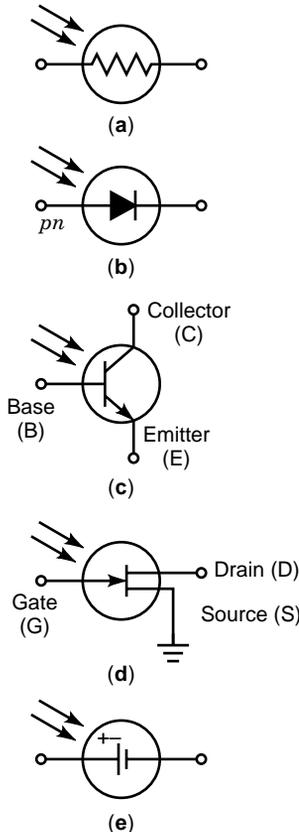

Fig. 80 Circuit symbols of some photosensors: (a) photoresistor; (b) photodiode; (c) phototransistor ($nnpn$); (d) photo-FET (n -channel); (e) photocell.

element. The lead on the p -type element forms the gate (G). The drain (D) and the source (S) are the two leads on the channel. The operation of an FET depends on the electrostatic field created by the potentials applied to the leads of the FET.

Under operating conditions of a photo-FET, the gate is reverse biased (i.e., a negative potential is applied to the gate of an n -channel photo-FET). When light is projected at the gate, the drain current i_d will increase. Hence, drain current (current at the D lead) can be used as a measure of light intensity.

Photocells Photocells are similar to photosensors except that a photocell is used as an electricity source rather than a sensor of radiation. Solar cells, which are more effective in sunlight are commonly available. A typical photocell is a semiconductor junction element made of a material such as single-crystal silicon, polycrystalline silicon, and cadmium sulfide. Cell arrays are used in moderate-power applications. Typical power output is 10 mW/cm^2 of surface area, with a potential of about 1.0 V. The circuit symbol of a photocell is given in Fig. 80e.

Charge-Coupled Device A charge-coupled device (CCD) is an integrated circuit (a monolith device) element of semiconductor material. A CCD made from silicon is schematically represented in Fig. 81. A silicon wafer (p type or n type) is oxidized to generate a layer of SiO_2 on its surface. A matrix of metal electrodes is deposited on the oxide layer and is linked to the CCD output leads. When light falls onto the CCD element, charge packets are generated within the substrate silicon wafer. Now if an external potential is applied to a particular electrode of the CCD, a potential well is formed under the electrode, and a charge packet is deposited here. This charge packet can be moved across the CCD to an output circuit by sequentially energizing the electrodes using pulses of external voltage. Such a charge packet corresponds to a pixel (a picture element). The circuit output is the video signal. The pulsing rate could be higher than 10 MHz. CCDs are commonly used in imaging application, particularly in video cameras. A typical CCD element with a facial area of a few square centimeters may detect 576×485 pixels, but larger elements

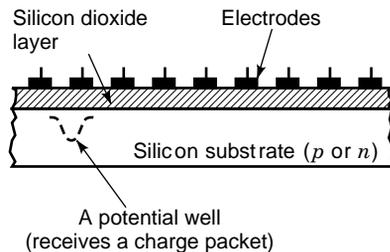

Fig. 81 A CCD.

(e.g., 4096×4096 pixels) are available for specialized applications. A charge injection device (CID) is similar to a CCD. In a CID, however, there is a matrix of semiconductor capacitor pairs. Each capacitor pair can be directly addressed through voltage pulses. When a particular element is addressed, the potential well there will shrink, thereby injecting minority carriers into the substrate. The corresponding signal, tapped from the substrate, forms the video signal. The signal level of a CID is substantially smaller than that of a CCD, as a result of higher capacitance.

Applications of Optically Coupled Devices One direct application is in the isolation of electric circuitry. When two circuits are directly connected through electrical connections (cables, wires, etc.), a two-way path is created at the interface for the electrical signals. In other words, signals in circuit A will affect circuit B and signals in circuit B, will affect circuit A. This interaction means that noise in one circuit will directly affect the other. Furthermore, there will be loading problems; the source will be affected by the load. Both these situations are undesirable. If the two circuits are optically coupled, however, there is only a one-way interaction between the two circuits (see Fig. 82). Variations in the output circuit (load circuit) will not affect the input circuit. Hence, the input circuit is isolated from the output circuit. The connecting cables in an electrical circuit can introduce noise components such as electromagnetic interference, line noise, and ground-loop noise. The likelihood of these noise components affecting the overall system is also reduced by using optical coupling. In summary, isolation between two circuits and isolation of a circuit from noise can be achieved by optical coupling. Optical coupling is widely used in communication networks (telephones, computers, etc.) and in circuitry for high-precision signal conditioning (e.g., for sophisticated sensors and control systems) for these reasons.

The medium through which light passes from the light source to the photosensor can create noise problems, however. If the medium is open (see Fig. 82), then ambient lighting conditions will affect the output circuit, resulting in an error. Also, environmental impurities (dust, smoke, moisture, etc.) will affect the light received by the photosensor. Hence, a more controlled medium of transmission would be desirable. Linking the light source and the photosensor using

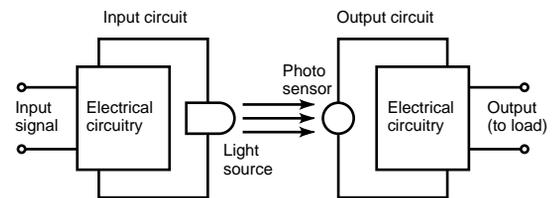

Fig. 82 An optically coupled device.

optical fiber is a good way to reduce problems due to ambient conditions in optically coupled systems.

Optical coupling may be used in relay circuits where a low-power circuit is used to operate a high-power circuit. If the relay that operates the high-power circuit is activated using an optical coupler, reaction effects (noise and loading) on the low-power circuit can be eliminated. Optical coupling is used in power electronics and control systems in this manner.

Many types of sensors and transducers that are based on optical methods do, indeed, employ optical coupling (e.g., optical encoders, fiberoptic tactile sensors). Optical sensors are widely used in industry for parts counting, parts detection, and level detection. In these sensors, a light beam is projected from a source to a photodetector, both units being stationary. An interruption of the beam through the passage of a part will generate a pulse at the detector, and this pulse is read by a counter or a parts detector. Furthermore, if the light beam is located horizontally at a required height, its interruption when the material fills into a container reaches that level could be used for fill control in the packaging industry. Note that the light source and the sensor could be located within a single package if a mirror is used to reflect light from the source back onto the detector. Further applications are within computer disk drive systems, for example, to detect the write protect notch as well as the position of the recording head.

6 INPUT DEVICES

George Grinstein and Marjan Trutschl

Human-computer interaction (HCI) is now a multidisciplinary area focusing on the interface and interactions between people and computer systems. Figure 83 presents a conceptual view of HCI: A user interacts with a system (typically a processor or device) using one or multiple input devices.

Input devices convert some form of energy, most often kinetic or potential energy, to electric energy. In this section we consider analog and digital input devices. Analog input devices generate voltages that vary over a continuous range ($R = V_{\max} - V_{\min}$) of values and are converted to binary values by an ADC. Digital input devices are based on binary digits. An input device that generates logical 0's and 1's, on and

off, respectively, is called a *binary switch*. A binary switch generates the binary digit 1 when the input voltage is equal to or greater than a specific threshold value and the binary digit 0 otherwise. A second type of digital input device approximates an analog signal and provides a binary stream. Thus, any device that produces an electrical signal or responds to an electrical signal can be used as an input device. Preprocessed analog (digitized) and digital signals generated by an input device are passed on to the processor/device for processing. Once processed, the processor/device may, and often does, generate a new signal or a series of signals. These signals can be used to trigger events on some attached output device.

Figure 84 shows examples of a signal produced by an analog input device. To be used with a digital computer, the analog signal can be processed to mimic an on/off switch or it can be digitized using an ADC. The performance of an ADC depends on its architecture. The more bits the ADC operates with, the better the resolution of the signal approximation.

Input devices can be further classified as acoustic, inertial, mechanical, magnetic, and optical input devices.

6.1 Devices

Based on their basic operation, input devices can be classified as 2-D, 3-D, 6-D, or n -D (degrees of freedom) input devices. Table 26 lists some of the most popular input devices and degrees of freedom associated with each. Many devices can fit in several categories. Also, as any device can emulate another, this table is to be used simply as a guide. Finally, there are other forms of input technologies that are described elsewhere in this encyclopedia.

Many of the aforementioned devices can be used in combinations with other input devices, thus providing the notion of either two-handed input or multimodal input. For example, the use of two data gloves is considered two-handed input, as is the use of a mouse along with a Spaceball, whereas the use of a mouse along with speech recognition is considered to be multimodal input.

6.2 Commonly Used Input Devices

Keyboard The keyboard is now considered the most essential input device and is used with the majority of computers. Keyboards provide a number of keys (typically more than 100) labeled with a letter or a function that the key performs. Keyboards manufactured for use with notebooks and palm computers or those designed for users with special needs typically provide a reduced set of keys. Different alphabets require different characters to be mapped to each key on the keyboard (i.e., English QWERTY versus German QWERTZ keyboard). Such mappings are achieved by reprogramming the keyboard's instruction set. Certain keys (e.g., ALT, CTRL, and SHIFT) can be used in conjunction with other keys, thus permitting one key to map to several different functions.

Mouse Since its creation at Xerox Palo Alto Research Center (PARC), the mouse has become the most popular 2-D input device and has a wide number of variants. Regardless of the variation, each mouse has one, two, or three buttons. For most mice, the motion of a ball, located underneath the mouse, is converted to planar motion—a set of *x* and *y* values—using a photoelectric switch as an input transducer. The photoelectric switch contains an LED as a source, a phototransistor as a sensor, and a circular perforated disk as a switch. When the light emitted from the diode reaches the sensor, a pulse (logic 1) is generated and passed on to the interface electronics. The frequency of pulses is interpreted as the velocity of the mouse. There are two such input transducers built in a mouse—one for the *x* and one for the *y* axis. Figure 85 shows the principle of motion-to-electric energy conversion.

The majority of mice use this principle of motion conversion. Optical mice take advantage of the reflective properties of mouse pads that have a grid of thin lines printed on their smooth and reflective surface. As the mouse passes across the line of a grid, a portion of

the light emitted from the LED is diffracted, resulting in a slight drop of a voltage on the sensor's side (Fig. 86). These drops of voltage are used to determine the direction and speed of movement of the mouse.

Trackball A trackball can be described as an inverted mouse. To move a cursor on the screen, the user moves

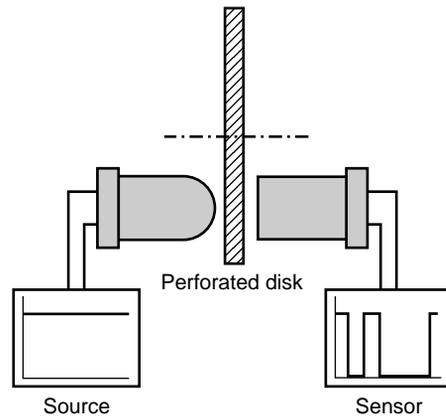

Fig. 85 Motion-to-energy conversion.

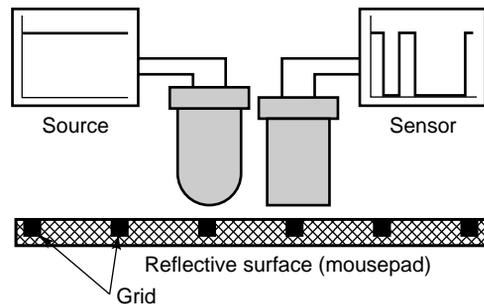

Fig. 86 Optical mouse structure.

the ball in the desired direction. The motion of the ball is translated to electric signals using a set of perforated disks (one for the x and the other for the y direction). Trackballs, like mice, are equipped with one or more buttons that are pressed to perform a desired operation. Many notebooks and portable computers provide built-in trackballs, as these require much less space than a mouse.

Joystick The joystick made its first major appearance in arcade machines in the early 1980s. The basic joystick is a 2-D input device that allows users to move a cursor or an object in any direction on a plane. Typically, a joystick consists of two major parts—a vertical handle (the stick) and a base—each providing one or more buttons that can be used to trigger events. To move the cursor or an object, the stick is moved in the desired direction. Figure 87 shows a major limitation imposed by the resolution of a joystick. The resolution in this example joystick makes it impossible to move in the indicated direction (desired direction), making navigation a bit difficult.

There are two major types of joysticks—*isotonic* and *isometric*. *Isotonic* joysticks are precision position-sensitive devices, used in animation, special-effects development, and games. These joysticks are equipped with a set of springs, which return the joystick to the center position when released. A stream of x and y values is generated based on and proportional to the angle between the initial and the current position of the control stick. Some implementations of isotonic joysticks are insensitive to the angle α . These use switches to provide information on direction. *Isometric* joysticks provide no spring action—the control stick does not move. The x and y values generated by the joystick are proportional to the force applied to the control stick. Some newer joysticks also have been provided with tactile and force feedback.

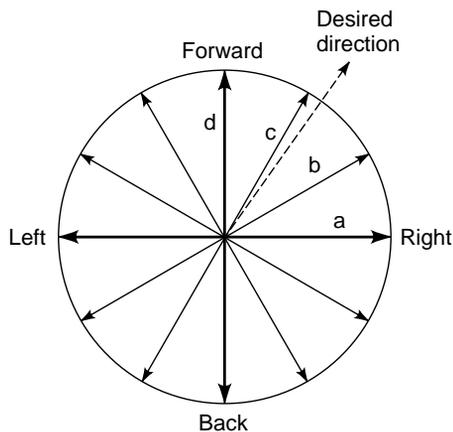

Fig. 87 Directional limitation of Joysticks.

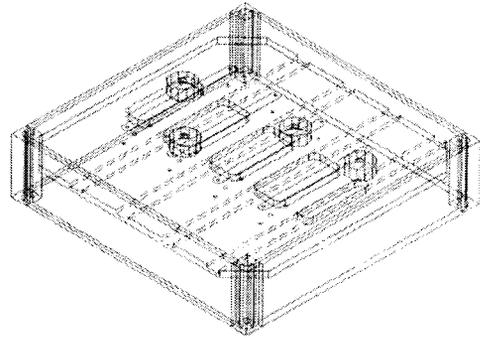

Fig. 88 Slider box. (Image courtesy of Simulation Special Effect, LLC).

Slider A slider is a 1-D input device (Fig. 88). Although sliders are usually implemented in software as part of a graphical user interface (GUI), slider boxes are available as input devices in applications requiring a large number of independent parameters to be controlled [as in musical instrument digital interface (MIDI) applications requiring multiple channels to be manipulated independently]. Most windowing systems incorporate sliders to support panning of the window's content or for color scale value selections.

Spaceball The Spaceball is a 6-D input device used primarily in computer-aided design and engineering, animation, virtual reality, and computer games. It enables users to manipulate a 3-D model with 6-degrees-of-freedom control (simultaneous x , y , z , translations and rotations) and as easily as if they were holding it in their hands. A Spaceball is often used in conjunction with the mouse. Spaceballs made their appearances initially with high-end graphic workstations, but this is not the case anymore. As desktop computers have become more powerful, many applications make use of the Spaceball and its derivatives.

Touchpad A touchpad is a 2-D input device developed for use in areas with limited space. Touchpads provide precise cursor control by using a fingertip moving on a rectangular area. Buttons located on the side of the rectangular input area can be programmed to perform specific operations as modified keys on keyboards. Touchpads are usually located under the SPACE bar or the cursor keys, or they can be attached to a computer through a serial port.

Input Tablet An input tablet is a variation of a touchpad. It is larger than a touchpad, and instead of a finger, a penlike device with a button to perform specific operations is used. A coil in the tablet generates a magnetic field and a wire grid in the tablet transmits the signal to the tablet's microprocessor. The output data include the pen's location, the pressure of the pen

on the tablet, and the tilt of the pen in relation to tablet. Input tablets are mostly used in the design arts and in mechanical and engineering computer-aided design.

Integrated Pointing Device—Stick A 2-D integrated pointing device, called a stick, is a miniature isometric joystick embedded between the keys on the keyboard. To move the cursor, the user pushes or pulls the stick in desired direction. The buttons associated with the stick are located under the SPACE bar on the keyboard.

Lightpen A lightpen is a penlike 2-D device attached to a computer through one of the communications ports or through a dedicated controller board. It is used to draw or select objects directly on the screen. Lightpens may be optically or pressure driven. An optically driven lightpen receives light from the refresh update on the screen; the x , y position of the refreshed pixel is then available for processing. A pressure-driven lightpen is triggered by pressing the lightpen on the screen or by pushing a button.

Touch Screen A touch screen is a special type of a 2-D hybrid device because it can both display and acquire information at the same time. On the input side, a touch screen contains a set of sensors in the x and y directions. These sensors may be magnetic, optical, or pressure. Users simply touch the screen, and the sensors in both x and y directions detect an event at some x and y coordinate. Since users tend to use a finger to interact with the touch screen, the resolution of the input device is not fully utilized. In fact, it is often limited to the size of a fingertip. Touch screens are very popular in menu-driven environments such as information booths, fast-food restaurants, and control rooms.

Scanner A scanner is a 2-D input device used to capture pictures, drawings, or text. Images, color or black and white, can be captured and stored in digital form for analysis, manipulation, or future retrieval. Associated application software is typically bundled with scanners. This includes imaging software, photo manipulation software, vector graphics conversion software, or text creation (using optical character recognition) software. Three major scanners are available: handheld, flatbed, and sheet scanners. Handheld scanners are suitable for small-scale scanning, flatbed scanners usually handle up to legal-size documents, and sheet scanners usually handle documents of fixed width but arbitrary length. Some engineering firms and geographers use special large-scale scanners for digitizing blueprints and maps.

Digitizer A digitizer can be considered either a 2-D or a 3-D input device. There are numerous kinds of digitizers available. Many older and less expensive systems require a great deal of manual work to acquire the data points. For example, the user may need to

draw a grid on the object to be digitized to enable the acquisition of coordinates for every point on that grid. This is both time consuming and error prone.

3-D Laser Digitizers Nonmanual digitizers can automate several parts of the digitization process. These are primarily laser-based scanners. An object is positioned on a podium and the scanner rotates the podium while the digitization takes place. Some digitizers revolve around the object when the object is too big or too heavy to be rotated easily around its axes. Such scanners project a beam of laser light onto the model. The intersection of the laser beam and the surface of the object creates a contour of the model captured by a camera and displayed on the screen. This can be done in real time, and a color camera can be used to generate a color model. Most laser scanners use laser triangulation to reconstruct the object.

Position Trackers Position trackers are used to detect motion and are often attached to objects or body parts. Trackers perform reasonably well. Newer trackers have removed the tethering limitation of older trackers. Newer technologies are also solving the line-of-sight problem (the receiver's requiring an unobstructed view of the sensors). Some trackers need to be recalibrated often to maintain a high degree of accuracy.

Mechanical. Mechanical position trackers use a rigid jointed structure with a known geometry. Such a structure has one fixed and one active end, with the position of the active end available in real time. Mechanical tracking devices are very fast (less than 5 ms response time) and very accurate. The accuracy depends on the accuracy of joint angle encoders. A tracker with a full-color head-coupled stereoscopic display can provide high-quality, full-color stereoscopic images and full 6 degrees of freedom (translation along x , y , and z as well as roll, pitch, yaw).

Magnetic. Magnetic trackers use a source that generates three fields of known strength. Detectors are attached to the object to be tracked and measure the magnetic field strengths at a given point. These values are used to determine 6 degrees of freedom in space. Magnetic trackers do not experience any line-of-sight problems and are scalable to many detectors. However, the amount of wiring increases as the number of detectors increases. Magnetic trackers do not operate well around ferrous materials.

Ultrasonic. Ultrasonic trackers are often attached to a virtual reality (VR) headset. The tracker consists of three receivers and three transmitters. The position and orientation of the object is calculated based on the time required for each transmitted signal to reach a receiver. Ferrous materials do not affect such trackers. However, ultrasonic trackers are affected by the line-of-sight problem and may be affected by other sources of ultrasonic harmonics.

High-Speed Video. High-speed video along with fiducial markings on a tracked object is used to determine the location of an object in space. A single picture or a series of pictures are acquired and later processed using image-processing techniques. Fiducial markings can also be located in the space (i.e., scene or walls) and the camera can be attached to the object itself. Such devices can then be used to control the navigation of a robot between two given locations. High-speed video is used for work in a large space because no extra wiring is necessary. Video is unaffected by ferrous and other metals, ultrasonic sound, and light. However, the line-of-sight problem does affect video-tracking systems.

Inertial. Inertial position trackers are used to measure orientation and velocity. They are untethered and are not limited by the range or the size of the volume they operate in. Inertial position trackers provide almost complete environmental immunity. Such trackers are sensitive to vibrations and can thus result in inaccurate readings.

Biological. Eye tracking is a relatively old technology although not in common use. Eye tracking can be used for control or monitoring. For example, a pilot can control various instruments by simply looking at them. A low-powered infrared (IR) beam is used to illuminate the eye, which in turn is captured using a small camera. The image is processed to track pupil and corneal reflection. Today's eye tracking devices operate at one degree of resolution. It takes approximately one-third of a second to select, acquire, and fix on an image. Modern applications of eye tracking include its use as an input device for the disabled.

Digital Whiteboard A digital whiteboard is a 2-D input device designed to replace traditional blackboards and whiteboards. Everything written on the digital whiteboard with a standard dry-erase marker can be transmitted to a computer. That information can then be used by any application, such as e-mail, fax, or teleconferencing.

Data Glove A data glove is an input device that uses properties of leaky fiber-optic cables or resistive strain gauges to determine the amount of movement of fingers and wrists. Leaky fiber-optic cables provide good data, but it is the resistive strain-based input gloves that provide more accurate data. Each data glove is often combined with a 3-D tracker and with 10 strain gauges—at least one for each finger joint—which provides a very high degree of freedom. The latest data gloves also have been extended to provide tactile/force feedback using pneumatic pistons and air bladders. Data gloves can be used along with gestures to manipulate virtual objects or to perform other tasks.

Microphone/Speech Recognition and Understanding The microphone has proved to be one of

the most useful input devices for digitizing voice and sound input or for issuing short commands that need to be recognized by a computer. Longer commands cannot be handled by simple recognition. Most sophisticated systems available today still cannot guarantee 100% understanding of human speech.

Monkeys or Mannequins The first monkeys were humanlike input devices with a skeleton and precision rheostats at the joints to provide joint angles. Monkeys can be used to set up and capture humanlike motions and offer much better degree-of-freedom match than other devices. Since the first monkeys, a series of animal-like input devices and building blocks have been created that allow users to create their own creatures.

Game Input Devices There are a number of other specialized input devices designed to make playing games a more exciting and more realistic experience. Most of these input devices offer additional degrees of freedom and can be used along with other input devices.

6.3 Conclusions

There are a large number of input devices, and the technology is rapidly changing. It is expected that speech recognition and command interpretation, gesture recognition for highly interactive environments (game and virtual), and real-time imaging will become more prominent in the next decade. These will increase the level of human participation in applications and the bandwidth of the data transferred.

7 INSTRUMENTS

Halit Eren

Measurement is essential for observing and testing scientific and technological investigations. It is so fundamental and important to science and engineering that the whole science can be said to be dependent on it. Instruments are developed for monitoring the conditions of physical variables and converting them into symbolic output forms. They are designed to maintain prescribed relationships between the parameters being measured and the physical variables under investigation. The physical parameter being measured is known as the *measurand*. The sensors and transducers are the primary sensing elements in the measuring systems that sense the physical parameters to produce an output. The energy output from the sensor is supplied to a transducer, which converts energy from one form to another. Therefore, a transducer is a device capable of transferring energy between two physical systems.

Measurement is a process of gathering information from a physical world and comparing this information with agreed standards. Measurement is carried out with instruments that are designed and manufactured to fulfill given specifications. After the sensor generates

the signals, the type of signal processing depends on the information required from it. A diverse range of sensors and transducers may be available to meet the measurement requirements of a physical system. The sensors and transducers can be categorized in a number of ways depending on the energy input and output, input variables, sensing elements, and electrical or physical principles. For example, from an energy input and output point of view, there are three fundamental types of transducers: modifiers self-generators, and modulators.

In modifiers a particular form of energy is modified rather than converted; therefore, the same form of energy exists at the input and the output. In self-generators, electrical signals are produced from nonelectric inputs without the application of external energy. These transducers produce very small signals, which may need additional conditioning. Typical examples are piezoelectric transducers and photovoltaic cells. Modulators, on the other hand, produce electric outputs from nonelectric inputs, but they require an external source of energy. Strain gauges are typical examples of such devices.

The functionality of an instrument can be broken into smaller elements, as illustrated in Fig. 89. Most measurement systems have a sensor or transducer stage, a signal-conditioning stage, and an output or termination stage. All instruments have some or all of these functional blocks. Generally, if the behavior of the physical system under investigation is known, its performance can be assessed by means of a suitable method of sensing, signal conditioning, and termination.

In the applications of instruments, the information about a physical variable is collected, organized, interpreted, and generalized. Experiments are conceived, performed, and repeated; as we acquire confidence in the results, they are expressed as scientific laws. The application of instruments ranges from laboratory conditions to arduous environments such as inside nuclear reactors or on satellite systems and spaceships. In order to meet diverse application requirements of high complexity and capability, many manufacturers have developed a large arsenal of instruments. Some of these manufacturers are listed in Table 27.

In recent years, rapid growth of integrated circuit (IC) electronics and the availability of cheap analog-to-digital and microprocessors have led to progress in the instrumentation field, with the development of

instruments, measuring techniques, distributed architectures, and standards aimed to improve performance.

Instruments are applied for static or dynamic measurements. The static measurements are relatively easy since the physical quantity (e.g., fixed dimensions and weights) does not change in time. If the physical quantity is changing in time, which is often the case, the measurement is said to be dynamic. In this case, steady-state and transient behavior of the physical variable must be analyzed so that it can be matched with the dynamic behavior of the instrument.

7.1 Design, Testing, and Use of Instruments

Instruments are designed on the basis of existing knowledge, which is gained either from the experiences of people about the physical process or from our structured understanding of the process. In any case, ideas conceived about an instrument must be translated into hardware and/or software that can perform well within the expected standards and easily be accepted by the end users.

Usually, the design of instruments requires many multidisciplinary activities. In the wake of rapidly changing technology, instruments are upgraded often to meet the demands of the marketplace. Depending on the complexity of the proposed instrument, it may take many years to produce an instrument for a relatively short commercial lifetime. In the design and production of instruments, we must consider such factors as simplicity, appearance, ease and flexibility of use, maintenance requirements, lower production costs, lead time to product, and positioning strategy in the marketplace.

In order to design and produce instruments, a firm must consider many factors. These include sound business plans, suitable infrastructure, plant, equipment, understanding of technological changes, skilled and trained personnel, adequate finance marketing and distribution channels, and a clear understanding about worldwide instrument and instrumentation system trends. It is important to choose the right product that is very likely to be in demand in the years to come. Here entrepreneurial management skills may be an important factor.

The design process itself may follow well-ordered procedures from idea to marketing stages. The process may be broken down into smaller tasks such as identifying specifications developing possible solutions for these specifications modeling, prototyping,

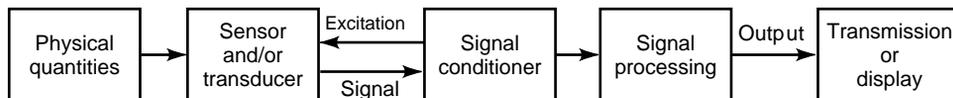

Fig. 89 An instrument has a number of relatively independent components that can be described as functional elements. These functional elements are the sensors and transducers, signal conditioners, and output or terminations. In general, if the behavior of the physical system is known, its performance is measured by a suitable arrangement and design of these components.

Table 27 List of Manufacturers

ABB, Inc. 501 Merritt 7, P.O. Box 5308 Norwalk, CT 06856-5308 Tel: 800-626-4999 Fax: 203-750-2263	Keithley Instrument, Inc. 28775-T Aurora Road Cleveland, OH 44139-1891 Tel: 800-552-1115 Fax: 440-248-6168
Allied Signal, Inc. 101 Columbia Road Morristown, NY 07962 Tel: 800-707-4555 Fax: 608-497-1001	MCS Calibration, Inc. Engineering Division 1533 Lincoln Avenue Halbrook, NY 11741 Tel: 800-790-0512 Fax: 512-471-6902
Bailey-Fisher and Porter Company 125 E County Line Road Wanminster, PA 18974 Tel: 800-268-8520 Fax: 215-674-7183	MSC Industrial Supply Company 151-T Sunnyside Boulevard Plainview, NY 11803 Tel: 800-753-7937 Fax: 516-349-0265
Consolidated Instrument, Inc. 510 Industrial Avenue Teterboro, NC 07608 Tel: 800-240-3633 Fax: 201-288-8006	National Instruments 6504 Bridge Point Parkway Austin, TX 78730-7186 Tel: 512-794-0100; 888-217-7186 Fax: 512-794-8411

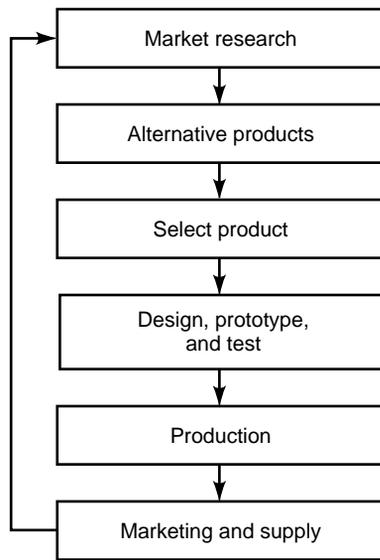

Fig. 90 Design process from the conception of ideas to marketing follows carefully considered stages. The proper identification and effective implementation of these stages is important in the success of a specific instrument in the marketplace.

installing and testing, making modifications manufacturing, planning marketing and distribution, evaluating customer feedback, and making design and technological improvements. Figure 90 illustrates the stages for the design and marketing of an instrument. Each one of these stages can be viewed in detail in the form of subtasks. For example, many different specification may be considered for a particular product. These specification include but are not limited to operational requirements, functional and technological requirements, quality, installation and maintenance, documentation and servicing, and acceptance level determination by the customers.

In recent years, computers have been used extensively in the instrument manufacturing industry in the form of computer-aided design (CAD), automated testing, and in other applications. The computer enables rapid access to knowledge-based information and makes design time considerably shorter thus enabling manufacturers to meet rapid demand.

In CAD systems, mechanical drafting software, electronic circuit design tools, control analysis tools, and mathematical and word processing tools are integrated to assist the design procedure. Design software is available from various manufacturers listed in Table 27.

Testing and Use of Instruments After the instrument is designed and prototyped, various evaluation tests may be conducted. These tests may be

made under reference conditions or under simulated environmental conditions. Some examples of reference condition tests are accuracy, response time, drift, and warmup time. Simulated environmental tests may be compulsory, being regulated by governments and other authorities. Some simulated environment tests include climatic test, drop test, dust test, insulation resistance test, vibration test, electromagnetic compatibility (EMC) tests, and safety and health hazard tests. Many of these tests are strictly regulated by national and international standards.

Adequate testing and proper use of instruments is important to achieve the best results out of them. When the instruments are installed, a regular calibration is necessary to ensure the consistency of the performance over the time period of operation. Incorrect measurements can cost a considerable amount of money or even result in the loss of lives.

For maximum efficiency an appropriate instrument for the measurement must be selected. Users should be fully aware of their application requirements, since instruments that do not fit their purpose will deliver false data resulting in wasted time and effort. When selecting the instrument, users must evaluate many factors such as accuracy, frequency response, electrical and physical loading effects, sensitivity, response time, calibration intervals, power supply needs, spare parts, technology, and maintenance requirements. They must ensure compatibility with their existing equipment.

Also, when selecting and implementing instruments, quality becomes an important issue from both quantitative and qualitative perspectives. The quality of an instrument may be viewed differently depending on the people involved. For example, quality as viewed by the designer may be an instrument designed on sound physical principles, whereas from the user's point of view quality may be reliability, maintainability, cost, and availability.

For the accuracy and validity of information collected from the instruments, correct installation and proper use become very important. The instruments must be fully integrated with the overall system. Sufficient background work must be conducted prior to installation to avoid a possible shutdown of the process that is longer than necessary.

Once the system is installed, the reliability of the instrument must be assessed, and its performance must be checked regularly. The *reliability* of the system may be defined as the probability that it will operate at an agreed level of performance for a specific period of time. The reliability of instruments follows a bathtub shape against time. Instruments tend to be unreliable in the early and later stages of their lives. During normal operations, if the process conditions change (e.g., installation of large machinery nearby), calibrations must be conducted to avoid possible performance deterioration of the instrument. Therefore, the correct operations of the instruments must be assured at all times throughout the lifetime of the device.

Once the instruments are installed, they may be left alone and expected to operate reliably. They may be communicating with other devices, and their performance may affect the performance of the rest of the system, as in the case of the process industry. In some applications, the instruments may be part of a large instrumentation system, taking a critical role in monitoring and/or controlling the process and operations. However, in many applications, instruments are used on a stand-alone basis for laboratory and experimental work, and the success of the experiments may entirely depend on their correct performance. In these cases, the experiments must be designed and conducted carefully by identifying the primary variables, controlling, selecting the correct instruments, assessing the relative performances, validating the results, and using the data effectively by employing comprehensive data analysis techniques. Set procedures for experimental designs can be found in various sources (e.g., see Ref. 97 as well as the Bibliography).

After having performed the experiments, the data must be analyzed appropriately. This can be done at various stages by examining the consistency of the data, performing appropriate statistical analyses, estimating the uncertainties of the results, relating the results to the theory, and correlating the data. Details of statistical data analysis can be found in many books; also many computer software programs are available for the purpose of analysis including common packages such as Microsoft Excel.

7.2 Instrument Response and Drift

Instruments respond to physical phenomena by sensing and generating signals. Depending on the type of instrument used and the physical phenomenon observed, the signals may be either slow or fast to change, and may also contain transients. The response of the instruments to the signals can be analyzed in a number of ways by establishing static and dynamic performance characteristics. Although, the static performances are relatively simple, the dynamic performances may be complex.

Static Response Instruments are often described by their dynamic ranges and full-scale deflection (span). The *dynamic range* indicates the largest and smallest quantities that can be measured. The *full-scale deflection* of an instrument refers to the maximum permissible value of the input quoted in the units of the particular quantity to be measured.

In instruments, the change in output amplitude resulting from a change in input amplitude is called the *sensitivity*. System sensitivity often is a function of external physical variables such as temperature and humidity. The relative ratio of the output signal to the input signal is the *gain*. Both, the gain and sensitivity are dependent on the amplitude of the signals and the frequency, which will be discussed in the section on dynamic response.

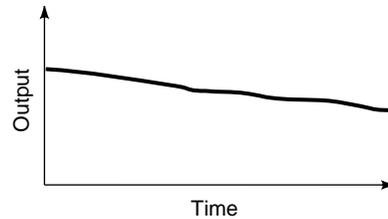

Fig. 91 Drift in the output of an instrument. The main causes of the drift are aging, temperature, ambient conditions, and component deterioration. The drift in an instrument may be predicted by performance analysis of components, past experience, environmental tests, and so on.

In the design stages or during manufacturing, there might be small differences between the input and output, which is called the *offset*. In other words, when the input is zero the output is not zero or vice versa. The signal output also may change in time, which is known as *drift*. The drift can occur for many reasons including temperature and aging. Fortunately, drift usually occurs in a predictable manner. A typical drift curve of an instrument against time is illustrated in Fig. 91.

During practical applications, readings taken from an instrument under the same conditions may not be repeatable. In this case, a repeatability test may be conducted, and statistical techniques must be employed to evaluate the repeatability of the instrument.

Dynamic Response The dynamic response of an instrument is characterized by its natural frequency, amplitude, frequency response, phase shift, linearity and distortions, rise and settling times, slew rate, and the like. These characteristics are a common theme in many instrumentation, control, and electronics books. Although sufficient analysis will be given here, the detailed treatment of the topic can be very lengthy and complex; Hence the full treatment of this topic is not within the scope of this section. Interested readers should refer to the literature (e.g., Ref. 98).

The dynamic response of an instrument can be linear or nonlinear. Fortunately, most instruments exhibit linear characteristics, leading to simple mathematical modeling by using differential equations such as

$$a_n \frac{d^n y}{dt^n} + a_{n-1} \frac{d^{n-1} y}{dt^{n-1}} + \cdots + a_0 y = x(t) \quad (104)$$

where x is the input variable or the forcing function, y is the output variable, and a_n, a_{n-1}, \dots, a_0 are the coefficient or the constants of the system.

The dynamic response of instruments can be categorized as zero-order, first-order or second-order responses. Although higher order instruments may exist, their behaviors can be understood adequately in

the form of a second-order system. From Eq. (104)

$$a_0y = x(t) \quad \text{zero order} \quad (105)$$

$$a_1 \frac{dy}{dt} + a_0y = x(t) \quad \text{first order} \quad (106)$$

$$a_2 \frac{d^2y}{dt^2} + a_1 \frac{dy}{dt} + a_0y = x(t) \quad \text{second order} \quad (107)$$

Equations (105)–(107) can be written as Laplace transforms, thus enabling analysis in the frequency domain,

$$\frac{Y(s)}{X(s)} = \begin{cases} 1 & (108) \\ \frac{1}{\tau_1s + 1} & (109) \\ 0 & \frac{1}{(\tau_1s + 1)(\tau_2s + 1)} \end{cases} \quad (110)$$

where s is the Laplace operator and τ is the coefficient also called time constant.

In zero-order instruments, there is no frequency dependence between the input and output. The amplitude change is uniform across the spectrum of all possible frequencies. In practice, such instruments are difficult to obtain, except in a limited range of operations.

In first-order instruments, the relation between the input and the output is frequency dependent. Figure 92 illustrates the response of a first-order instrument for a unit step input in the time domain. Mathematically, the output may be written as

$$y(t) = Ke^{-t/\tau} \quad (111)$$

where K and τ are constants determined by the system parameters. In many cases, the input signals may be a complex rather than a simple step input. In the analysis, we need to multiply the transfer function, the second member of Eq. (109), by the Laplace transform of the input signal and then transform it back to the time domain if we are to understand the nature of transient and steady-state responses. Also, if the first-order

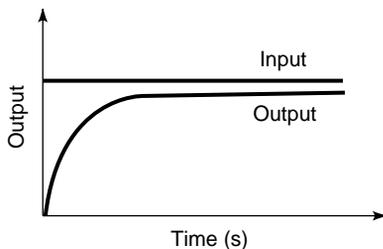

Fig. 92 First-order instrument responds to a step input in an exponential form. For a good response the time delay must be small. Drift is usually expressed in percentage of output.

systems are cascaded, the relative magnitudes of the time constants become important; some may be dominant, and others may be neglected. Second-order systems exhibit the laws of simple harmonic motion, which can be described by linear wave equations. Equation (110) may be rearranged as

$$\frac{X(s)}{Y(s)} = \frac{1/a_0}{s^2/\omega_n^2 + 2\zeta s/\omega_n + 1} \quad (112)$$

where ω_n is the natural or undamped frequency (radians per second) and ζ is the damping ratio.

As can be seen, the performance of instruments become a function of natural frequency and the damping ratio of the system. The natural frequency and damping ratios are related to the physical parameters of the devices, such as mass and dimensions. In the design stages, these physical parameters may be selected, tested, and modified to obtain a desired response from the system.

Typical time response of a second-order system to unit step inputs is illustrated in Fig. 93. The response here indicates that a second-order system can either resonate or be unstable. Furthermore, we can deduce that, since the second-order system is dependent on time, wrong readings can be made depending on the time that the results are taken. Clearly, recording the output when the instrument is still under transient conditions will give an inadequate representation of the physical variable. The frequency compensation, selection of appropriate damping, acceptable time responses, and rise time settling time of instruments may need careful attention in both the design and

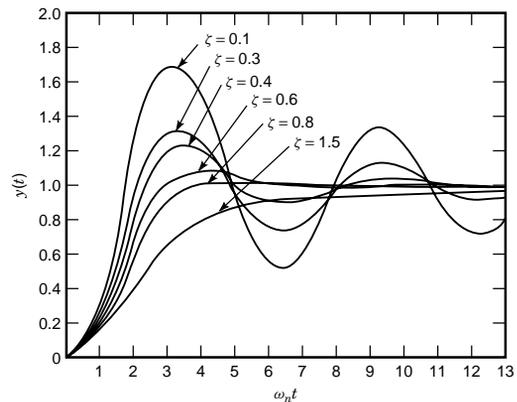

Fig. 93 Unit step time responses of a second-order system with various damping ratios. The maximum overshoot, delay, rise, settling times, and frequency of oscillation depend on the damping ratio. A smaller damping ratio gives a faster response but larger overshoot. In many applications, a damping ratio of 0.707 is preferred.

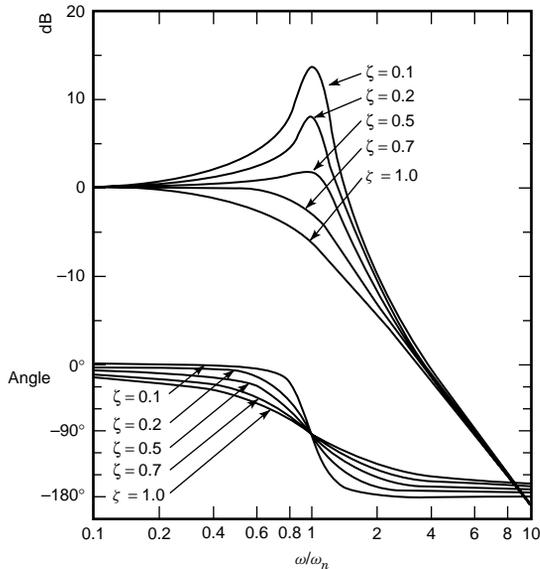

Fig. 94 Bode plots of gains and phase angles against frequency of a second-order system. Curves are functions of frequencies as well as damping ratios. These plots can be obtained theoretically or by practical tests conducted in the frequency range.

application stages of an instrument. In these systems, system analysis is essential to ensure that they can measure the input measurand adequately.

A typical frequency dependence of gain and phase angle between input and output is illustrated in Fig. 94 in the form of Bode diagrams. Here, the *bandwidth*, which is the frequencies over which the gain is reasonably constant, is also shown. Usually, half power point (3 dB), which symbolizes 70.7% of the maximum value, is taken as the bandwidth.

An important concept in instruments is *response time*, which can be described as the time required for the instrument to respond to an input signal change. For automatic measurements, the response time is an indication of how many readings can be done per second. Response time is affected by many factors such as analog-to-digital (A/D) conversion time, settling time, delays in electronic components, and delays in sensors.

7.3 Measurement Errors and Error Control Systems

The performance of an instrument depends on its static and dynamic characteristics. The performance may be indicated by its *accuracy*, which may be described as the closeness of measured values to the real values of the variable. The total response is a combination of dynamic and static responses. If the signals generated by the physical variable are changing rapidly, then the dynamic properties of the instrument become important. For slowly varying systems the dynamic errors

may be neglected. In order to describe the full relationships between the inputs and outputs, differential equations can be used, as discussed previously.

The performance of an instrument may also be decided by other factors, such as the magnitudes of errors; the *repeatability*, which indicates the closeness of sets of measurements made in the short term; and the *reproducibility* of the instrument. The reproducibility is the closeness of sets of measurements when repeated in similar conditions over a long period of time.

The ideal or perfect instrument would have perfect sensitivity, reliability, and repeatability without any spread of values and would be within the applicable standards. However, in many measurements, there will be imprecise and inaccurate results as a result of internal and external factors. The departure from the expected perfection is called the *error*. Often, sensitivity analyses are conducted to evaluate the effect of individual components that are causing these errors. Sensitivity to the affecting parameter can be obtained by varying that one parameter and keeping the others constant. This can be done practically by using the developed instruments or mathematically by means of appropriate models.

When determining the performance of an instrument, it is essential to appreciate how errors arise. There may be many sources of errors; therefore, it is important to identify these sources and draw up an error budget. In the error budget, there may be many factors, such as (a) imperfections in electrical and mechanical components (e.g., high tolerances and noise or offset voltages), (b) changes in component performances (e.g., shift in gains, changes in chemistry, aging, and drifts in offsets), (c) external and ambient influence (e.g., temperature, pressure, and humidity), and (d) inherent physical fundamental laws (e.g., thermal and other electrical noises, Brownian motion in materials, and radiation).

In instrumentation systems, errors can be broadly classified as systematic, random, or gross.

Systematic Errors Systematic errors remain constant with repeated measurements. They can be divided into two basic groups as instrumental errors and environmental errors. Instrumental errors are inherent within the instrument, arising because of the mechanical structure, electronic design, improper adjustments, wrong applications, and so on. They can also be subclassified as loading error, scale error, zero error, and response time error. The environmental errors are caused by environmental factors such as temperature and humidity. Systematic errors can also be viewed as static or dynamic errors.

Systematic errors can be quantified by mathematical and graphical means. They can be caused by the non-linear response of the instrument to different inputs as a result of hysteresis. They also emerge from wrong biasing, wear and aging, and other factors such as modifying the effects environment (e.g., interference). Typical systematic error curves are illustrated in Fig. 95.

Because of the predictability of systematic errors, deterministic mathematics can be employed. In the

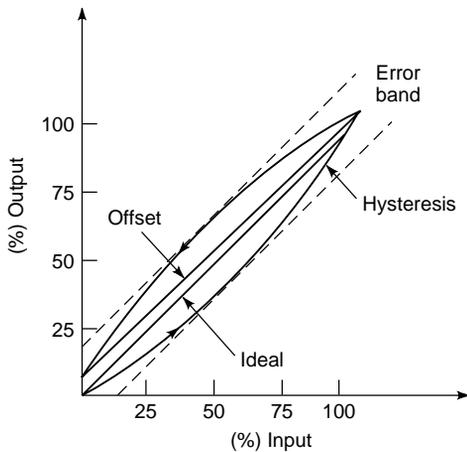

Fig. 95 Systematic errors are static errors and they can be quantified theoretically or experimentally. There are many different types, including hysteresis, linearity, and offset. They are contained within an error band typical to particular instrument.

simplest form, the error of a measurement may be expressed as

$$\Delta x(t) = x_m(t) - x_r(t) \quad (113)$$

where $\Delta x(t)$ is the absolute error, $x_r(t)$ is the correct reference value, and $x_m(t)$ is the measured value.

From Eq. (113), the relative error $r_e(t)$ may be calculated as

$$r_e(t) = \frac{\Delta x(t)}{x_r(t)} \quad (114)$$

However, in complex situations, correction curves obtained either empirically or theoretically may be used. Manufacturers usually supply correction curves, especially if their products embrace wide ranging and different applications (e.g., slurries with changing characteristics in time).

In many applications, the measurement system is made up of many components that have errors in their own rights. The deterministic approach may be adapted to calculate the overall propagated error of the system, as

$$y = f(x_1, x_2, x_3, \dots, x_n) \quad (115)$$

where y is the overall output and x_1, x_2, \dots are the components affecting the output.

Each variable affecting the output will have its own absolute error of Δx_i . The term Δx_i indicates the mathematically or experimentally determined error of each component under specific operating conditions. The overall performance of the overall system with the errors may be expressed as

$$y \pm \Delta y = f(x_1 \pm \Delta x_1, x_2 \pm \Delta x_2, \dots, x_n \pm \Delta x_n) \quad (116)$$

For an approximate solution, the Taylor series may be applied to Eq. (116). By neglecting the higher order terms of the series, the total absolute error Δy of the system may be written as

$$\Delta y = \left| \frac{\Delta x_1 \delta y}{\delta x_1} \right| + \left| \frac{\Delta x_2 \delta y}{\delta x_2} \right| + \dots + \left| \frac{\Delta x_n \delta y}{\delta x_n} \right| \quad (117)$$

The absolute error is predicted by measuring or calculating the values of the errors of each contributing component.

Slight modification of Eq. (116) leads to uncertainty analysis, where

$$w_y = [(w_1 \delta y / \delta x_1)^2 + (w_2 \delta y / \delta x_2)^2 + \dots + (w_n \delta y / \delta x_n)^2]^{1/2} \quad (118)$$

where w_y is the uncertainty of the overall system and w_1, w_2, \dots, w_n are the uncertainties of affecting the component.

Uncertainty differs from error in that it involves such human judgmental factors as estimating the possible values of errors. In measurement systems, apart from the uncertainties imposed by the instruments, experimental uncertainties also exist. In evaluating the total uncertainty, several alternative measuring techniques should be considered and assessed, and estimated accuracies must be worked out with care.

Random and Gross Errors Random errors appear as a result of rounding, noise and interference, backlash and ambient influences and so on. In experiments, the random errors vary by small amounts around a mean value. Therefore, the future value of any individual measurement cannot be predicted in a deterministic manner. Random errors may not easily be offset electronically; therefore, in the analysis and compensation, stochastic approaches are adapted by using the laws of probability.

Depending on the system, the random error analysis may be made by applying different probability distribution models. But, most instrumentation systems obey normal distribution laws; therefore, the Gaussian model can broadly be applied enabling the determination of the mean values, standard deviations, confidence intervals, and the like, depending on the number of samples being taken. A typical example of a Gaussian curve is given in Fig. 96. The mean value \bar{x} and the standard deviation σ may be found by

$$\bar{x} = \frac{\sum x_i}{n} \quad (119)$$

and

$$\sigma = \frac{\sum (x_i - \bar{x})^2}{n - 1} \quad (120)$$

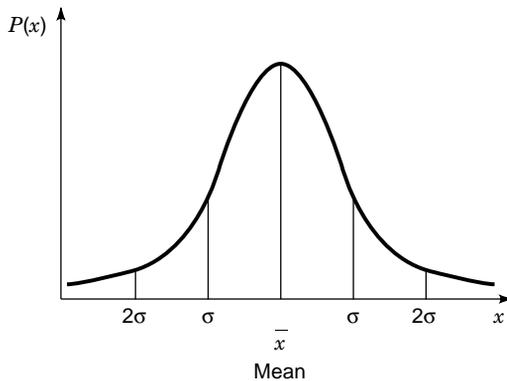

Fig. 96 Random errors of instruments can be analyzed by using probability methods. In many instruments the errors can be described by a Gaussian distribution curve.

Discussions relating to the application of stochastic theory in error analysis are very lengthy and will not be repeated here. Interested readers should refer to the literature (e.g., Ref. 98a).

Gross errors are the result of human mistakes, equipment fault, and the like. Human errors may occur in the process of observations or during the recording and interpretation of experimental results. A large number of errors can be attributed to carelessness, the improper adjustment of instruments, the lack of knowledge about the instrument and the process, and so on. These errors cannot be treated mathematically and eliminated completely, but they can be minimized by having different observers repeat the experiments.

Error Reduction Techniques Controlling errors is an essential part of instruments and instrumentation systems. Various techniques are available to achieve this objective. The error control begins in the design stages by choosing the appropriate components, filtering, and bandwidth selection, by reducing the noise, and by eliminating the errors generated by the individual subunits of the complete system. In a good design, the errors of the previous group may be compensated adequately by the following groups.

The accuracy of instruments can be increased by postmeasurement corrections. Various calibration methods may be employed to alter parameters slightly to give correct results. In many cases, calibration graphs, mathematical equations, tables, the experiences of the operators, and the like are used to reduce measurement errors. In recent years, with the application of digital techniques and intelligent instruments, error corrections are made automatically by computers or the devices themselves.

In many instrumentation systems, the application of compensation strategy is used to increase static and dynamic performances. In the case of static characteristics, compensations can be made by many methods

including introducing opposing nonlinear elements in the system, using isolation and zero environmental sensitivity, opposing compensating environmental inputs, using differential systems, and employing feedback systems. On the other hand, the dynamic compensation can be achieved by applying these techniques as well as by reducing harmonics, using filters adjusting bandwidth, using feedback compensation techniques, and the like.

Open-loop and close-loop dynamic compensations are popular methods employed in both static and dynamic error corrections. For example, using high-gain negative feedback can reduce the nonlinearity generated by the system. A recent and fast developing trend is the use of computers for estimating measured values and providing compensation during the operations if any deviations occur from the estimated values.

7.4 Standards and Reference Materials

Standards of fundamental units of length, time, weight, temperature, and electrical quantities have been developed for measurements to be consistent all over the world. The length and weight standards—the meter and the kilogram—are kept in the International Bureau of Weights and Measures in Sèvres, France. Nevertheless, in 1983 the meter was defined as the length of the path traveled by light in a vacuum in the fraction $1/299,792,458$ of a second, which was adopted as the standard meter. The standard unit of time—second—is established in terms of known oscillation frequencies of certain devices, such as the radiation of the cesium-133 atom. The standards of electrical quantities are derived from mechanical units of force, mass, length, and time. Temperature standards are established as international scale by taking 11 primary fixed points. If different units are involved, the relationship between different units are defined in fixed terms. For example, $1 \text{ lbm} = 453.59237 \text{ g}$.

Based on these standards, primary international units, SI (Système International d'Unités), are established for mass, length, time, electric current, luminous intensity, and temperature, as illustrated in Table 28. From these units, SI units of all physical quantities can be derived as exemplified in Table 29. The standard multiplier prefixes are illustrated in Table 30.

Table 28 Basic SI Units

Quantity	Unit	Symbol
Length	meter	m
Mass	kilogram	kg
Time	second	s
Electric current	ampere	A
Temperature	kelvin	K
Amount of substance	mole	mol
Luminous intensity	candela	cd
Plane angle	radian	rad
Solid angle	steradian	sr

Femto	f	10^{-15}
Atto	a	10^{-18}

In addition to primary international standards, standard instruments are available having stable and precisely defined characteristics that are used as references for other instruments that are performing the same function. Hence, the performance of an instrument can be cross-checked against a known device. At a global level, checking is done by using an international network of national and international laboratories, such as the National Bureau of Standards (NBS), the National Physical Laboratory (NPL), and the Physikalisch-Technische Bundesanstalt of Germany. A treaty between the world's national laboratories regulates the international activity and coordinates development, acceptance, and intercomparisons. Basically, standards are kept in four stages:

1. *International standards* represent certain units of measurement with maximum accuracy possible within today's available technology. These standards are under the responsibility of an international advisory committee and are not available to ordinary users for comparison or calibration purposes.
2. *Primary standards* are the national standards maintained by national laboratories in different parts of the world for verification of secondary standards. These standards are independently calibrated by absolute measurements that are periodically made against the international standards. The primary standards are compared against each other.
3. *Secondary standards* are maintained in the laboratories of industry and other organizations. They are periodically checked against primary standards and certified.
4. *Working standards* are used to calibrate general laboratory and field instruments.

Another type of standard is published and maintained by the Institute of Electrical and Electronics Engineer (IEEE) in New York. These standards are for test procedures, safety rules, definitions nomenclature, and so on. The IEEE standards are adopted by many organizations around the world. Many nations also have their own standards for test procedures, instrument usage procedures, safety, and the like.

7.5 Calibration, Calibration Conditions, and Linear Calibration Model

The calibration of all instruments is essential for checking their performances against known standards. This provides consistency in readings and reduces errors, thus validating the measurements to be valid universally. After an instrument is calibrated, future operation is deemed to be error bounded for a given period of time for similar operational conditions. The calibration procedure involves comparison of the instrument against primary or secondary standards. In some cases, it may be sufficient to calibrate a device against another one with a known accuracy.

Many nations and organizations maintain laboratories with the primary functions of calibrating instruments and field measuring systems that are used in everyday operations. Examples of these laboratories are National Association of Testing Authorities (NATA) of Australia and the British Calibration Services (BCS).

Calibrations may be made under static or dynamic conditions. A typical calibration procedure of a complex process involving many instruments is illustrated in Fig. 97. In an ideal situation, for an instrument that responds to a multitude of physical variables, a commonly employed method is to keep all inputs constant except one. The input is varied in increments in

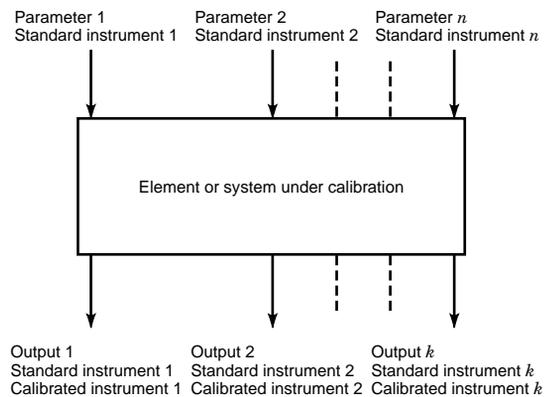

Fig. 97 Instruments are frequently calibrated sequentially for all affected inputs. Calibrations are made under static or dynamic conditions, usually keeping all inputs constant and varying only one and observing the output. Calibration continues until all other inputs are covered.

increasing and decreasing directions over a specific range. The observed output then becomes a function of that single input. The calibration is continued in a similar manner until all other inputs are covered. For better results, this procedure may be repeated by varying the sequences of inputs, thus developing a family of relationships between the inputs and outputs. As a result of these calibration readings, the input and output relation usually demonstrates statistical characteristics. From these characteristics, appropriate calibration curves can be obtained, and other statistical techniques can be applied.

In many instruments, the effect of a single input may not represent the true output values when one input is varied and all others are kept constant. In these cases, calibration is conducted by varying several inputs simultaneously. Throughout the calibration procedure, the n number of variables of the system are monitored by appropriate standard instruments. The rule of thumb is that each calibrated variable must have a traceable ladder starting from laboratory standards and secondary standards leading to primary standards. This is known as the linear calibration model or traceability.

Most instrument manufacturers supply calibrated instruments and reliable information about their products. But their claims of accuracy and reliability must be taken at face value. Therefore, in many cases, application-specific calibrations must be made periodically within the recommended calibration intervals. Usually, manufacturers supply calibration programs. In the absence of such programs, it is advisable to conduct frequent calibrations in the early stages of installation and lengthen the period between calibrations as the confidence builds based on satisfactory performance. Recently, with the wide applications of digital systems, computers can make automatic and self-calibrations as in the case of many intelligent instruments. In these cases, postmeasurement corrections are made, and the magnitudes of various errors are stored in the memory to be recalled and used in laboratory and field applications.

7.6 Analog and Digital Instruments

Instruments can be analog or digital or a combination of the two. Nowadays, most instruments are produced to be digital because of the advantages that they offer. However, the front end of majority of instruments are still analog; that is, the majority of sensors and transducers generate analog signals. Initially, the signals are conditioned by analog circuits before they are put into digital form for signal processing. It is important

to mention that digital instruments operating purely on digital principles are developing fast. For instance, today's smart sensors contain the complete signal condition circuits in a single chip integrated with the sensor itself. The output of smart sensors can be interfaced directly with other digital devices.

In analog instruments, the useful information is conveyed by changes in amplitudes, phases, or frequencies or a combination of the three. These signals can be deterministic or nondeterministic. In all analog or digital instruments, as in the case with all signal-bearing systems, there are useful signals that respond to the physical phenomena and unwanted signal resulting from various forms of noise. In the case of digital instruments, additional noise is generated in the process of A/D conversion.

Analog signals can also be nondeterministic; that is, the future state of the signal cannot be determined. If the signal varies in a probabilistic manner, its future can be foreseen only by statistical methods. The mathematical and practical treatment of analog and digital signals having deterministic, stochastic, and nondeterministic properties is a very lengthy subject and a vast body of information can be found in the literature; therefore, they will not be treated here.

As is true of all instruments, when connecting electronic building blocks, it is necessary to minimize the loading effects of each block by ensuring that the signal is passed without attenuation, loss, or magnitude and phase alterations. It is also important to ensure maximum power transfer between blocks by appropriate impedance-matching techniques. Impedance matching is very important in all instruments but particularly at a frequency of 1 MHz and above. As a rule of thumb, output impedances of the blocks are usually kept low, and input impedances are kept high so that the loading effects can be minimized.

Analog Instruments Analog instruments are characterized by continuous signals. A purely analog system measures, transmits, displays, and stores data in analog form. The signal conditioning is usually made by integrating many functional blocks such as bridges, amplifiers, filters, oscillators, modulators, offsets and level converters, buffers, and the like, as illustrated Fig. 98. Generally, in the initial stages, the signals produced by the sensors and transducers are conditioned mainly by analog electronics, even if they are configured as digital instruments later. Therefore, we pay more attention to analog instruments, keeping in mind

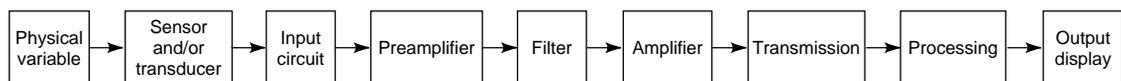

Fig. 98 Analog instruments measure, transmit, display, and store data in analog form. Signal conditioning usually involves such components as bridges, amplifiers, filters, oscillators, modulators, offsets and level converters, buffers, and so on. These components are designed and tested carefully to suit the characteristics of particular instruments.

that much of the information given here also may be used in various stages of the digital instruments.

Instrument bridges are commonly used to measure such basic electrical quantities as resistance, capacitance, inductance, impedance, and admittance. Basically, they are two-port networks in which the component to be measured is connected to one of the branches of the network. There are two basic groups, ac and dc bridges. Also, there are many different types in each group, such as Wheatstone and Kelvin dc bridges and Schering, Maxwell, Hay, and Owen ac bridges. In a particular instrument, the selection of the bridge to be employed and the determination of values and tolerances of its components is very important. It is not our intent to cover all bridges here; however, as typical example of an ac bridge, a series RC bridge is given in Fig. 99. We also offer some analysis to illustrate briefly their typical operational principles. At balance,

$$Z_1 Z_3 = Z_x Z_z \quad (121)$$

Substitution of impedance values gives

$$R_3 \left(R_1 - \frac{j}{\omega} C_1 \right) = \left(R_x - \frac{j}{\omega} C_x \right) R_2 \quad (122)$$

Equating the real and imaginary terms gives the values of unknown components as

$$R_x = \frac{R_1 R_3}{R_2} \quad (123)$$

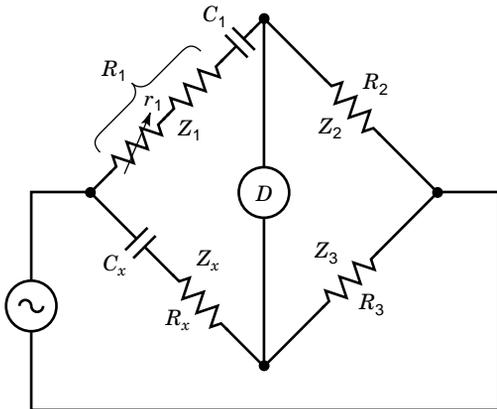

Fig. 99 A series RC bridge wherein the unknown capacitance is compared with a known capacitance. The voltage drop across R_1 balances the resistive voltage drop in branch Z_2 . The bridge balance is achieved relatively easily when capacitive branches have substantial resistive components. The resistors R_1 and either R_2 or R_3 are adjusted alternately to obtain the balance.

and

$$C_x = \frac{C_1 R_2}{R_3} \quad (124)$$

In instruments, the selection and use of amplifier and filter are also very important since many transducers generate extremely weak signals in comparison to the noise existing in the device. Today, operational amplifier and high-precision instrumentation amplifier are the building blocks of modern instruments.

The operation amplifier may be used as inverting and noninverting amplifiers and by connecting suitable external components, they can be configured to perform many other functions, such as multipliers, adders, limiters, and filters. Instrumentation amplifiers are used in situations where operational amplifiers do not meet the requirements. They are essentially high-performance differential amplifiers consisting of several closed-loop operational amplifiers. The instrumentation amplifier has improved common-mode rejection ratios (CMRR) (up to 160 dB), high input impedances (up to 500 M Ω), low output impedance, low offset currents and voltages, and better temperature characteristics. To illustrate amplifier in instrumentation systems, a typical current amplifier used in charge amplification is illustrated in Fig. 100. In this circuit, if the input impedance of the operational amplifier is high, output is not saturated, and the differential input voltage is small, it is possible to write

$$\frac{1}{C_f} \int i_f dt = e_{ex} - e_{ai} - e_{ex} \quad (125)$$

$$\frac{1}{C_x} \int i_x dt = e_o - e_{ai} = e_o \quad (126)$$

$$i_f + i_x - i_{ai} = 0 = i_f + i_x \quad (127)$$

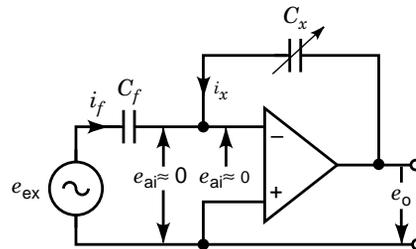

Fig. 100 Using an operational amplifier signal processor is useful to eliminate the nonlinearity in the signals generated by capacitive sensors. With this type of arrangement, the output voltage can be made to be directly proportional to variations in the signal representing the nonlinear operation of the device.

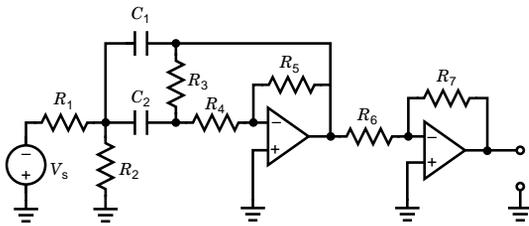

Fig. 101 Filtering is used in various stages of signal processing to eliminate unwanted components of signals. They can be designed and constructed to eliminate or pass signals at certain frequency ranges. Suitable arrangements of components yield to bandpass, high-pass, bandpass, bandstop, and notch filters. Filters can be classified as active and passive.

Manipulation of these equations gives

$$e_0 = \frac{-C_f e_{ex}}{C_x} \quad (128)$$

However, a practical circuit requires a resistance across C_f to limit output drift. The value of this resistance must be greater than the impedance of C_f at the lowest frequency of interest.

Filtering is used to reject unwanted components of signals. For example, by using a filter that narrows the bandwidth, the broadband noise energy is reduced, and unwanted signals outside the passband are rejected. Analog filters can be designed by using various techniques, such as Butterworth, Chebyshev, and Bessel-Thomson filters. They can be low-pass, high-pass, bandpass, bandstop, and notch filters. Filters can be classified as active and passive. Active filters involve active components such as operational or instrumentation amplifiers whereas passive filters are configured completely by inductive, capacitive, and resistive components. The choice of active or passive filter depends on the available components, the precision required, and the frequency of operations. A typical filter used in instrument is given in Fig. 101.

Digital Instruments In modern instruments, the original data acquired from the physical variables are usually in analog form. This analog signal is converted to digital before being passed on to the other parts of the system. For conversion purposes, analog-to-digital converters are used together with appropriate

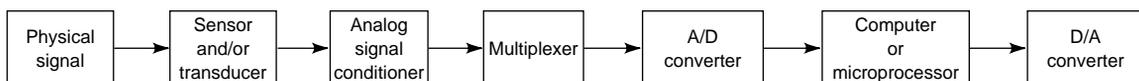

Fig. 102 Digital instruments have more signal-processing components than analog instruments. Usually, analog signals are converted to digital form by analog-to-digital (A/D) converters. The digital instruments have the advantage of processing, storing, and transmitting signals more easily than their analog counterparts.

sample-and-hold devices. In addition, analog multiplexers enable the connection of a number of transducers to the same signal-processing media. The typical components of a digital instrument are illustrated in Fig. 102. The digital systems are particularly useful in performing mathematical operations and storing and transmitting data.

Analog-to-digital conversion involves three stages: sampling, quantization, and encoding. The Nyquist sampling theorem must be observed during sampling; that is, "the number of samples per second must be at least twice the highest frequency present in the continuous signal." As a rule of thumb, depending on the significance of the high frequencies, the sampling must be about 5–10 times the highest frequency of the signal. The next stage is the quantization, which determines the resolution of the sampled signals. The quantization error decreases as the number of bits increases. In the encoding stage, the quantized values are converted to binary numbers to be processed digitally. Figure 103 illustrates a typical A/D sampling process of an analog signal.

After the signals are converted to digital form, the data can be further processed by employing such various techniques as fast Fourier transform (FFT) analysis, digital filtering, sequential or logical decision making, correlation methods, spectrum analysis, and so on.

Virtual Instruments (VIs) Traditional instruments have three basic components—acquisition and control,

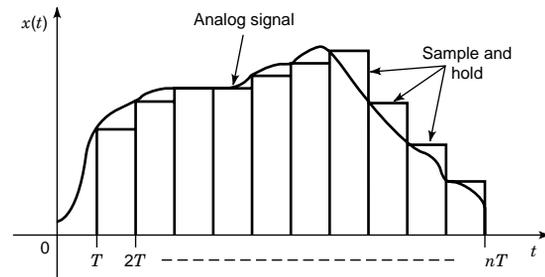

Fig. 103 Analog-to-digital converters involve three stages: sampling, quantization, and encoding. However, the digitization introduces a number of predictable errors. After the conversion, the data can be processed by techniques such as FFT analysis, discrete Fourier transform (DFT) analysis, digital filtering, sequential or logical decision making, correlation methods, spectrum analysis, and so on.

data analysis, and data presentation. In VIs, the use of digital techniques, software, and computers replace the display and processing capabilities of most traditional instruments. In this technology, plug-in data acquisition (DAQ) boards, PC cards (PCMCIA), and parallel-port input-output (I/O) devices are used to interface sensors and transducers of the system under investigation to computers. There are standard interface buses such as VXIbus, which stands for VMEbus Extensions for Instrumentation (also known as the IEEE Standard 1155-1992).

Once the system is interfaced, the computer can be programmed to act just like a stand-alone instrument, but offering additional benefit of flexibility of the processing, display, and storage. In VIs, the data can be saved or loaded in memory to be processed in popular spreadsheet programs and word processors, and a report generation capability complements the raw data storage by adding timestamps, measurements, user names, and comments.

VI technology allows the user to build test systems that fit specific applications. The VI software can be programmed to resemble familiar instrument panels, including knobs and dials. The user interface tools include knobs, meters, gauges, dials, tank displays, thermometers, graphs, strip charts, and the like to simulate the appearance of traditional instruments. Computer displays can show more colors and allow users to quickly change the way they display test data and controls as required. The software also contains analysis libraries with high-powered statistics, curve fitting, signal processing, and filtering to standard dynamic link libraries (DLLs).

Designing a VI system is similar to designing a test system with stand-alone instruments. The first step is to determine what types of signals are needed to measure, including their frequencies, amplitudes, and other signal characteristics together with the level of accuracy expected from these signals. To develop the software for the test application, a programming language or test development software package needs to be selected such as C or Microsoft Visual Basic. Since the display is not fixed as on a stand-alone instrument, it can be as complex or as simple as the application requires.

Nowadays, users can configure their VIs to update front panels and display real-time, animated VIs over the Internet. The toolkits let applications be published over the web and viewed with a standard web browser with little additional programming. With these tools, developers can monitor VIs running in remote locations, publish experiment results on the Web, and automatically notify operators of alarm conditions or status information.

7.7 Control of Instruments

Instruments can be manual, semiautomatic, or fully automatic. Manual instruments need human intervention for adjustment, parameter setting, and interpreting readings. Semiautomatic instruments need limited

intervention such as the selection of operating conditions and so on. In the fully automatic instruments, however, the variables are measured either periodically or continuously without human intervention. The information is either stored or transmitted to other devices automatically. Some of these instruments can also measure the values of process variables and regulate their deviations from preset points.

It is often necessary to measure many parameters of a process by using two or more instruments. The resulting arrangement for performing the overall measurement function is called the measurement system. In measurement systems, instruments operate in an autonomously but coordinated manner. The information generated by each device is communicated between instruments themselves, or between the instrument and other devices such as recorders, display units, and computers. The coordination of instruments can be done in three ways: analog to analog, analog to digital, and digital to digital.

Analog systems consist of instruments that generate continuous current and voltage waveforms in response to the physical variations. The signals are processed by using analog electronics; therefore, signal transmission between the instruments and other devices is also done in the analog form. In assembling these devices, the following characteristics must be considered:

Signal transmission and conditioning

Loading effects and buffering

Proper grounding and shielding

Inherent and imposed noises

Ambient conditions

Signal level compatibility

Impedance matching

Proper display units

Proper data storage media

Offset and level conversion is used to convert the output signal of an instrument from one level to another, compatible with the transmission medium in use. In analog systems, signals are usually transmitted at suitable current levels (4–20 mA). In this way, change in impedance does not affect the signal levels, and standard current signal levels can easily be exchanged.

In digital instrumentation systems, analog data are converted and transmitted in digital form. The transmission of data between digital devices can be done relatively easily, by using serial or parallel transmission techniques. However, as the measurement system becomes large by the inclusion of many instruments, the communication becomes complex. To avoid this complexity, message interchange standards are used for digital signal transmission such as RS-232 and IEEE-488 VXIbus.

Many instruments are manufactured with output ports to pass measurement data and various control signals. The IEEE-488 (also known as the GPIB) bus

is one of the established industry standard instrumentation interfacing. It enables simultaneous measurements by interfacing up to 15 instruments together at the same time. It has 16 signal lines distributed as 8 data lines, 3 control lines, and 5 general interface management lines. The line configuration of an IEEE-488 bus is given in Fig. 104. Once connected, any one device can transfer data to one or more other devices on the bus. All devices must be able to perform at least one of the following roles: talker, listener, controller. The minimum device consists of one talker and one listener without a controller. The length of cables connected to the bus cannot exceed 20 m, and the maximum data rate is restricted to 250 kbytes per second.

RS-232 is issued by the Electronic Industries Association (EIA). It uses serial binary data interchange and applies specifically to the interconnection of data communication equipment (DCE) and data terminal equipment (DTM). Data communications equipment may include modems, which are the devices that convert digital signals suitable for transmission through telephone lines. The RS-232 uses standard DB-25 connectors, the pin connection is given in Table 31. Although 25 pins are assigned, a complete data transmission is possible by using only three pins—2, 3, and 7. The transmission speed can be set to certain baud rates such as 19,200 bits per second and can be used for synchronous or non-synchronous communication purposes. The signal voltage levels are very flexible with any voltage between -3 and -25 V representing logic 1 and any voltage between $+3$ and $+25$ V representing logic 0.

In many industrial applications, the current loop digital communication is used. This communication is similar to analog current loop systems, but the signal is transmitted in digital form, with 20 mA signifying logic 1 and 0 mA representing logic 0. Depending on

the external noise sources in the installation environment, the current loop can be extended up to 2 km.

When data are transmitted distances greater than those permitted by the RS-232 or current loop, the modem, microwave, or RF transmissions are used. In this case, various signal modulation techniques are necessary to convert digital signals to suitable formats. For example, most modems, with medium-speed asynchronous data transmission, use frequency-shift keyed (FSK) modulation. The digital interface with modems uses various protocols such as MIL-STD-188C to transmit signals in simplex, half-duplex, or full-duplex forms depending on the directions of the data flow. The simplex interface transmits data in one direction, whereas full duplex transmits it in two directions simultaneously.

Table 31 RS-232 Pin Connections

Pin Number	Direction	Function
1	—	Frame ground
2	Out	Transmitted data (–Tx/D)
3	In	Received data (–Rx/D)
4	Out	Request to send (RTS)
5	In	Clear to send (CTS)
6	In	Data set ready (DSR)
7	—	Signal ground (SG)
8	In	Received line signal detector (DCD)
9	Out	+ Transmit current loop data
11	Out	– Transmit current loop data
18	In	+ Receive current loop data
20	Out	Data terminal ready (DTR)
22	In	Ring indicator (RI)
25	In	– Receive current loop return

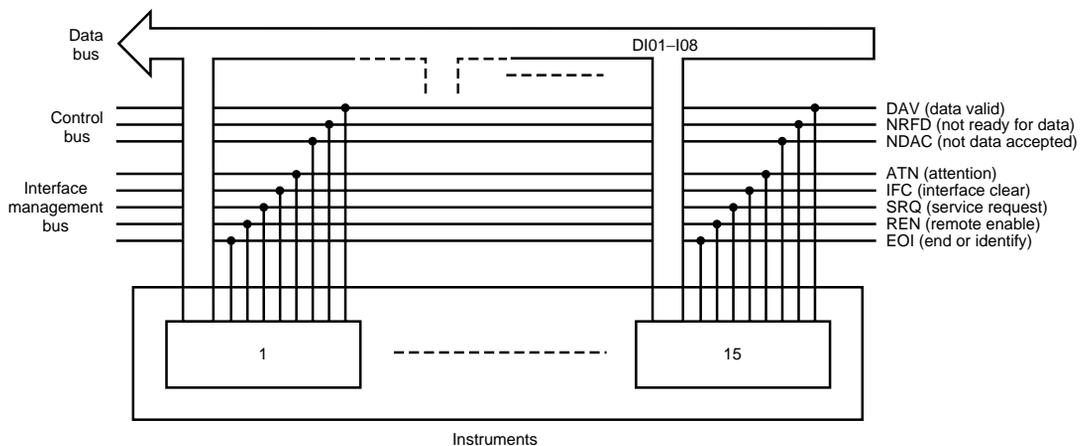

Fig. 104 The IEEE-488 or the GPIB bus is an industry standard for interface medium. It has 8 data lines, 3 control lines, and 5 general interface management lines. In noisy environments the maximum length of cable is recommended to be not more than 20 m.

As far as industrial applications are concerned, several standards for digital data transmission are available, commonly known as *field buses* in the engineering literature. For example, WorldFIP and Profibus have been developed and Foundation Fieldbus is under development to increase the performance of the 20-mA current loop. New devices allow for an increase in the data rates (e.g., National Instruments chips and boards operating with high-speed protocol HS488 for 8 Mbytes/s transfer rate). A new standard is under discussion at the IEEE by the working group for higher performance IEEE Std. 488.1, with a very high increase in the data rate.

Concerning the design software, there are important tools that help implement control (application) software for automatic measuring equipment, such as LabWindows and LabVIEW from National Instruments and VEE from Hewlett-Packard.

In many applications, many instruments (say over 1000) may be used to monitor and control the process as in the case of computer-integrated manufacturing (CIM). In these cases, instruments are networked either in groups or as whole via a center computer or group of computers. Appropriate network topologies (e.g., star, ring, field bus) may be employed to enable the signal flow between the instruments and computers, among the instruments themselves, or between instruments and control panels.

7.8 Industrial Measuring Instruments

In industry, instruments are used to sense and maintain the functions of the process. Because the requirements of diverse industries are different, the instruments are made quite differently to suit applicational differences from one industry to another. Here, instruments specific to some industries will be discussed briefly.

The process industry uses instruments extensively for on-line monitoring and off-line analysis. Specific instruments are used commonly for sensing variables such as temperature, pressure, volumetric and mass flow rate, density, weight, displacement, pH levels, color, absorbency, viscosity, material flow, dew point, organic and inorganic components, turbidity, solid and liquid level, humidity, and particle size distribution. The selection and use of these instruments constitute an important part of process engineering, which is a discipline in its own right. Additional information can be found in the Bibliography (e.g., Ref. 97).

In medical technology, there are three basic types of instruments—imaging, physiological measurements, and laboratory analysis. In imaging and physiological measurements, the instruments are closely linked with patients. Some examples of these instruments are X-ray tomography, nuclear magnetic resonance (NMR) and nuclear spin tomography, ultrasound imaging, thermography, brain and nervous system sensors, and respiratory sensors. Many instruments are based on the radiation and sound, force and tactile sensing, electromagnetic sensing, and chemical and bioanalytical sensors.

Power plants are instrumented for maximum availability, operational safety, and environmental planning. Therefore, their measurements must be as accurate as possible and reliable. Instruments are used for temperature, pressure, flow, level, vibration measurements, and water, steam, and gas analysis. For example, gas analysis requires instruments to measure carbon compounds, sulfur and nitrogen compounds, and dust and ash contents.

Environmental monitoring requires a diverse range of instruments for air, water, and biological monitoring. Instruments are used for measuring various forms of radiation, chemical hazards, air pollutants, and organic solvents. Many sophisticated instruments are also developed for remote monitoring via satellites, and they operate on optical, microwave, and RF electromagnetic radiation principles.

In automobiles, instruments are used to assist drivers by sensing variables such as cooling, braking, fuel consumption, humidity control, speed, travel route monitoring, and position sensing. Instruments also find applications for safety and security purposes, such as passenger protection and locking and antitheft systems. Recently, with the advent of micromachined sensors, many diverse instruments such as engine control, fuel injection, air regulation, and torque sensing are developed.

The manufacturing industry, especially automated manufacturing, requires a diverse range of instruments. Machine diagnosis and process parameters are made by instruments based on force, torque, pressure, speed, temperature, and electrical parameter-sensing instruments. Optics, tactile arrays, and acoustic scanning instruments are used for pattern recognition. Distance and displacement measurements are made by many methods (e.g., inductive, capacitive, optical, and acoustic techniques).

Aerospace instrumentation requires an accurate indication of physical variables and the changes in these variables. Instruments are designed to suit specific conditions of operations. Some of the measurements are gas temperature and pressure, fluid flow, aircraft velocity, aircraft icing, thrust and acceleration, load, strain and force, position, altitude sensing, and direction finding.

8 INTEGRATED CIRCUITS

N. Ranganathan and Raju D. Venkataramana

The invention of the transistor in 1947 by William Shockley and his colleagues John Bardeen and Walter Brattain at Bell Laboratories, Murray Hill, NJ, launched a new era of ICs. The transistor concept was based on the discovery that the flow of electric current through a solid semiconductor material like silicon can be controlled by adding impurities appropriately through the implantation processes. The transistor replaced the vacuum tube due to its better reliability, lesser power requirements, and, above all, its much

smaller size. In the late 1950s, Jack Kilby of Texas Instruments developed the first integrated circuit. The ability to develop flat or planar ICs, which allowed the interconnection of circuits on a single substrate (due to Robert Noyce and Gordon Moore), began the microelectronics revolution. The substrate is the supporting semiconductor material on which the various devices that form the integrated circuit are attached. Researchers developed sophisticated photolithography techniques that helped in the reduction of the minimum feature size, leading to larger circuits being implemented on a chip. The miniaturization of the transistor led to the development of integrated circuit technology in which several hundreds and thousands of transistors could be integrated on a single silicon die. IC technology led to further developments, such as microprocessors, mainframe computers, and supercomputers.

Since the first integrated circuit was designed following the invention of the transistor, several generations of integrated circuits have come into existence: SSI (small-scale integration) in the early 1960s, MSI (medium-scale integration) in the latter half of the 1960s, and LSI (large-scale integration) in the 1970s. The VLSI (very large scale integration) era began in the 1980s. While the SSI components consisted on the order of 10–100 transistors or devices per integrated circuit package, the MSI chips consisted of anywhere from 100 to 1000 devices per chip. The LSI components ranged from roughly 1000 to 20,000 transistors per chip, while the VLSI chips contain on the order of up to 3 million devices. When the chip density increases beyond a few million, the Japanese refer to the technology as ULSI (ultra large scale integration), but many in the rest of the world continue to call it VLSI. The driving factor behind integrated circuit technology was the scaling factor, which in turn affected the circuit density within a single packaged chip. In 1965, Gordon Moore predicted that the density of components per integrated circuit would continue to double at regular intervals. Amazingly, this has proved true, with a fair amount of accuracy.⁹⁹

Another important factor used in measuring the advances in IC technology is the minimum feature size or the minimum line width within an integrated circuit (measured in microns). From about 8 μm in the early 1970s, the minimum feature size has decreased steadily, increasing the chip density or the number of devices that can be packed within a given die size. In the early 1990s, the minimum feature size decreased to about 0.5 μm , and currently 0.3, 0.25, and 0.1 μm technologies (also called deep submicron technologies) are becoming increasingly common. IC complexity refers, in general, to the increase in chip area (die size), the decrease in minimum feature size, and the increase in chip density. With the increase in IC complexity, the design time and the design automation complexity increase significantly. The advances in IC technology are the result of many factors, such as

high-resolution lithography techniques, better processing capabilities, reliability and yield characteristics, sophisticated design automation tools, and accumulated architecture, circuit, and layout design experience.

8.1 Basic Technologies

The field of integrated circuits is broad. The various basic technologies commonly known are shown in Fig. 105. The inert substrate processes, further divided as thin- and thick-film processes, yield devices with good resistive and temperature characteristics. However, they are mostly used in low-volume circuits and in hybrid ICs. The two most popular active substrate materials are silicon and gallium arsenide (GaAs). The silicon processes can be separated into two classes: MOS (the basic device is a metal–oxide–semiconductor field-effect transistor) and bipolar (the basic device is bipolar junction transistors). The bipolar process was commonly used in the 1960s and 1970s and yields high-speed circuits with the overhead of high-power dissipation and the disadvantage of low density. The transistor–transistor logic (TTL) family of circuits constitutes the most popular type of bipolar and is still used in many high-volume applications. The ECL devices are used for high-speed parts that form the critical path delay of the circuit. The MOS family of processes consists of PMOS, NMOS, CMOS, and BiCMOS. The term *PMOS* refers to a MOS process that uses only *p*-channel transistors, and *NMOS* refers to a MOS process that uses only *n*-channel transistors. PMOS is not used much due to its electrical characteristics, which are not as good as the *n*-channel FETs, primarily since the mobility of the *n*-channel material is almost twice compared to the mobility of the *p*-channel material. Also, the NMOS devices are smaller than the PMOS devices, and thus PMOS do not give good packing density.

CMOS was introduced in the early 1960s; however, it was only used in limited applications, such as watches and calculators. This was primarily due to the fact that CMOS had slower speed, less packing density, and latchup problems although it had a high noise margin and lower power requirements. Thus, NMOS was

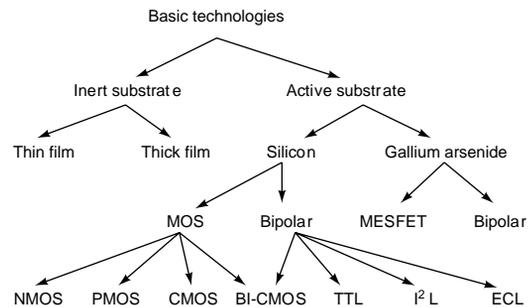

Fig. 105 Overview of basic technologies.

preferred over CMOS, in general, until the p -channel devices developed began to have similar characteristics as the n MOS and both the p -channel and n -channel transistors started delivering close to equal amounts of currents with similar transistor sizes. In the 1980s and the 1990s, the need for lower power consumption was the driving factor, and thus CMOS emerged as the leading IC technology.¹⁰⁰ The BiCMOS technology combines both bipolar and CMOS devices in a single process. While CMOS is preferred for logic circuits, BiCMOS is preferred for input/output (I/O) and driver circuits due to its low input impedance and high current driving capability.

Since the 1980s, efforts have been directed toward designing digital ICs using GaAs devices. In many high-resolution radar systems, space systems, high-speed communication circuits, and microwave circuits, the integrated circuits need to operate at speeds beyond several gigahertz. In silicon technology, it is possible to obtain speeds on the order of up to 10 GHz using ECL circuits, which is almost pushing the limits of the silicon technology. In GaAs technology, the basic device is the metal–semiconductor (Schottky gate) field-effect transistor, called the GaAs MESFET. Given similar conditions, the electrons in n -type GaAs material travel twice faster than in silicon. Thus, the GaAs circuits could function at twice the speed than the silicon ECL circuits for the same minimum feature size. The GaAs material has a larger bandgap and does not need gate oxide material, as in silicon, which makes it immune to radiation effects. Also, the GaAs

material has very high resistivity at room temperatures and lower parasitic capacitances, yielding high-quality transistor devices. However, the cost of fabricating large GaAs circuits is significantly high due to its low reliability and yield characteristics (primarily due to the presence of more defects in the material compared to silicon). The fabrication process is complex, expensive, and does not aid scaling. Also, the hole mobility is the same as in silicon, which means GaAs is not preferable for complementary circuits. Thus, the GaAs technology has not been as successful as initially promised. Since CMOS has been the most dominant technology for integrated circuits, we examine the MOS transistor and its characteristics as a switch in the next section.

8.2 MOS Switch

The MOSFET is the basic building block of contemporary CMOS circuits, such as microprocessors and memories. A MOSFET is a unipolar device; that is, current is transported by means of only one type of polarity (electrons in an n type and holes in a p type). In this section, we describe the basic structure of MOSFETS and their operation and provide examples of gates built using MOS devices.

Structure The basic structure of a MOSFET (n and p type) is shown in Fig. 106. We describe the structure of an n -type MOSFET.^{101,102} It consists of four terminals with a p -type substrate into which two n^+ regions are implanted. The substrate is a silicon

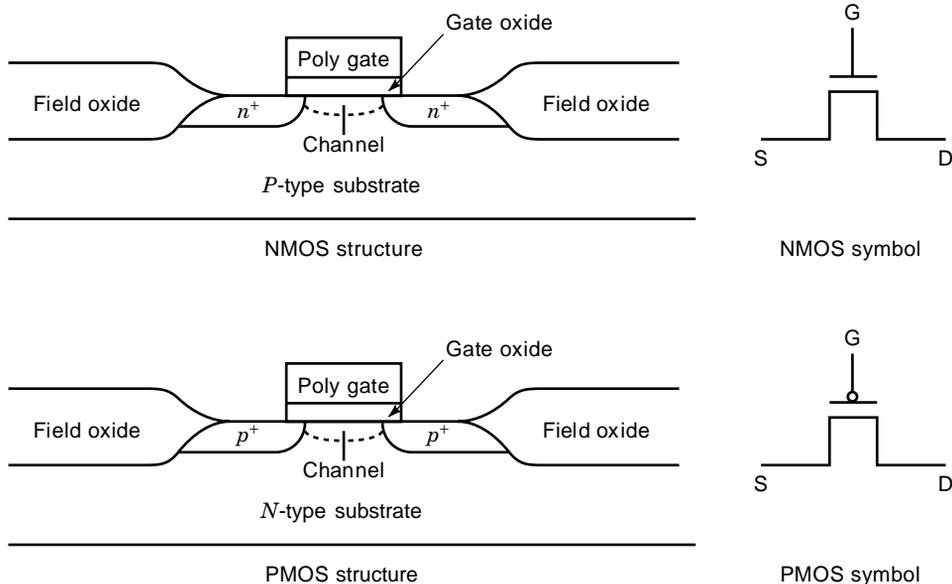

Fig. 106 Structure of n - and p -type MOSFET.

wafer that provides stability and support. The region between the two n^+ regions is covered by an insulator, typically polysilicon and a metal contact. This contact forms the gate of the transistor. The insulating layer is required to prevent the flow of current between the semiconductor and the gate. The two n^+ regions form the source and the drain. Due to the symmetry of the structure, the source and the drain are equivalent. The gate input controls the operation of the MOSFET. A bias voltage on the gate causes the formation of a channel between the n^+ regions. This channel causes a connection between the source and drain and is responsible for the flow of the current. The MOSFET is surrounded by a thick oxide, called the field oxide, which isolates it from neighboring devices. Reversal of n and p types in the discussion will result in a p -type MOSFET. Typical circuit symbols for n -type and p -type MOSFETS are also shown in Fig. 106.

Operation When no gate bias is applied, the drain and the source behave as two pn junctions connected in series in the opposite direction. The only current that flows is the reverse leakage current from the source to the drain. When a positive voltage is applied to the gate, the electrons are attracted and the holes are repelled. This causes the formation of an inversion layer or a channel region. The source and the drain are connected by a conducting n channel through which the current can flow. This voltage-induced channel is formed only when the applied voltage is greater than the threshold voltage, V_t . MOS devices that do not conduct when no gate bias is applied are called *enhancement mode* or normally OFF transistors. In n MOS enhancement mode devices, a gate voltage greater than V_t should be applied for channel formation. In p MOS enhancement mode devices, a negative gate voltage whose magnitude is greater than V_t must be applied. MOS devices that conduct at zero gate bias are called normally ON or *depletion mode* devices. A gate voltage of appropriate polarity depletes the channel of majority carriers and hence turns it OFF.

Considering an enhancement mode n -channel transistor, when the bias voltage is above the predefined threshold voltage, the gate acts as a closed switch between the source and drain, the terminals of which become electrically connected. When the gate voltage is cut off, the channel becomes absent, the transistor stops conducting, and the source and the drain channels get electrically disconnected. Similarly, the p -channel transistor conducts when the gate voltage is beneath the threshold voltage and stops conducting when the bias voltage is increased above the threshold. The behavior of the MOS transistor as a switch forms the fundamental basis for implementing digital Boolean circuits using MOS devices.

Output Characteristics We describe the basic output characteristics^{103,104} of a MOS device in this subsection. There are three regions of operation for a MOS device:

1. Cutoff region
2. Linear region
3. Saturation region

In the cutoff region, no current flows and the device is said to be off. When a bias, V_{gs} , is applied to the gate such that $V_g > V_t$, the channel is formed. If a small drain voltage, V_{ds} , is applied, drain current, I_{ds} , flows from source to drain through the conducting channel. The channel acts like a resistance, and the drain current is proportional to the drain voltage. This is the linear region of operation. As the value of V_{ds} is increased, the channel charge near the drain decreases. The channel is pinched off when $V_{ds} = V_{gs} - V_t$. An increase in V_{ds} beyond the pinch-off value causes little change in the drain current. This is the saturation region of operation of the MOS device. The output characteristics of n - and p -type devices is shown in Fig. 107. The equations that describe the regions of operation can be summarized as follows:

$$I_{ds} = \begin{cases} 0 & \text{if } V_{gs} \leq V_t & \text{(cutoff)} \\ k/2[2(V_{gs} - V_t)V_{ds} - V_{ds}^2] & & \\ \text{if } V_g > V_t, V_{ds} \leq (V_{gs} - V_t) & \text{(linear)} \\ k/2(V_{gs} - V_t)^2 & & \\ \text{if } V_g > V_t, V_{ds} > (V_{gs} - V_t) & \text{(saturation)} \end{cases}$$

where k is the transconductance parameter of the transistor. A detailed analysis of the structure and operation of MOS devices is described in Refs. 101, 103, 105, and 106.

CMOS Inverter The basic structure of an inverter is shown in Fig. 108, and the process cross section is shown in Fig. 109. The gates of both the NMOS and the PMOS transistors are connected. The PMOS transistor is connected to the supply voltage V_{dd} , and the NMOS transistor is connected to G_{nd} . When a logical 0 is applied at the input V_{in} , then the PMOS

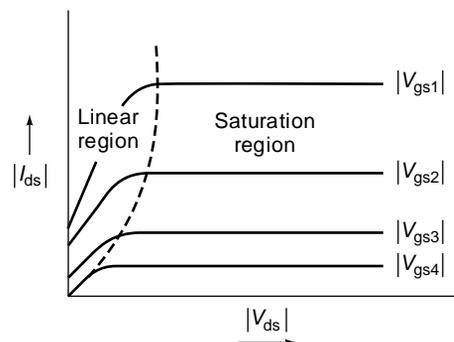

Fig. 107 Output characteristics of MOS transistor.

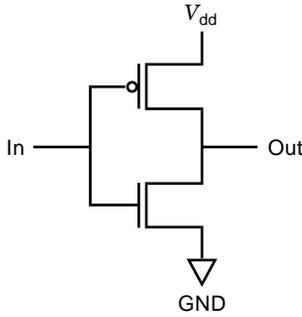

Fig. 108 Circuit schematic of inverter.

device is on and the output is pulled to V_{dd} . Hence the output is a logical 1. On the other hand, when a logical 1 is applied at the input, then the NMOS transistor is on and the output is pulled to the ground. Hence we have a logical 0. The operating regions of the transistor are shown in Fig. 110. In region I, the n device is off and the p device operates in the linear region. Hence the output is pulled to V_{dd} . In region II, the n and p devices operate in the linear and saturation region depending on the input voltage. In region III, the p device is cut off and the n device is operating in the linear region. The output is pulled to the ground. In region II, when both the transistors are on simultaneously, a short is produced between V_{dd} and G_{nd} . This accounts for the short circuit power dissipation in CMOS logic.

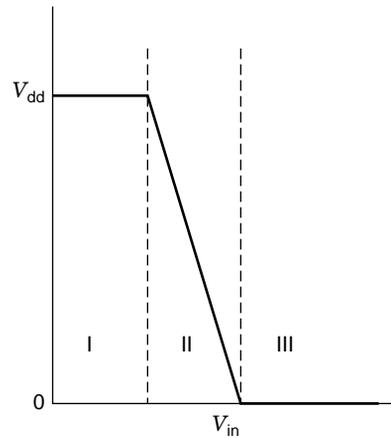

Fig. 110 Operating regions of transistor.

Transmission Gate Consider the device shown in Fig. 111, which represents an NMOS or a PMOS device. By suitably controlling the gate bias, the device can be made to turn on or off. It behaves as an electrical switch that either connects or disconnects the points s and d . An NMOS device is a good switch when it passes a logical 0, and a PMOS is a good switch when it passes a logical 1. In CMOS logic, both the NMOS and PMOS devices operate together. In general, the NMOS transistor pulls down the output

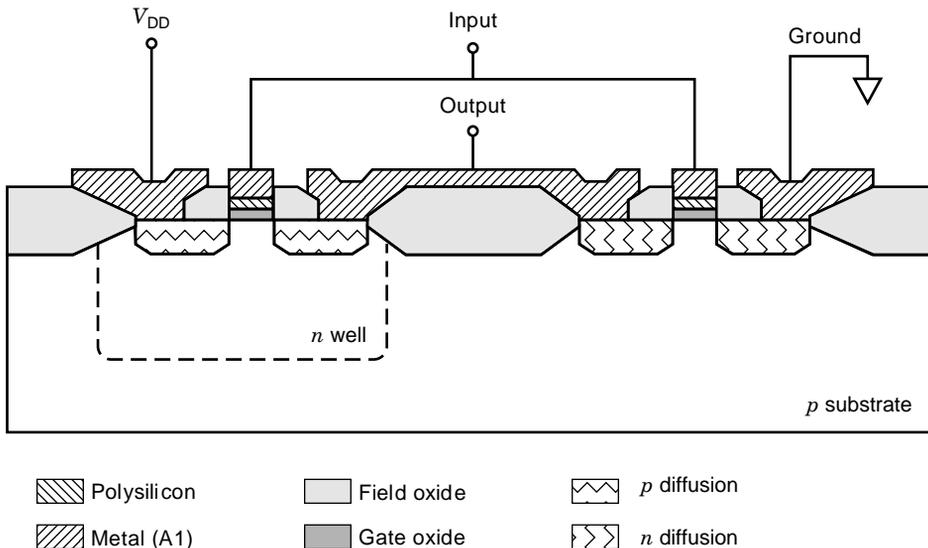

Fig. 109 Process cross section of n -well inverter.

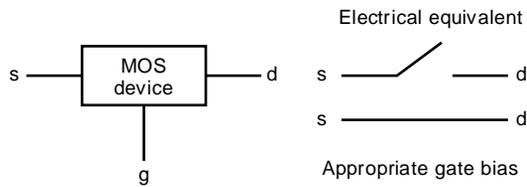

Fig. 111 A MOS device as switch.

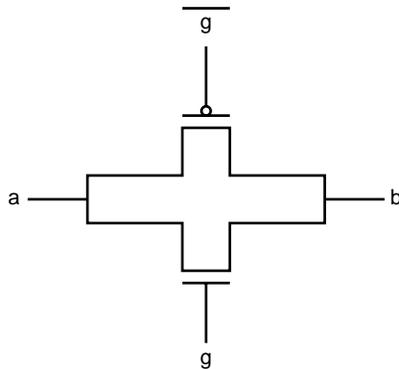

Fig. 112 Transmission gate.

node to logical 0, and the PMOS device pulls up a node to logical 1. A transmission gate is obtained by connecting the two in parallel, as shown in Fig. 112. The control signal (say, g) applied to the n -type device is complemented and applied to the p -type device. When g is high, both the transistors are on and hence a good 1 or a 0 is passed. When g is low, both the devices are off. This is also called a complementary switch, or a C SWITCH.¹⁰³

NAND and NOR Gates CMOS combinational gates are constructed by connecting the PMOS and NMOS devices in either series or parallel to generate different logical functions. The structures for a two-input NAND and NOR gate are shown in Fig. 113.

NAND Gate. The p devices are connected in parallel, and the n devices are connected in series. When either of the inputs A or B is a logical 0, the output is pulled high to V_{dd} . When both A and B are high, then the output is pulled to the ground. Hence this structure implements the operation $f = (AB)'$.

NOR Gate. Similarly, in the NOR gate, the p devices are connected in series and the n devices are connected in parallel. When either of the inputs A or B is a logical 1, then the output is pulled to the ground. When both A and B are low, then the output is pulled

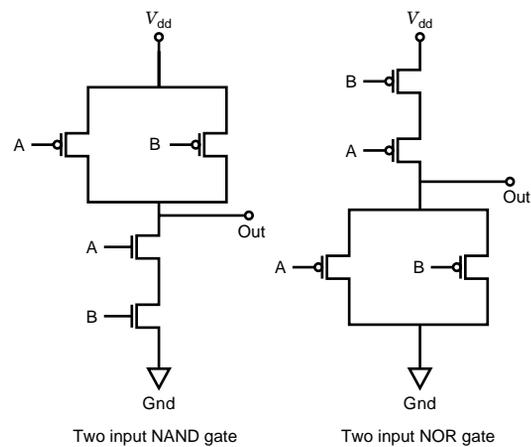

Fig. 113 Two-input NAND and NOR gate.

to V_{dd} . Hence this structure implements the operation $f = (A + B)'$. The p structure is the logical dual of the n structure. An n input NAND and NOR gate can be constructed in a similar fashion.

8.3 IC Design Methodology

To design and realize VLSI circuits, several factors play key roles. The goal of an IC designer is to design a circuit that meets the given specification and requirements while spending minimum design and development time avoiding design errors. The designed circuit should function correctly and meet the performance requirements, such as delay, timing, power, and size. A robust design methodology has been established over the years, and the design of complex integrated circuits has been made possible essentially due to advances in VLSI design automation. The various stages in the design flow are shown in Fig. 114. The design cycle ranges from the system-level specification and requirements to the end product of a fabricated, packaged, and tested integrated circuit. The basic design methodology is briefly described here, and the various stages are discussed in detail in the following sections using simple examples.

The first step is to determine the system-level specifications such as the overall functionality, size, power, performance, cost, application environment, IC fabrication process, technology, and chip-level and board-level interfaces required. There are several tradeoffs to be considered. The next step is the functional design and description, in which the system is partitioned into functional modules and the functionality of the different modules and their interfaces to each other are considered. The issues to be considered are regularity and modularity of structures, subsystem design, data flow organization, hierarchical design approach, cell types, geometric placements, and communication between the different blocks.

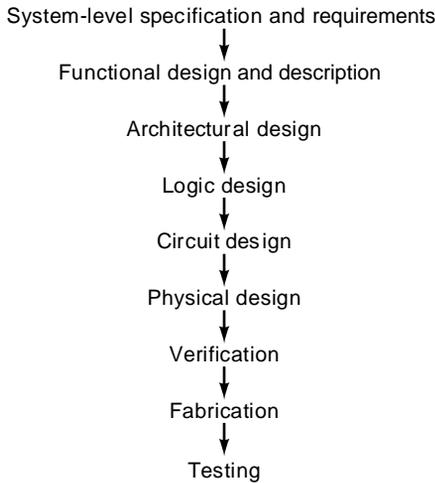

Fig. 114 IC design methodology.

Once the functionality of the various modules is determined, the architectural design of the modules is pursued. Many design alternatives are considered toward optimization. This stage also includes the design of any hardware algorithms to be mapped onto architectures. A behavioral-level description of the architecture is obtained and verified using extensive simulations, often with an iterative process. This stage is critical in obtaining an efficient circuit in the end and for simplifying the steps in some of the following stages. In the logic design stage, the architectural blocks are converted into corresponding gate-level logic designs, Boolean minimization is performed, and logic simulation is used to verify the design at this level. In some design flows the circuit could be synthesized from the logic level by using gate-level libraries (this is referred to as logic synthesis). The logic design usually includes a conventional logic design approach and a nontraditional design, such as precharge logic. At this stage, gate delays are considered and timing diagrams are derived to verify the synchronization of the various logic modules. The next step is the circuit design stage, which essentially involves converting the logic design modules into a circuit representation. At this stage, the essential factors considered are clocking, switching speeds or delays, switching activity and power requirements, and other electrical characteristics (e.g., resistance, capacitance).

The most complex step in VLSI design automation is the physical design, which includes floor planning, partitioning, placement, routing, layout, and compaction. This process converts the given circuit design or description into a physical layout that is a geometric representation of the entire circuit. Each step of the physical design by itself is complex and takes significant amounts of iterations and time. The various types

of transistors, the interconnecting wires, and contacts between different wires and transistors are represented as different geometric patterns consisting of many layers placed according to several design rules that govern a given fabrication technology and process. The floor-planning step involves higher level planning of the various components on the layout. The partitioning step converts the overall circuit into smaller blocks to help the other steps. It is usually impractical to synthesize the entire circuit in one step. Thus, logic partitioning is used to divide the given circuit into a smaller number of blocks, which can be individually synthesized and compacted. This step considers the size of the blocks, the number of blocks, and the interconnections between the blocks and yields a netlist for each block that can be used in the further design steps.

During the next step, which is the placement of the blocks on the chip layout, the various blocks are placed such that the routing can be completed effectively and the blocks use minimum overall area, avoiding any white spaces. The placement task is iterative in that an initial placement is obtained first and evaluated for area minimization and effective routing possibility, and alternate arrangements are investigated until a good placement is obtained. The routing task completes the routing of the various interconnections, as specified by the netlists of the different blocks. The goal is to minimize the routing wire lengths and minimize the overall area needed for routing. The routing areas between the various blocks are referred to as channels or switchboxes. Initially, a global routing is performed in which a channel assignment is determined based on the routing requirements, and then a detailed routing step completes the actual point-to-point routing.

The last step in the physical design is the compaction step, which tries to compact the layout in all directions to minimize the layout area. A compact layout leads to less wire lengths, lower capacitances, and more chip density since the chip area is used effectively. The compaction step is usually an interactive and iterative process in which the user can specify certain parameters and check if the compaction can be achieved. The goal of compaction, in general, is to achieve minimum layout area. The entire physical design process is iterative and is performed several times until an efficient layout for the given circuit is obtained.

Once the layout is obtained, design verification needs to be done to ensure that the layout produced functions correctly and meets the specification and requirements. In this stage, design rule checking is performed on the layout to make sure that the geometric placement and routing rules and the rules regarding the separation of the various layers, the dimensions of the transistors, and the width of the wires are followed correctly. Any design rule violations that occurred during the physical design steps are detected and removed. Then circuit extraction is performed to complete the functional verification of the layout. This step verifies

the correctness of the layout produced by the physical design process. After layout verification the circuit layout is ready to be submitted for fabrication, packaging, and testing. Usually, several dies are produced on a single wafer and the wafer is tested for faulty dies. The correct ones are diced out and packaged in the form of a pin grid array (PGA), dual in-line package (DIP), or any other packaging technology. The packaged chip is tested extensively for functionality, electrical and thermal characteristics, and performance. The process of designing and building an integrated circuit¹⁰⁷ that meets the performance requirements and functions perfectly depends on the efficiency of the design automation tools.

8.4 Circuit Design

To create performance-optimized designs, two areas have to be addressed to achieve a prescribed behavior: (a) circuit or structural design, and (b) layout or physical design. While the layout design is discussed in a later section, this section focuses on the former.

A logic circuit must function correctly and meet the timing requirements. There are several factors that can result in the incorrect functioning of a CMOS logic gate: (a) incorrect or insufficient power supplies, (b) noise on gate inputs, (c) faulty transistors, (d) faulty connections to transistors, (e) incorrect ratios in ratioed logic, and (f) charge sharing or incorrect clocking in dynamic gates. In any design, there are certain paths, called *critical paths*, that require attention to timing details since they determine the overall functional frequency. The critical paths are recognized and analyzed using timing analyzer tools and can be dealt with at four levels:

1. Architecture
2. RTL/logic level
3. Circuit level
4. Layout level

Designing an efficient overall functional architecture helps to achieve good performance. To design an efficient architecture, it is important to understand the characteristics of the algorithm being implemented as the architecture. At the register transfer logic (RTL)/logic level, pipelining, the type of gates, and the fan-in and the fan-out of the gates are to be considered. Fan-in is the number of inputs to a logic gate, and fan-out is the number of gate inputs that the output of a logic gate drives. Logic synthesis tools can be used to achieve the transformation of the RTL level. From the logic level, the circuit level can be designed to optimize a critical speed path. This is achieved by using different styles of CMOS logic, as explained later in this section. Finally, the speed of a set of logic can be affected by rearranging the physical layout. The following techniques can be used for specific design constraints.

The various CMOS logic structures that can be used to implement circuit designs are as follows:

1. *CMOS Complementary Logic.* The CMOS complementary logic gates are designed as ratioless circuits. In these circuits, the output voltage is not a fraction of the V_{dd} (supply), and the gates are sized to meet the required electrical characteristics of the circuits. The gate consists of two blocks, an n block and a p block, that determine the function of the gate. The p block is a dual of the n block. Thus, an n -input gate will consist of $2n$ transistors.
2. *Pseudo-NMOS Logic.* In this logic, the load device is a single p transistor with the gate connected to V_{dd} ^(103,108). This is equivalent to replacing the depletion NMOS load in a conventional NMOS gate by a p device. The design of this style of gate^{109,110} involves ratioed transistor sizes to ensure proper operation and is shown in Fig. 115. The static power dissipation that occurs whenever the pull-down chain is turned on is a major drawback of this logic style.
3. *Dynamic CMOS Logic.* In the dynamic CMOS logic style, an n -transistor logic structure's output node is precharged to V_{dd} by a p transistor and conditionally discharged by an n transistor connected to V_{ss} .¹⁰³ The input capacitance of the gate is the same as the pseudo-NMOS gate. Here, the pull-up time is improved by virtue of the active switch, but the pull-down time is increased due to the ground. The disadvantage of this logic structure is that the inputs can only change during the precharge phase and must be stable during the evaluate portion of the cycle. Figure 116 depicts this logic style.

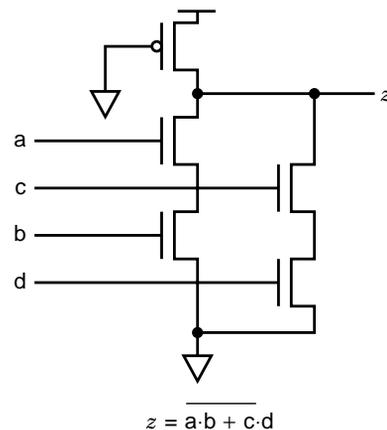

Fig. 115 Pseudo-NMOS logic.

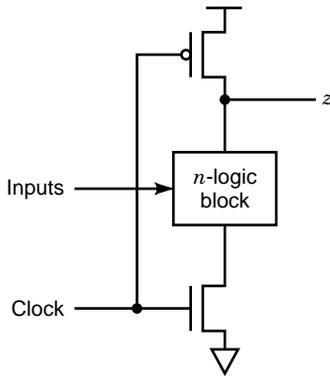

Fig. 116 Dynamic CMOS logic.

4. *Clocked CMOS Logic.* To build CMOS logic gates with low-power dissipation,¹¹¹ this logic structure was proposed. The reduced dynamic power dissipation is realized due to the metal gate CMOS layout considerations. The gates have larger rise and fall times because of the series clocking transistors, but the capacitance is similar to the CMOS complementary gates. This is a recommended strategy for “hot electron” effects because it places an additional n transistor in series with the logic transistors.¹¹²
5. *CMOS Domino Logic.* This is a modification of the clocked CMOS logic, in which a single clock is used to precharge and evaluate a cascaded set of dynamic logic blocks. This involves incorporating a static CMOS inverter into each logic gate,¹¹³ as shown in Fig. 117. During precharge, the output node is charged high and hence the output of the buffer is low. The transistors in the subsequent logic blocks

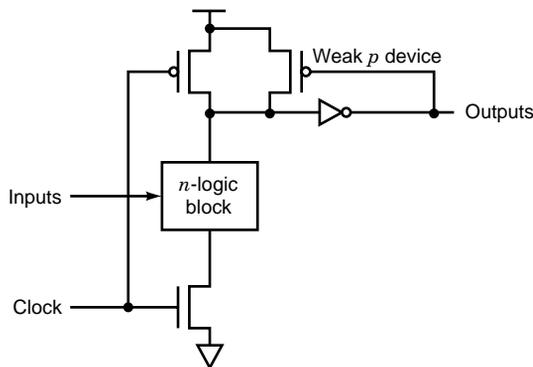

Fig. 117 CMOS domino logic.

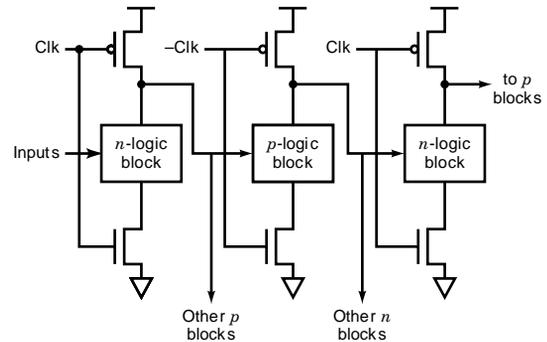

Fig. 118 NP domino logic.

will be turned off since they are fed by the buffer. When the gate is evaluated, the output will conditionally go low (1–0), causing the buffer to conditionally go high (0–1). Hence, in a cascaded set of logic blocks, each state evaluates and causes the next stage to evaluate, provided the entire sequence can be evaluated in one clock cycle. Therefore, a single clock is used to precharge and evaluate all logic gates in a block. The disadvantages of this logic are that (a) every gate needs to be buffered, and (b) only noninverting structures can be used.

6. *NP Domino Logic (Zipper CMOS).* This is a further refinement of the domino CMOS.^{114–116} Here, the domino buffer is removed, and the cascading of logic blocks is achieved by alternately composed p and n blocks, as is shown in Fig. 118. When the clock is low, all the n -block stages are precharged high while all the p -block stages are precharged low. Some of the advantages of the dynamic logic styles include (a) smaller area than fully static gates, (b) smaller parasitic capacitances, and (c) glitch-free operation if designed carefully.
7. *Cascade Voltage Switch Logic (CVSL).* The CVSL is a differential style of logic requiring both true and complement signals to be routed to gates.¹¹⁷ Two complementary NMOS structures are constructed and then connected to a pair of cross-coupled p pull-up transistors. The gates here function similarly to the domino logic, but the advantage of this style is the ability to generate any logic expression involving both inverting and noninverting structures. Figure 119 gives a sketch of the CVSL logic style.
8. *Pass Transistor Logic.* Pass transistor logic is popular in NMOS-rich circuits. Formal methods for deriving pass transistor logic for NMOS are presented in Ref. 118. Here, a set of control signals and a set of pass signals are applied to the gates and sources of the n transistor,

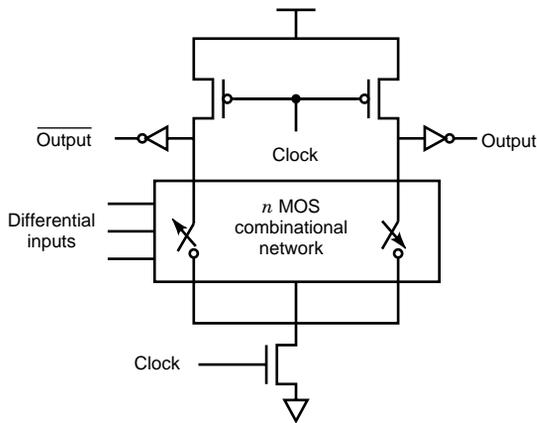

Fig. 119 Cascade voltage switch logic.

correspondingly. From these signals, the truth table for any logic equation can be realized.

9. *Source Follower Pull-Up Logic (SFPL)*. This is similar to the pseudo-NMOS gate except that the pull-up is controlled by the inputs.¹¹⁹ In turn, this leads to the use of smaller pull-down circuits. The SFPL gate style reduces the self-loading of the output and improves the speed of the gate. Therefore, it shows a marked advantage in high fan-in gates.

Using the various design styles, any circuit design can be built in a hierarchical fashion. The basic gates are first built, from which functional blocks like a multiplexer or an adder circuit can be realized. From these basic blocks, more complex circuits can be constructed. Once a design for a specific application has been designed, the functionality of the circuit needs to be verified. Also, other constraints, like the timing and electrical characteristics, have to be studied before the design can be manufactured. The techniques and tools to achieve this are the subject of the next section.

8.5 Simulation

Simulation is required to verify if a design works the way it should. Simulation can be performed at various levels of abstraction. A circuit can be simulated at the logic level, the switch level, or with reference to the timing. Simulation is a critical procedure before committing the design to silicon. The simulators themselves are available in a wide variety of types.¹²⁰

Logic-Level Simulation Logic-level simulation occurs at the highest level of abstraction. It uses primitive models of NOT, OR, AND, NOR, and NAND gates. Virtually all digital logic simulators are event driven (i.e., a component is evaluated based on when an event occurs on its inputs). Logic simulators are

categorized according to the way the delays are modeled in the circuit: (a) unit-delay simulators, in which each component is assumed to have a delay of one time unit, and (b) variable-delay simulators, which allow components to have arbitrary delays. While the former helps in simulating the functionality of the circuit, the latter allows for more accurate modeling of the fast-changing nodes.

The timing is normally specified in terms of an inertial delay and a load-dependent delay, as follows:

$$T_{\text{gate}} = T_{\text{intrinsic}} + C_{\text{load}} \times T_{\text{load}}$$

where T_{gate} = delay of the gate
 $T_{\text{intrinsic}}$ = intrinsic gate delay
 C_{load} = actual load in some units (pF)
 T_{load} = delay per load in some units (ns/pF)

Earlier, logic simulators used preprogrammed models for the gates, which forced the user to describe the system in terms of these models. In modern simulators, programming primitives are provided that allow the user to write models for the components. The two most popular digital simulation systems in use today are VHDL and Verilog.

Circuit-Level Simulation The most detailed and accurate simulation technique is referred to as *circuit analysis*. Circuit analysis simulators operate at the circuit level. Simulation programs typically solve a complex set of matrix equations that relate the circuit voltages, currents, and resistances. They provide accurate results but require long simulation times. If N is the number of nonlinear devices in the circuit, then the simulation time is typically proportional to N^m , where m is between 1 and 2. Simulation programs are useful in verifying small circuits in detail but are unrealistic for verifying complex VLSI designs. They are based on transistor models and hence should not be assumed to predict accurately the performance of designs. The basic sources of error include (a) inaccuracies in the MOS model parameters, (b) an inappropriate MOS model, and (c) inaccuracies in parasitic capacitances and resistances. The circuit analysis programs widely used are the SPICE program, developed at the University of California at Berkeley,¹²¹ and the ASTAP program from IBM.¹²² HSPICE¹²³ is the commercial variant of these programs. The SPICE program provides various levels of modeling. The simple models are optimized for speed, while the complex ones are used to get accurate solutions. As the feature size of the processes is reduced, the models used for the transistors are no longer valid and hence the simulators cannot predict the performance accurately unless new models are used.

Switch-Level Simulation Switch-level simulation is simulation performed at the lowest level of abstraction. These simulators model transistors as switches

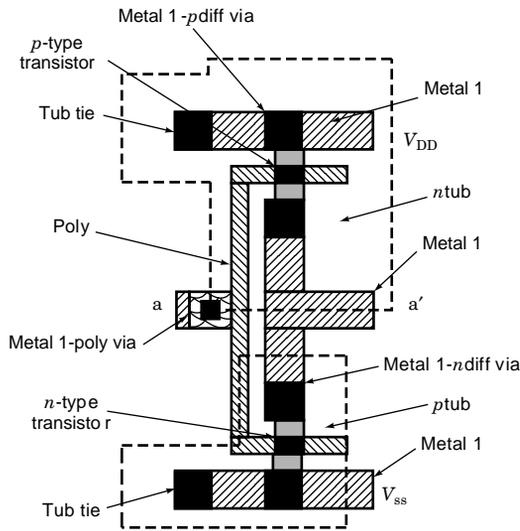

Fig. 121 Transistor layout of inverter.

standardized among many institutions, and have a small number of exceptions for specific processes. Figure 121 gives the layout of the inverter, with the design rules specified.

To design and verify layouts, different CAD tools can be used. The most important of these are the layout editors,¹²⁸ design rule checkers, and circuit extractors. The editor is an interactive graphic program that allows us to create and delete layout elements. Most editors work on hierarchical layouts, but some editors, like Berkeley's

Magic tool,¹²⁹ work on a symbolic layout. The latter include somewhat more detail than the stick diagram but are still more abstract than the pure layout. The design rule checker, or DRC, programs look for design rule violations in the layouts. Magic has an on-line design rule checking. The circuit extractor is an extension of the DRC programs. While the DRC must identify transistors and vias to ensure proper checks, the circuit extractor performs a complete job of component and wire extraction. It produces a netlist, which lists the transistors in the layouts and the electrical nets that connect their terminals.

Physical Design From the circuit design of a certain application and the design rules of a specific process, the physical design problem is to generate a geometric layout of the transistors of the circuit design conforming to the specific design rules. From this layout, photomasks can be generated that will be used in the fabrication process. To achieve this, the different modules of the design need to be placed first and then electrical connections between them realized through the metal layers. For instance, a two-layer

metallization would allow the designer to lay out metal both vertically and horizontally on the floorplan. Whenever the wire changes direction, a via can be used to connect the two metal layers. Due to the complexity of this problem, most authors treat module placement and the routing between modules as two separate problems, although they are related critically. Also, in former days, when designs were less complex, design was done by hand. Now we require sophisticated tools for this process.

Placement. Placement is the task of placing modules adjacent to each other to minimize area or cycle time. The literature consists of a number of different placement algorithms that have been proposed.¹³⁰⁻¹³³ Most algorithms partition the problem into smaller parts and then combine them, or start with a random placement solution and then refine it to reach the optimal. The modules are usually considered as rectangular boxes with specific dimensions. The algorithms then use different approaches to fit these boxes in a minimal area or to optimize them to certain other constraints. For instance, consider a certain number of modules with specific dimensions and a given area in which to fit them. This is similar to the bin-packing algorithm. After the placement step, the different modules are placed in an optimal fashion and the electrical connections between them need to be realized.

Routing. Once the modules have been placed, we need to create space for the electrical connections between them. To keep the area of the floorplan minimal, the first consideration is to determine the shortest path between nodes, although a cost-based approach may also be used. The cost is defined to include an estimate of the congestion, number of available wire tracks in a local area, individual or overall wire length, and so on. Since the problem is a complex one, the strategy is to split the problem into global or loose routing and local or detailed routing. Global routing is a preliminary step, in which each net is assigned to a particular routing area, and the goal is to make 100% assignment of nets to routing regions while minimizing the total wire length. Detailed routing then determines the exact route for each net within the global route. There are a number of approaches to both of these problems.

Global Routing. Global routing¹³⁴ is performed using a wire-length criterion because all timing critical nets must be routed with minimum wire length. The routing area itself can be divided into disjoint rectangular areas, which can be classified by their topology. A two-sided channel is a rectangular routing area with no obstruction inside and with pins on two parallel sides. A switch box is a rectangular routing area with no obstructions and signals entering and leaving through all four sides.¹³⁵ The focus in this problem is only to create space between the modules for all the nets and not to determine the exact route. The algorithms

proceed by routing one net at a time, choosing the shortest possible path. Since there is a lot of dependency among the nets, different heuristics are used to generate the least possible routing space in which to route the nets. Once space is created for all the nets, the exact route of each net can be determined.

Detailed Routing. Detailed routing is usually done by either a maze-search or a line-search algorithm. The maze-running algorithm^{136,137} proposed by Lee–Moore finds the shortest path between any two points. For this, the layout is divided into a grid of nodes, in which each node is weighted by its distance from the source of the wire to be routed. The route that requires the smallest number of squares is then chosen. If a solution exists, this algorithm will find it, but an excessive amount of memory is required to achieve this. In the linesearch algorithm, vertical and horizontal lines are drawn from the source and the target, followed by horizontal or vertical lines that intersect the original lines. This is repeated until the source and target meet. There are also a number of other heuristic algorithms that exploit different characteristics of the design to generate optimal routing solutions. Genetic algorithms and simulated annealing approaches to this problem have gained importance in recent years.

An introduction to the various algorithms that have been proposed for layouts can be found in Ref. 138. Once the layout has been determined and the photomasks made, the circuit can go to the fabrication plant for processing.

8.7 Fabrication

The section describes the approach used in building integrated circuits on monolithic pieces of silicon. The process involves the fabrication of successive layers of insulating, conducting, and semiconducting materials, which have to be patterned to perform specific functions. The fabrication therefore must be executed in a specific sequence, which constitutes an IC process flow. The manufacturing process itself is a complex interrelationship of chemistry, physics, material science, thermodynamics, and statistics.

Semiconducting materials, as the name suggests, are neither good conductors nor good insulators. While there are many semiconducting elements, silicon is primarily chosen for manufacturing ICs because it exhibits few useful properties. Silicon devices can be built with a maximum operating temperature of about 150°C due to the smaller leakage currents as a result of the large bandgap of silicon (1.1 eV). IC planar processing requires the capability to fabricate a passivation layer on the semiconductor surface. The oxide of silicon, SiO₂, which could act as such a layer, is easy to form and is chemically stable. The controlled addition of specific impurities makes it possible to alter the characteristics of silicon. For these reasons, silicon is almost exclusively used for fabricating microelectronic components.

Silicon Material Technology Beach sand is first refined to obtain semiconductor-grade silicon. This is then reduced to obtain electronic-grade polysilicon in the form of long, slender rods. Single-crystal silicon is grown from this by the Czochralski (CZ) or float-zone (FZ) methods. In CZ growth, single-crystal ingots are pulled from molten silicon contained in a crucible. For VLSI applications, CZ silicon is preferred because it can better withstand thermal stresses¹³⁹ and offers an internal gettering mechanism that can remove unwanted impurities from the device structures on wafer surfaces.¹⁴⁰ FZ crystals are grown without any contact to a container or crucible and hence can attain higher purity and resistivity than CZ silicon. Most high-voltage, high-power devices are fabricated on FZ silicon. The single-crystal ingot is then subjected to a complex sequence of shaping and polishing, known as wafering, to produce starting material suitable for fabricating semiconductor devices. This involves the following steps:

1. The single-crystal ingot undergoes routine evaluation of resistivity, impurity content, crystal perfection size, and weight.
2. Since ingots are not perfectly round, they are shaped to the desired form and dimension.
3. The ingots are then sawed to produce silicon slices. The operation defines the surface orientation, thickness, taper, and bow of the slice.
4. To bring all the slices to within the specific thickness tolerance, lapping and grinding steps are employed.
5. The edges of the slices are then rounded to reduce substantially the incidence of chipping during normal wafer handling.
6. A chemical-mechanical polishing¹⁴¹ step is then used to produce the highly reflective and scratch- and damage-free surface on one side of the wafer.
7. Most VLSI process technologies also require an epitaxial layer, which is grown by a chemical vapor deposition process.

The most obvious trend in silicon material technology is the increasing size of the silicon wafers. The use of these larger-diameter wafers presents major challenges to semiconductor manufacturers. Several procedures have been investigated to increase axial impurity uniformity. These include the use of double crucibles, continuous liquid feed (CLF) systems,¹⁴² magnetic Czochralski growth (MCZ),^{142,143} and controlled evaporation from the melt.

Epitaxial Layer The epitaxial growth process is a means of depositing a single-crystal film with the same crystal orientation as the underlying substrate. This can be achieved from the vapor phase, liquid phase, or solid phase. Vapor-phase epitaxy has the

widest acceptance in silicon processing, since excellent control of the impurity concentration and crystalline perfection can be achieved. Epitaxial processes are used for the fabrication of advanced CMOS VLSI circuits because epitaxial processes minimize latch-up effects. Also in the epitaxial layer, doping concentration can be accurately controlled, and the layer can be made oxygen and carbon free. Epitaxial deposition is a chemical vapor deposition process.¹⁴⁴ The four major chemical sources of silicon used commercially for this deposition are (a) silicon tetrachloride (SiCl_4), (b) trichlorosilane (SiHCl_3), (c) dichlorosilane (SiH_2Cl_2), and (d) silane (SiH_4). Depending on particular deposition conditions and film requirements, one of these sources can be used.

Doping Silicon The active circuit elements of the IC are formed within the silicon substrate. To construct these elements, we need to create localized *n*-type and *p*-type regions by adding the appropriate dopant atoms. The process of introducing controlled amounts of impurities into the lattice of the monocrystalline silicon is known as *doping*. Dopants can be introduced selectively into the silicon using two techniques: diffusion and ion implantation.

Diffusion. The process by which a species moves as a result of the presence of a chemical gradient is referred to as diffusion. Diffusion is a time- and temperature-dependent process. To achieve maximum control, most diffusions are performed in two steps. The first step is predeposition,¹⁴⁵ which takes place at a furnace temperature and controls the amount of impurity that is introduced. The second step, the drive-in step,¹⁴⁵ controls the desired depth of diffusion.

Predeposition. In predeposition, the impurity atoms are made available at the surface of the wafer. The atoms of the desired element in the form of a solution of controlled viscosity can be spun on the wafer, in the same manner as the photoresist. For these spin-on dopants, the viscosity and the spin rate are used to control the desired dopant film thickness. The wafer is then subjected to a selected high temperature to complete the predeposition diffusion. The impurity atoms can also be made available by employing a low-temperature chemical vapor deposition process in which the dopant is introduced as a gaseous compound—usually in the presence of nitrogen as a diluent. The oxygen concentration must be carefully controlled in this operation to prevent oxidation of the silicon surface of the wafer.

Drive-In. After predeposition the dopant wafer is subjected to an elevated temperature. During this step, the atoms further diffuse into the silicon crystal lattice. The rate of diffusion is controlled by the temperature employed. The concentration of the dopant atoms is maximum at the wafer surface and reduces as the silicon substrate is penetrated further. As the atoms migrate

during the diffusion, this concentration changes. Hence a specific dopant profile can be achieved by controlling the diffusion process. The dopant drive-in is usually performed in an oxidizing temperature to grow a protective layer of SiO_2 over the newly diffused area.

Ion Implantation. Ion implantation is a process in which energetic, charged atoms or molecules are directly introduced into the substrate. Ion implantation^{146,147} is superior to the chemical doping methods discussed previously. The most important advantage of this process is its ability to control more precisely the number of implanted dopant atoms into substrates. Using this method, the lateral diffusion is reduced considerably compared to the chemical doping methods. Ion implantation is a low-temperature process, and the parameters that control the ion implantation are amenable to automatic control. After this process the wafer is subjected to annealing to activate the dopant electrically. There are some limitations to this process. Since the wafer is bombarded with dopant atoms, the material structure of the target is damaged. The throughput is typically lower than diffusion doping process. Additionally, the equipment used causes safety hazards to operating personnel.

Photolithography Photolithography is the most critical step in the fabrication sequence. It determines the minimum feature size that can be realized on silicon and is a photoengraving process that accurately transfers the circuit patterns to the wafer. Lithography^{148,149} involves the patterning of metals, dielectrics, and semiconductors. The photoresist material is first spin coated on the wafer substrate. It performs two important functions: (a) precise pattern formation and (b) protection of the substrate during etch. The most important property of the photoresist is that its solubility in certain solvents is greatly affected by exposure to ultraviolet radiation. The resist layer is then exposed to ultraviolet light. Patterns can be transferred to the wafer using either positive or negative masking techniques. The required pattern is formed when the wafer undergoes the development step. After development, the undesired material is removed by wet or dry etching.

Resolution of the lithography process is important to this process step. It specifies the ability to print minimum size images consistently under conditions of reasonable manufacturing variation. Therefore, lithographic processes with submicron resolution must be available to build devices with submicron features. The resolution is limited by a number of factors, including (a) hardware, (b) optical properties of the resist material, and (c) process characteristics.¹⁵⁰

Most IC processes require 5–10 patterns. Each one of them needs to be aligned precisely with those already on the wafer. Typically, the alignment distance between two patterns is less than $0.2\ \mu\text{m}$ across the entire area of the wafer. The initial alignment is made with respect to the crystal lattice structure of the

wafer, and subsequent patterns are aligned with the existing ones. Earlier, mask alignment was done using *contact printing*,^{151,152} in which the mask is held just off the wafer and visually aligned. The mask is then pressed into contact with the wafer and impinged with ultraviolet light. There is a variation of this technique called *proximity printing*, in which the mask is held slightly above the wafer during exposure. Hard contact printing was preferred because it reduced the diffraction of light, but it led to a number of yield and production problems. So the projection alignment and exposure system was developed, in which the mask and wafer never touch and an optical system projects and aligns the mask onto the wafer. Since there is no damage to the mask or photoresist, the mask life is virtually unlimited. VLSI devices use projection alignment as the standard production method.

Junction Isolation When fabricating silicon ICs, it must be possible to isolate the devices from one another. These devices can then be connected through specific electrical paths to obtain the desired circuit configuration. From this perspective, the isolation technology is one of the critical aspects of IC fabrication. For different IC types, like NMOS, CMOS, and bipolar, a variety of techniques have been developed for device isolation. The most important technique developed was termed LOCOS, for LOCAL Oxidation of Silicon. This involves the formation of semirecessed oxide in the nonactive or field areas of the substrate. With the advent of submicron-size device geometries, alternative approaches for isolation were needed. Modified LOCOS processes, trench isolation, and selective epitaxial isolation were among the newer approaches adopted.

LOCOS. To isolate MOS transistors, it is necessary to prevent the formation of channels in the field regions. This implies that a large value of V_T is required in the field region, in practice about 3–4 V above the supply voltage. Two ways to increase the field voltage are to increase the field oxide thickness and raise the doping beneath the field oxide. Thicker field oxide regions cause high enough threshold voltages but unfortunately lead to step coverage problems, and hence thinner field oxide regions are preferred. Therefore, the doping under the field oxide region is increased to realize higher threshold voltages. Nevertheless, the field oxide is made 7–10 times thicker than the gate oxide. Following this, in the channel-stop implant step, ion implantation is used to increase the doping under the field oxide. Until about 1970, the thick field oxide was grown using the *grow-oxide-and-etch* approach in which the oxide is grown over the entire wafer and then etched over the active regions. Two disadvantages of this approach prevented it from being used for VLSI applications: (a) Field-oxide steps have sharp upper corners, which poses a problem to the subsequent metallization steps; and (b) channel-stop implant must be performed before

the oxide is grown. In another approach, the oxide is selectively grown over the desired field regions. This process was introduced by Appels and Kooi in 1970¹⁵³ and is widely used in the industry. This process is performed by preventing the oxidation of the active regions by covering them with a thin layer of silicon nitride. After etching the silicon nitride layer, the channel-stop dopant can be implanted selectively. The process has a number of limitations for submicron devices. The most important of these is the formation of the “bird’s beak,” which is a lateral extension of the field oxide into the active areas of the device. The LOCOS bird’s beak creates other problems as junctions become shallower in CMOS ICs. The LOCOS process was therefore modified in several ways to overcome these limitations: (a) etched-back LOCOS, (b) polybuffered LOCOS, and (c) sealed-interface local oxidation (SILO).¹⁵⁴

Non-LOCOS Isolation Technologies. There have been non-LOCOS isolation technologies for VLSI and ultra-large-scale integration (ULSI) applications. The most prominent of these is *trench* isolation technology. Trench technologies are classified into three categories: (a) shallow trenches (<1 μm), (b) moderate depth trenches (1–3 μm), and (c) deep, narrow trenches (>3 μm deep, <2 μm wide). Shallow trenches are used primarily for isolated devices of the same type and hence are considered a replacement to LOCOS. The buried oxide (BOX)¹⁵⁵ isolation technology uses shallow trenches refilled with a silicon dioxide layer, which is etched back to yield a planar surface. This technique eliminates the bird’s beak of LOCOS. The basic BOX technique has certain drawbacks for which the technique is modified

Metallization This subsection describes the contact technology to realize the connections between devices and how the different metal layers are connected to realize the circuit structure.

Contact Technology. Isolated active-device regions in the single-crystal substrate are connected through high-conductivity, thin-film structures that are fabricated over the silicon dioxide that covers the surface. An opening in the SiO_2 must be provided to allow *contacts* between the conductor film and the Si substrate. The technology involved in etching these contacts is referred to as contact technology. These contacts affect the circuit behavior because of the parasitic resistances that exist in the path between the metal-to-Si substrate and the region where the actual transistor action begins. Conventional contact fabrication involves the fabrication of a contact to silicon at locations where the silicon dioxide has been etched to form a window. It involves the following steps:

1. In regions where contacts are to be made, the silicon substrate is heavily doped.

2. A window or *contact hole* is etched in the oxide that passivates the silicon surface.
3. The silicon surface is cleaned to remove the thin native-oxide layer that is formed rapidly when the surface is exposed to an oxygen-containing ambient.
4. The metal film is deposited on the wafer and makes contact with silicon wherever contact holes were created. Aluminum is the most commonly used metal film
5. After depositing the metal, the contact structure is subjected to a thermal cycle known as *sintering* or *annealing*. This helps in bringing the Si and metal into intimate contact.

Aluminum is desired as an interconnect material because its resistivity, $2.7 \mu\Omega\text{-cm}$, is very low, and it offers excellent compatibility with SiO_2 . Al reacts with SiO_2 to form Al_2O_3 , through which the Al can diffuse to reach the Si, forming an intimate Al–Si contact. But using pure Al has certain disadvantages. Since Al is polycrystalline in nature, its grain boundaries offer very fast diffusion paths for the Si at temperatures above 400°C . Hence, if a large volume of Al is available, a significant quantity of the Si can diffuse into Al. As a result, the Al from the film moves rapidly to fill in the voids created by the migrating Si, which leads to large leakage currents or electrically shorting the circuit. This effect is referred to as *junction spiking*.¹⁵⁶ To prevent junction spiking, different techniques are used:

1. Add approximately 1% of Si to Al.
2. Add a diffusion barrier to prevent Si from diffusing into Al.
3. Decrease sintering temperature, but this increases contact resistance.
4. Add a “barrier” metal to the contact hole.¹⁵⁷

Of these techniques, the most commonly used is the barrier metal. The idea is to block or hinder Al from intermixing with Si. There are three main types of contact barrier metallurgies: (a) sacrificial barrier, (b) passive barrier, and (c) stuffed barrier.

The use of Al has its own problems, the most important being its high resistivity and electromigration. There is also the problem with “hillock” formation. Hillocks are formed due to the thermal expansion mismatch among Al, SiO_2 , and Si. As the wafer is cooled, thermal expansion mismatch forms stresses (usually compressive), which forms these hillocks. Therefore, copper metallization has been gaining importance. Copper is preferred over Al because it has a low resistivity ($1.2 \mu\Omega\text{-cm}$) and is resistant to electromigration. In fact, copper is added in small quantities to Al to reduce the electromigration problem of Al. However, there are some real problems with copper that need to be addressed before it can replace Al:

1. Cu is a terrible contaminant in Si. It has a very high diffusivity in Si and causes junction leakage, which degrades the gate oxide integrity (GOI).
2. Cu diffuses and drifts easily through SiO_2 . Hence, Cu needs to be encapsulated for use in metallization.
3. Cu oxidizes to CuO easily.
4. The etch chemistry for Cu is highly contaminated, and the wafers need to be held at higher temperatures.

Typical process steps involved in the fabrication of a $0.8\text{-}\mu\text{m}$ LOCOS *n*-well inverter are as follows:

1. Wafer: 1×10^{15} to 1×10^{16} CZ(*p*) with $\langle 100 \rangle$ crystal orientation. Epitaxial layer required because of latch-up. The thickness is $2\text{--}16 \mu\text{m}$ with 5×10^{15}
2. Grown screen oxide layer, with the thickness in the range $400\text{--}1000$.
3. Expose the *n*-well photo on the wafer.
4. An *n*-well ion implant. Use $1 \times 10^{13}/\text{cm}^2$ phosphorus. The voltage used is 60 keV to 2 MeV .
5. An *n*-well drive-in. This step is carried out at 1050 to 1100°C for $2\text{--}6 \text{ h}$. This activates the dopant atoms. The drive-in depth is around $1\text{--}10 \mu\text{m}$.
6. Perform LOCOS process.
 - 6.1. Strip wafer.
 - 6.2. Pad oxide. Thickness is $100\text{--}400$.
 - 6.3. Pad nitride. Thickness is $1000\text{--}2000$. Low-pressure chemical vapor deposition (LPCVD) silicon nitride is used.
 - 6.4. Expose the diffusion photo on the wafer.
 - 6.5. Etch the nitride layer.
 - 6.6. Expose the block field (BF) photo. This is the inverse of the *n*-well photo and prevents the formation of the parasitic transistors between adjacent transistors.
 - 6.7. Field ion implantation. $1 \times 10^{13}/\text{cm}^2$ boron at 60 keV .
 - 6.8. Strip the BF and the resist layer.
 - 6.9. Grow the field oxide. The thickness is about $4000\text{--}6000$ of SiO_2 . The process used is a pyro process at $900\text{--}1050^\circ\text{C}$ for $3\text{--}6 \text{ h}$.
 - 6.10. Strip the pad nitride layer by dipping the wafer in H_3PO_4 .
 - 6.11. Strip the pad oxide layer by dipping the wafer in $50:1 \text{ HF}$.
7. Grow a sacrificial oxide layer and strip it. The thickness is about $600\text{--}1000$. The sacrificial oxide layer eats into the bare silicon, thus exposing fresh silicon area on which the device can be grown.

8. Grow a sacrificial gate oxide layer. Here the thickness is about 80–130. This layer protects the gate when the V_T implant is done.
9. V_T implant. Two masks, one for the n region and one for the p region, are used. The concentration is 1×10^{11} to $1 \times 10^{12}/\text{cm}^2$ at 5–30 keV.
10. Strip the sacrificial gate oxide layer using a 50:1 HF solution.
11. Grow the gate oxide layer. Typical thickness is 80–130. The gate oxide layer is grown at 800–900°C for 20 min.
12. Polysilicon is deposited all over the wafer. LPCVD silane is used at 620°C for a blanket deposition. The typical thickness is 2500–4000.
13. Polysilicon doping is done by ion implantation using 5×10^{15} phosphorus.
14. The polysilicon etch is a very critical photo/etch process.
 - 14.1. Polysilicon photo is exposed on the wafer.
 - 14.2. Reactive ion etch (RIE) is used to etch the polysilicon.
 - 14.3. The resist is stripped.
15. Diffusion processing
 - 15.1. Mask the p^+ regions.
 - 15.2. Perform n^+ source/drain ion implantation using $5 \times 10^{15}/\text{cm}^2 \text{As}^{75}$ at 40 keV. Arsenic is used because it is slow and does not diffuse deep into the silicon substrate.
 - 15.3. Perform n^+ anneal at 900°C for 15 min to activate the dopant.
 - 15.4. Strip the resist.
 - 15.5. Mask the n^+ regions.
 - 15.6. Perform p^+ source/drain ion implantation using $1 \times 10^{15}/\text{cm}^2 \text{BF}_2/\text{B}^{11}$ at 5–20 keV.
 - 15.7. Source/drain anneal at 900°C for 30 min in an oxidizing atmosphere. This is a rapid thermal process.
 - 15.8. Strip the resist off.
16. Interlevel dielectric. Boro-phospho silicon glass (BPSG) is used because it flows well. Typical thickness is 5000–8000. A 900°C reflow anneal is also performed.
17. The contact photo is exposed on the wafer. This is critical to the layout density.
18. The contacts are etched using RIE.
19. After etching, the contact resist is stripped off.
20. Metallization. Ti barrier metallurgy is used. The actual contact is made with an alloy of Al/Cu/Si with percentages 98, 1, and 1%, respectively. The Al alloy is sputtered onto the wafer. The typical thickness is about $1.2\mu\text{m}$.

21. The metal-1 layer photo is exposed.
22. Metal-1 etch.
23. Strip resist.
24. Foaming gas anneal is performed to improve the mobility of the electrons and relieve stress on the wafer.

The inverter is finally fabricated. Figure 109 describes the process cross section of this inverter after the various steps have been performed.

8.8 Testing

Testing is a critical factor in the design of circuits. The purpose of testing is to verify conformance to the product definition. To understand the complexity of this problem, consider a combinational circuit with n inputs. A sequence of 2^n inputs must be applied and observed to test the circuit exhaustively. Since the number of inputs are high for VLSI circuits, testing the chip exhaustively is impossible. Hence, this becomes an area of importance to circuit design. There are three main areas that need to be addressed to solve this problem:

1. Test generation
2. Test verification
3. Design for testability

Test generation corresponds to the problem of generating a minimum number of tests to verify the behavior of a circuit. The problem of test verification which is commonly gauged by performing fault simulations, involves evaluating measures of the effectiveness of a given set of test vectors. Circuits can also be designed for testability.

Test Generation Test generation¹⁵⁸ involves the search for a sequence of input vectors that allow faults to be detected at the primary device outputs. VLSI circuits are typically characterized by buried flip-flop asynchronous circuits, indeterminate states, complex clock conditions, multiple switching of inputs simultaneously, and nonfunctional inputs. Due to these factors, an intimate knowledge of the internal circuit details is essential to develop efficient test strategies. The goal of a test generation strategy^{159,160} is multifold: (a) chip design verification in conjunction with the designer, (b) incorporation of the customer's specifications and patterns into the manufacturing test program, and (c) fault detection by fault simulation methods.

Test Verification Test verification¹⁶¹ involves calculating measures for how efficient the test vectors for a given circuit are. This is often accomplished by using fault models.¹⁶² Fault simulation requires a good circuit simulator to be efficient and is hence closely related to logic simulation and timing analysis. While

the logic simulator verify the functionality of a design and ensures that the timing constraints are met, the fault simulator tells the designer if enough analysis has been performed to justify committing the design to silicon. In fault simulation, the true value of a circuit and its behavior under possible faults is simulated. The fault model is a hypothesis based on an abstract model of the circuit, conformed to some precise real physical defects. To begin with, the simulator generates a fault list that identifies all the faults to be modeled. Then a set of test vectors is simulated against the fault-free and faulty models. Those faults that cause an erroneous signal at an output pin are considered as detected faults. Now the fault coverage of the test vector set can be computed as the number of faults detected over the total number of faults modeled.

The most widely used fault model is the single stuck-at fault model. This model assumes that all faults occur due to the shorting of a signal node with the power rail. A number of faults can be detected by this model, but a major disadvantage of this model is its assumption that all faults appear as stuck-at faults. The limitations of this model have led to the increased use of other models, like the stuck-open¹⁶³ and bridging fault models.¹⁶⁴ The former can occur in a CMOS transistor or at the connection to a transistor. The bridging faults are short circuits that occur between signal lines. These represent a frequent source of failure in CMOS ICs. A majority of the random defects are manifested as timing delay faults in static CMOS ICs. These are faults in which the increased propagation delay causes gates to exceed their rated specifications. The statically designed circuits have a transient power supply that peaks when the gates are switching and then settles to a low current value in the quiescent state. The quiescent power supply current,¹⁶⁵ known as I_{DDQ} , can be used as an effective test to detect leakage paths due to defects in the processing. The measured I_{DDQ} of a defect-free CMOS IC is approximately 20 nA. Most physical defects will elevate I_{DDQ} by one to five orders of magnitude. Thus the I_{DDQ} testing approach can be used to detect shorts not detectable by the single stuck-at fault model.

There are several other ways of applying logic and fault simulation to testing:

1. **Toggle Testing.** This is the cheapest, simplest, and least time-consuming method of applying simulation to testing. Toggle testing provides a testability measure by tracking the activity of circuit nodes. From a set of vectors, the method identifies those parts of the network that exhibit no activity. Since the test vectors do not affect these nodes, faults occurring here cannot be detected by the fault simulator.
2. **Fault Simulation of Functional Tests.** The outputs of the functional simulator can be used in the design process as an effective design analysis tool. The lists of detectable and undetectable faults generated by the simulator can be used to

locate problems in the design and correct them. This results in substantial savings in development and manufacturing.

3. **Fault Simulation after New Test Vector Generation.** High-quality testing in a reasonable time frame would require an efficient test pattern generation system and a fault simulator. Test vectors are first generated to detect specific faults, and the fault simulator determines the quality of the vector set. In this scenario, it becomes important to fault simulate after every new test vector is generated in order to catch multiple faults. Accelerated fault simulation is faster than test pattern generation.

Design for Testability *Design for testability* commonly refers to those design techniques that produce designs for which tests can be generated by known methods. The advantage of these techniques are (a) reduced test generation cost, (b) reduced testing cost, (c) high-quality product, and (d) effective use of computer-aided design tools. The key to designing circuits that are testable are two concepts, *controllability* and *observability*. Controllability is defined as the ability to set and reset every node that is internal to the circuit. Observability is defined as the ability to observe either directly or indirectly the state of any node in the circuit. There are programs like SCOAP¹⁶⁶ that, given a circuit structure, can calculate the ability to control or observe internal circuit nodes. The concepts involved in design for testability can be categorized as follows: (a) ad hoc testing, (b) scan-based test techniques, and (c) built-in self-test (BIST).

Ad Hoc Testing. Ad hoc testing comprises techniques that reduce the combinational explosion of testing. Common techniques partition the circuit structure and add test points. A long counter is an example of a circuit that can be partitioned and tested with fewer test vectors. Another technique is the use of a bus in a bus-oriented system for testing. The common approaches can be classified as (a) partitioning techniques, (b) adding test points, (c) using multiplexers, and (d) providing for easy state reset.

Scan-Based Test Techniques. Scan-based approaches stem from the basic tenets of controllability and observability. The most popular approach is the level-sensitive scan design, or LSSD, approach, introduced by IBM.¹⁶⁷ This technique is illustrated in Fig. 122. Circuits designed based on this approach operate in two modes—namely normal mode and test mode. In the normal mode of operation, the shift register latches act as regular storage latches. In the test mode, these latches are connected sequentially and data can be shifted in or out of the circuit. Thus, a known sequence of data (controllability) can be input to the circuit and the results can be shifted out of the circuit using the registers (observability). The primary disadvantage of this approach is the increased

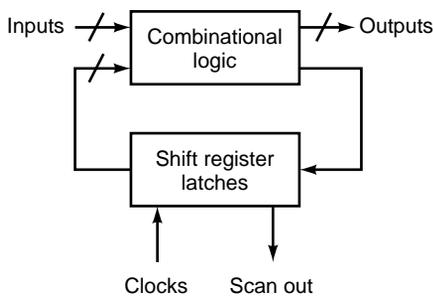

Fig. 122 Level-sensitive scan design.

complexity of the circuit design and the increased external pin count. The serial scan approach is similar to the LSSD, but the design of the shift register latch is simplified to obtain faster circuits. For most circuit designs, only the input and output register need be made scannable. This technique makes the designer responsible for deciding which registers need to be scanned and is called the partial serial scan technique.¹⁶⁸ The parallel scan¹⁶⁹ approach is an extension of the serial scan in which the registers are arranged in a sort of a grid, where on a particular column all the registers have a common read/write signal. The registers that fall on a particular row have common data lines. Therefore, the output of a register can be observed by enabling the corresponding column and providing the appropriate address. Data can also be written into these registers in a similar fashion.

Built-In Self-Test. Signature analysis¹⁷⁰ or cyclic redundancy checking can be used to incorporate a built-in self-test module in a circuit. This involves the use of a linear feedback shift register, as depicted in Fig. 123. The value in the register will be a function of the value and number of latch inputs and the counting function of the signature analyzer. The good part of the circuit will have a particular number or signature in the register, while the faulty portion will have a different number. The signature analysis approach can be merged with the level-sensitive scan design approach to create a structure called a built-in logic block observation, or BILBO.¹⁷¹ Yet another approach

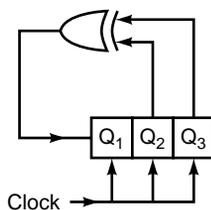

Fig. 123 Linear feedback shift register.

to built-in test is called a design for autonomous test, in which the circuit is partitioned into smaller structures that are tested exhaustively. The partitioning method involves the use of multiplexers. The syndrome testing method, in which all possible inputs are applied and the number of 1's at the outputs is counted, is also a test method that requires exhaustive testing. The resultant value is compared to that of a known good machine.

Other Tests So far we have discussed techniques for testing logic structures and gates. But we need testing approaches at the chip level and the system level also. Most approaches for testing chips rely on the aforementioned techniques. Memories, for instance, can use the built-in self-test techniques effectively. Random logic is usually tested by full serial scan or parallel scan methods. At the system level, traditionally the "bed-of-nails" testers have been used to probe points of interest. But with the increasing complexity of designs, system designers require a standard to test chips at the board level. This standard is the IEEE 1149 boundary scan¹⁷² architecture. ICs that are designed based on this standard enable complete testing of the board. The following types of tests can be performed in a unified framework: (a) connectivity test between components, (b) sampling and setting chip I/Os, and (c) distribution and collection of built-in self-test results.

9 MICROPROCESSORS

Robert P. Colwell

In 1972, Intel Corporation sparked an industrial revolution with the world's first microprocessor, the 4004. The 4004 replaced the logic of a numeric calculator with a general-purpose computer, implemented in a single silicon chip. The 4004 is shown in Fig. 124. The 4004 integrated 2300 transistors and ran at a clock rate of 108 kHz (108,000 clock cycles per second). In 1997, Intel introduced the Pentium II processor, running at 300 MHz (300 million clock cycles per second) and incorporating nearly 8 million transistors. The Pentium II processor is shown in Fig. 125. In 2000, Intel introduced the Pentium 4.

From the 4004's humble beginning, the microprocessor has assumed an importance in the world's economy similar to that of the electric motor or the internal combustion engine. Microprocessors now supply more than 90% of the world's computing needs, from small portable and personal desktop computers to large-scale supercomputers such as Intel's Teraflo machine, which contains over 9000 microprocessors. A variant of the microprocessor, the microcontroller, has become the universal controller in machines from automobile engines to audio systems to wristwatches.

9.1 Microprocessors and Computers

Microprocessors are the processing units or the "brains" of the computer system. Every action that microprocessors perform is specified by a computer program that

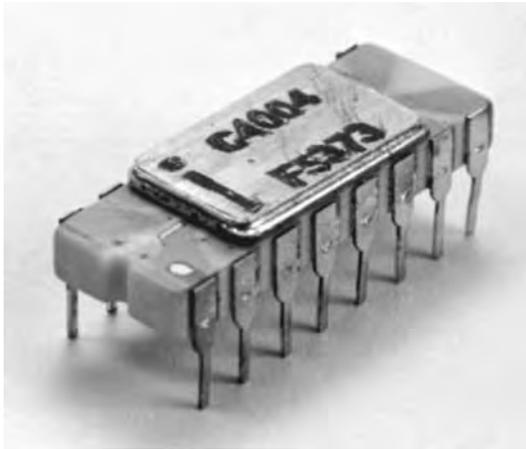

Fig. 124 World's first microprocessor, the Intel 4004, ca. 1971. Originally designed to be a less expensive way to implement the digital logic of a calculator, the chip instead spawned a computing revolution that still shows no signs of abating.

has been encoded into “object code” by a software program known as a compiler. Directed by another software program known as the operating system (e.g., Microsoft's Windows), the microprocessor locates the desired application code on the hard drive or compact disk and orders the drive to begin transferring the program to the memory subsystem so that the program can be run.

Digital electronic computers have at least three major subsystems:

- A memory to hold the programs and data structures
- An I/O subsystem
- A central processor unit (CPU)

A microprocessor is the central processor subsystem, implemented on a single chip of silicon.

In microprocessor-based computer systems, the I/O subsystem moves information into and out of the computer system. I/O subsystems usually include some form of nonvolatile storage, which is a means of remembering data and programs even when electrical

Fig. 125 The 1998 successors to the line of microprocessors started by the 4004, Intel's Pentium II processor, mounted within its Single-Edge Cartridge Connector (SECC). This picture shows the cartridge with its black case removed. On the substrate within the cartridge, the large octagonal package in the center is the Pentium II CPU itself. The rectangular packages to the right and left of the CPU are the cache chips. The small components mounted on the substrate are resistors and capacitors needed for power filtering and bus termination.

power is not present. Disk drives, floppy drives, and certain types of memory chips fulfil this requirement in microprocessor-based systems. Keyboards, trackballs, and mice are common input devices. Networks, modems, and compact discs are also examples of I/O devices. The memory subsystem, a place to keep and quickly access programs or data, is usually random-access memory (RAM) chips.

Microprocessors and microcontrollers are closely related devices. The differences are in how they are used. Essentially, microcontrollers are microprocessors for embedded control applications. They run programs that are permanently encoded into read-only memories and optimized for low cost so that they can be used in inexpensive appliances (printers, televisions, power tools, and so on). The versatility of a microcontroller is responsible for user-programmable VCRs and microwave ovens, the fuel-savings of an efficient managed automobile engine, and the convenience of sequenced traffic lights on a highway and of automated bank teller machines.

Microprocessor software is typically created by humans who write their codes in a high-level language such as C or Fortran. A compiler converts that source code into a machine language that is unique to each particular family of microprocessors. For instance, if the program needs to write a character to the screen, it will include an instruction to the microprocessor that specifies the character, when to write it, and where to put it. Exactly how these instructions are encoded into the 1's and 0's (bits) that a computer system can use determines which computers will be able to run the program successfully. In effect, there is a contract between the design of a microprocessor and the compiler that is generating object code for it. The compiler and microprocessor must agree on what every computer instruction does, under all circumstances of execution, if a program is to perform its intended function. This contract is known as the computer's instruction set. The instruction set plus some additional details of implementation such as the number of registers (fast temporary storage) are known as the computer's instruction set architecture (ISA). Programs written or compiled to one ISA will not run on a different ISA. During the 1960s and 1970s, IBM's System/360 and System/370 were the most important ISAs. With the ascendancy of the microprocessor, Intel's x86 ISA vied with Motorola's MC68000 for control of the personal computer market. By 1997, the Intel architecture was found in approximately 85% of all computer systems sold.

Early microprocessor instruction set architectures, such as the 4004, were designed to operate on 8-bit data values (operands). Later microprocessors migrated to 16-bit operands, including the microprocessor in the original IBM PC (the Intel 8088). Microprocessors settled on 32-bit operands in the 1980s, with the Motorola 68000 family and Intel's 80386. In the late 1980s, the microprocessors being used in the fastest servers and high-end workstations began to run into the intrinsic

addressability limit of 4 GB (four gigabytes, or four billion bytes, which is 2 raised to the power 32). These microprocessors introduced 64-bit addressing and data widths. It is likely that 64-bit computing will eventually supplant 32-bit microprocessors. It also seems likely that this will be the last increase in addressability that the computing industry will ever need because 2 raised to the power 64 is an enormous number of addresses.

Prior to the availability of microprocessors, computer systems were implemented in discrete logic, which required the assembly of large numbers of fairly simple digital electronic integrated circuits to realize the basic functions of the I/O, memory, and central processor subsystems. Because many (typically thousands) of such circuits were needed, the resulting systems were large, power-hungry, and costly. Manufacturing such systems was also expensive, requiring unique tooling, hand assembly, and a large amount of human debug effort to repair the inevitable flaws that accumulate during the construction of such complex machinery. In contrast, the fabrication process that underlies the microprocessor is much more economical. As with any silicon-integrated circuit, microprocessor fabrication is mainly a series of chemical processes performed by robots. So the risk of introducing human errors that would later require human debugging is eliminated. The overall process can produce many more microprocessors than discrete methods could.

9.2 Moore's Law

In 1964, Gordon Moore made an important observation regarding the rate of improvement of the silicon-integrated circuit industry. He noted that the chip fabrication process permitted the number of transistors on a chip to double every 18 months. This resulted from the constantly improving silicon process that determines the sizes of the transistors and wiring on the integrated circuits. Although he made the initial observation on the basis of experience with memory chips, it has turned out to be remarkably accurate for microprocessors as well. Moore's law has held for well over 30 years. Figure 126 plots the number of transistors on each Intel microprocessor since the 4004.

These improvements of the underlying process technology have fueled the personal computer industry in many different ways. Each new process generation makes the transistors smaller. Smaller transistors are electrically much faster, allowing higher clock rates. Smaller wires represent less electrical capacitance, which also increases overall clock rates and reduces power dissipation. The combination of both permits far more active circuitry to be included in new design. Constant learning in the silicon fabrication plants have also helped drive up the production efficiency, or yield, of each new process to be higher than its predecessor, which also helps support larger die sizes per silicon chip.

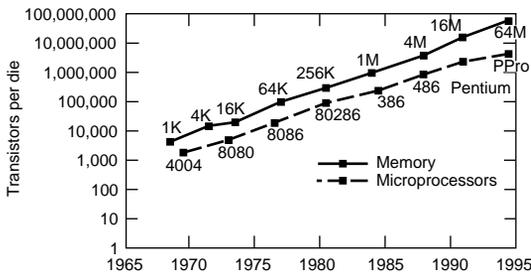

Fig. 126 Moore's law has accurately predicted the number of transistors that can be incorporated in microprocessors for over 25 years. Since this transistor count strongly influences system performance, this remarkable "law" has become one of the central tenets in the field of computers and integrated electronics. It guides the design of software, hardware, manufacturing production capacity, communications, and corporate planning in nearly every major area.

The impact of this progression has been profound for the entire industry. The primary benefit of a new microprocessor is its additional speed over its predecessors, at ever better price points. The effect of Moore's law has been for each new microprocessor to become obsolete within only a few years after its introduction. The software industry that supplies the applications to run on these new microprocessors expects this performance improvement. The industry tries to design so that its new products will run acceptably on the bulk of the installed base but can also take advantage of the new performance for the initially small number of platforms that have the new processor. The new processor's advantages in price/performance will cause it to begin to supplant the previous generation's volume champion. The fabrication experience gained on the new product allows its price to be driven ever downward until the new design completely takes over. Then an even more advanced processor on an even better process technology is released, and the hardware/software spiral continues.

9.3 Microprocessor Architectures

Another factor in the performance improvement of microprocessors is its microarchitecture. Microarchitecture refers to *how* a microprocessor's internal systems are organized. The microarchitecture is not to be confused with its instruction set architecture. The ISA determines what kind of software a given chip can execute. The earliest microprocessors (e.g., Intel 4004, 4040, 8008, 8080, 8086) were simple, direct implementations of the desired ISA. But as the process improvements implied by Moore's law unfolded, microprocessor designers were able to borrow many microarchitectural techniques from the mainframes that preceded them, such as caching (Intel's 486, MC68010), pipelining (i486 and all subsequent chips),

parallel superscalar execution (Pentium processor), superpipelining (Pentium Pro processor), and out-of-order and speculative execution (Pentium Pro processor, MIPS R10000, DEC Alpha 21264).

Microprocessor designers choose their basic microarchitectures very carefully because a chip's microarchitecture has a profound effect on virtually every other aspect of the design. If a microarchitecture is too complicated to fit a certain process technology (e.g., requires many more transistors than the process can economically provide), then the chip designers may encounter irreconcilable problems during the chip's development. The chip development may need to wait for the next process technology to become available. Conversely, if a microarchitecture is not aggressive enough, then it could be very difficult for the final design to have a high enough performance to be competitive.

Microarchitectures are chosen and developed to balance efficiency and clock rate. All popular microprocessors use a synchronous design style in which the microarchitecture's functions are subdivided in a manner similar to the way a factory production line is subdivided into discrete tasks. And like the production line, the functions comprising a microprocessor's microarchitecture are pipelined, such that one function's output becomes the input to the next. The rate at which the functions comprising this pipeline can complete their work is known as the pipeline's clock rate. If the functions do not all take the same amount of time to execute, then the overall clock rate is determined by the slowest function in the pipeline.

One measure of efficiency for a microarchitecture is the average number of clock cycles required per instruction executed (CPI). For a given clock rate, fewer clocks per instruction implies a faster computer. The more efficient a microarchitecture is, the fewer the number of clock cycles it will need to execute the average instruction. Therefore, it will need fewer clock cycles to run an entire program. However, the desire for high microarchitectural efficiency is often in direct conflict with designing for highest clock rate. Generally, the clock rate is determined by the time it takes a signal to traverse the slowest path in the chip, and adding transistors to a microarchitecture to boost its efficiency usually makes those paths slower.

Figure 127 illustrates the functional block diagram of the Intel 486, a very popular microprocessor of the early 1990s. (The microarchitectures of microprocessors that followed the 486, such as the Pentium processor or the Pentium Pro processor, are too complex to be described here.) The prefetch unit of the 486 fetches the next instruction from the instruction cache at a location that is either the next instruction after the last instruction executed or some new fetch address that was calculated by a previous branch instruction. If the instruction requested is not present in the cache, then the bus interface unit generates an access to main memory across the processor bus, and the memory sends the missing instruction back to the cache. The requested instruction is sent to the instruction decode

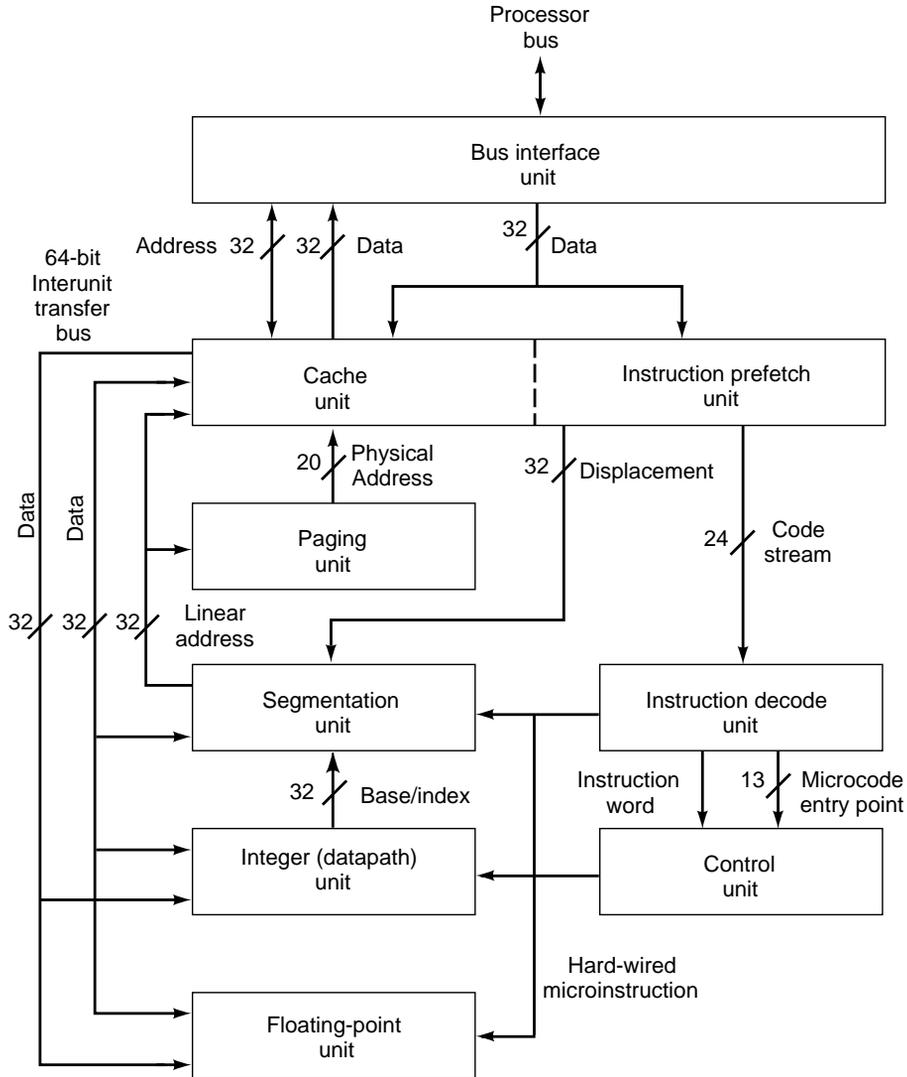

Fig. 127 Block diagram of the most popular microprocessor of the early 1990s, the Intel i486. The various blocks shown work together to execute the Intel Architecture instruction set with approximately 1.1M transistors. Newer designs, such as the Pentium processor, or the P6 microarchitecture at the core of the latest Pentium II processor, are much more complicated.

unit, which extracts the various field of the instruction, such as the opcode (the operation to be performed), the register or registers to be used in the instruction, and any memory addresses needed by the operation. The control unit forwards the various pieces of the instruction to the places in the microarchitecture that need them (register designators to the register file, memory addresses to the memory interface unit, opcode to the appropriate execution unit).

Certain very complex instructions are implemented in an on-chip read-only memory called the microcode. When the instruction decoder encounters one of these, it signals a microcode entry point for the microcode unit to use in supplying the sequence of machine operations that correspond to that complex macroinstruction.

Although it is not obvious from the block diagram, the Intel 486 microarchitecture is pipelined, which allows the machine to work on multiple instructions

at any given instant. While one instruction is being decoded, another instruction is accessing its registers, a third can be executing, and a fourth is writing the results of an earlier execution to the memory subsystem.

See Ref. 173–176 for sources of more details on designing microarchitectures.

9.4 Evolution of ISAs

Although microprocessor ISAs are crucial in determining which software will run on a given computer system, they are not static and unchangeable. There is a constant urge to develop the ISA further, adding new instructions to the instruction set or (much more rarely) removing old obsolete ones. Almost all old ISAs have many instructions, typically hundreds, some of which are quite complicated and difficult for compilers to use. Such architectures are known as complex instruction set computers (CISC). In the early 1980s, substantial academic research was aimed at simplifying ISAs [reduced instruction set computers (RISC)], and designing them with the compiler in mind, in the hopes of yielding much higher system performance. Some important differences remain, such as the number of registers, but with time the differences in implementations between these two design philosophies have diminished. RISC ISAs have adopted some of the complexity of the CISC ISAs, and the CISC designers borrowed liberally from the RISC research. Examples of the CISC design style are the Intel x86, the Motorola MC68000, the IBM System/360 and/370, and the DEC VAX. RISC ISAs include MIPS, PowerPC, Sun's Sparc, Digital Equipment Corp. Alpha, and Hewlett-Packard PA-RISC.

9.5 Coprocessors and Multiple Processors

Some microprocessor systems have included a separate chip known as a coprocessor. This coprocessor was intended to improve the system's performance at some particular task that the main microprocessor was unsuited for. For example, in the Intel 386 systems, the microprocessor did not implement the floating-point instruction set; that was relegated to a separate numerics coprocessor. (In systems that lacked the coprocessor, the microprocessor would emulate the floating-point functions, albeit slowly, in software.) This saved die size and power on the microprocessor in those systems that did not need high floating-point performance, yet it made the high performance available in systems that did need it, via the coprocessor. However, in the next processor generation, the Intel 486, enough transistors were available on the microprocessor, and the perceived need for floating-point performance was large enough, that the floating-point functions were directly implemented on the microprocessor.

Floating-point coprocessors have not reappeared, but less integrated hardware for providing audio (sound generation cards) and fast graphics are quite common

in personal computers of the 1990s, which are similar to the coprocessors of the past. As the CPUs get faster, they can begin to implement some of this functionality in their software, thus potentially saving the cost of the previous hardware. But the audio and graphics hardware also improves, offering substantially faster functionality in these areas, so that buyers are tempted to pay a small amount extra for a new system.

9.6 High-End Microprocessor Systems

Enough on-chip cache memory and external bus bandwidth is now available that having multiple microprocessors in a single system has become a viable proposition. These microprocessors share a common platform, memory, and I/O subsystem. The operating system attempts to balance the overall computing workload equitably among them. Dedicated circuits on the microprocessor's internal caches monitor the traffic on the system buses, in a procedure known as "snooping" the bus, to keep each microprocessor's internal cache consistent with every other microprocessor's cache. The system buses are designed with enough additional performance so that the extra microprocessors are not starved.

In the late 1990s, systems of 1, 2, and 4 microprocessors became more common. Future high-end systems will probably continue that trend, introducing 8, 16, 32, or more microprocessors organized into clusters. As of the mid-1990s, the fastest computers in the world no longer relied on exotic specialized logic circuits but were composed of thousands of standard microprocessors.

9.7 Future Prospects for Microprocessors

From their inception in 1971, microprocessors have been riding an exponential growth curve in the number of transistors per chip, delivered performance, and growth in the installed base. But no physical process can continue exponential growth forever. It is of far more than academic interest to determine when microprocessor development will begin to slow and what form such a slowdown will take.

For example, it is reasonable to surmise that the process technology will eventually hit fundamental limitations in the physics of silicon electronic devices. The insulators most commonly used in an integrated circuit are layers of oxide, and these layers are only a few atoms thick. To keep these insulators from breaking down in the presence of the electric fields on an integrated circuit, designers try to lower the voltage of the chip's power supply. At some point, the voltage may get so low that the transistors no longer work.

Power dissipation is becoming an increasingly important problem. The heat produced by fast microprocessors must be removed so that the silicon continues to work properly. As the devices get faster, they also generate more heat. Providing the well-regulated electrical current for the power supply, and then removing the heat, means higher expense in the

system. With the 486 generation, aluminum blocks with large machined surface areas, known as heat sinks, became commonplace. These heat sinks help transfer the heat from the microprocessor to the ambient air inside the computer; a fan mounted on the chassis transfers this ambient air outside the chassis. With the Pentium processor generation, a passive aluminum block was no longer efficient enough, and a fan was mounted directly on the heat sink itself. Future microprocessors must find ways to use less power, transfer the heat more efficiently and inexpensively to the outside, and modulate their operations to their circumstances more adroitly. This may involve slowing down when high performance is temporarily unnecessary, changing their power supply voltages in real time, and managing the program workload based on each program's thermal characteristics.

Microprocessor manufacturers face another serious challenge: complexity, combined with the larger and less technically sophisticated user base. Microprocessors are extremely complicated, and this complexity will continue to rise commensurate with, among other things:

- Higher performance
- Higher transistor counts
- The increasing size of the installed base (which makes achieving compatibility harder)
- New features to handle new workloads
- Larger design teams
- More difficult manufacturing processes

This product complexity also implies a higher risk that intrinsic design or manufacturing flaws may reach the end user undetected. In 1994, such a flaw was found in Intel's Pentium processor, causing some floating-point divides to return slightly wrong answers. A public relations debacle ensued, and Intel took a \$475 million charge against earnings, to cover the cost of replacing approximately 5 million microprocessors. In the future, if existing trends continue, microprocessor manufacturers may have tens or even hundreds of millions of units in the field. The cost of replacing that silicon would be prohibitive. Design teams are combating this problem in a number of ways, most notably by employing validation techniques such as random instruction testing, directed tests, protocol checkers, and formal verification.

What really sets microprocessors apart from the other tools that humankind has invented is the chameleonlike ability of a computer to change its behavior completely under the control of software. A computer can be a flight simulator, a business tool for calculating spreadsheets, an Internet connection engine, a household tool to balance the checkbook, and a mechanic to diagnose problems in the car. The faster the microprocessor and its supporting chips within the computer, the wider the range of applicability across the problems and opportunities that people face. As microprocessors

continue to improve in performance, there is ample reason to believe that the computing workloads of the future will evolve to take advantage of the new features and higher performance, and applications that are inconceivable today will become commonplace.

Conversely, one challenge to the industry could arise from a saturated market that either no longer needs faster computers or can no longer afford to buy them. Or perhaps the ability of new software to take advantage of newer, faster machines will cease to keep pace with the development of the hardware itself. Either of these prospects could conceivably slow the demand for new computer products enough to threaten the hardware/software spiral. Then the vast amounts of money needed to fund new chip developments and chip manufacturing plants would be unavailable.

However, negative prognostications about computers or microprocessors have been notoriously wrong in the past. Predictions such as "I think there is a world market for maybe five computers" (Thomas Watson, chairman of IBM, 1943) or "photolithography is no longer useful beyond one micron line widths" have become legendary for their wrongheadedness. It is usually far easier to see impending problems than to conceive ways of dealing with them, but computer history is replete with examples of supposedly immovable walls that turned out to be tractable.

In its short life, the microprocessor has already proven itself to be a potent agent of change. It seems a safe bet that the world will continue to demand faster computers and that this incentive will provide the motivation for new generations of designers to continue driving the capabilities and applications of microprocessors into areas as yet unimagined.

10 OSCILLOSCOPES

Andrew Rusek

The oscilloscope, or the *scope*, is an important tool in engineering. The oscilloscope displays a graph of an electrical signal on a screen. In its basic operational mode, the oscilloscope graphs instantaneous signal values versus time. Displayed waveforms have three basic components: *Y*, the vertical or amplitude component; *X*, the horizontal or time component; *Z*, the signal brightness or intensity. Single channel and multichannel oscilloscopes are available. The most popular is a two-channel instrument for which a single trace display with channel multiplexing is available. In this case not only instantaneous signal values versus time, but also amplitude waveform component versus the other, can be observed.

Oscilloscopes are used in physics, electronics, instrumentation and measurements, communications, control, mechanical engineering, and many other areas

where nonelectrical signal can be converted into electrical signals. The graphical display allows a user to determine many signal parameters, such as:

- Voltage and time values
- Frequency, period, and rise and fall times
- Phase shift
- Noise level, jitter
- Frequency ratio of two signals
- Calculated Fourier spectrum
- Calculated statistical parameters
- Calculated mathematical functions of signals, such as the integral, derivative, sum, difference, and product

Two major types of oscilloscopes have emerged over the last decade: analog and digital. Within these two categories, a number of operational modes can be distinguished. There are real-time data acquisition and display scopes, real-time acquisition and equivalent or transformed-time display scopes, and random data acquisition and random display scopes. A typical analog scope directly acquires signal and displays them on the screen in real time. An analog sampling scope can operate in real time and low signal frequencies, and in equivalent time at high frequencies. A digital scope can operate in real time or in equivalent time to acquire signals, but the display shows the reconstructed signal in the equivalent-time mode, which allows for great reduction of the display unit speed, which in turn achieves great reduction of the scope cost. Currently, the major oscilloscope manufacturers, such as Agilent Technologies, Tektronix, and LeCroy, do not list analog scopes in their catalogs but many analog scopes have been used recently and will be used in the near future. The digital scopes, also called digitizing or digital storage oscilloscopes, are considerably more powerful and flexible for signal inspection and

analysis. Signal digitization has opened unlimited possibilities for signal storage and processing.

10.1 Analog Scopes

Analog scopes without sampling acquire and display waves in real time. The most critical part of the analog oscilloscope is a CRT, whose maximum speed of wave tracing limits the speed of the entire scope. Figure 128 shows the simplified structure of a CRT. The beam of electrons generated by the cathode is directed toward the fluorescent screen by a set of electrodes. The beam makes a bright spot on the screen at a position controlled by the voltages applied to the vertical and horizontal deflection plates. The tube can have a single or a double beam system. The latter has two separate beam-forming and deflection structures. The tube shown in Fig. 128 employs a two-stage electron acceleration process. The electrons emitted from the cathode are formed into the beam, whose density is controlled by the cylindrical electrode. Later, the beam is focused and deflected passing through the vertical and horizontal deflection plates. Final acceleration, called postdeflection acceleration (which is necessary to produce a visible spot on the screen), is achieved by applying very high voltage, at least several kilovolts, to a distributed electrode located inside the tube between the deflection plates and the screen. The inner surface of the screen is covered with a phosphor, which emits visual radiation on being bombarded by electrons. The length of time during which the phosphor emits radiation until its level decays to 10% of the initial value is called the persistence. Several types of phosphor inner coatings are applied in CRTs. The most popular phosphor, P 31, exhibiting high luminance and reasonable persistence of about 32 ms,¹⁷⁷ is found in most CRTs.

In analog scopes, an image of a nonrepetitive signal fades quickly or slowly, depending upon the tube persistence. Fast single-shot events may not be registered by a classical CRT whose screen directly reacts to the

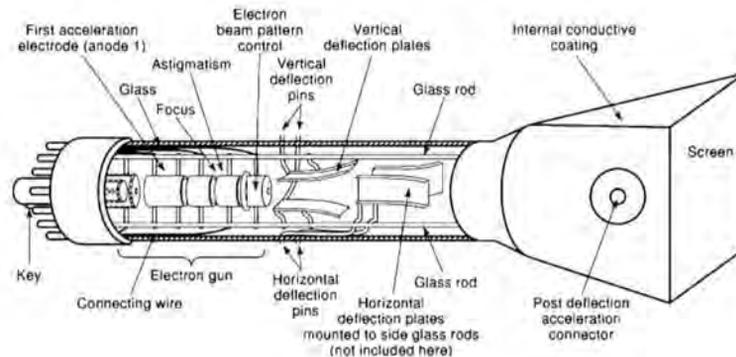

Fig. 128 Internal structure of a CRT.

electron current delivered to it. In order to enhance the quality of writing, microchannel plate CRTs are used in some analog scopes.¹⁷⁸ Inside the tube, an array of hollow glass fiber is located. The fiber internally coated with a semiconductor, multiply the number of electrons through secondary emission when activated by an adequately accelerated electron beam. The beam deflection can be affected by the proximity of power supplies, especially transformers, and chokes. To avoid interference, the tubes and potentially interfering components are well shielded.

The block diagram of a typical analog scope is shown in Fig. 129. The vertical channels, A and B,

include input coupling circuits, attenuators, preamplifiers delay line, and differential output amplifier driving the vertical plates of the CRT, as shown in Fig. 130. Quite often, voltage or current probes are connected to the inputs to provide better interfacing with the tested circuits. The horizontal section of the oscilloscope is composed of triggering unit with its coupling circuits, trigger shaping unit, trigger level control, and trigger holdoff units; a sweep generator, which define the main time base of the scope; and a differential output amplifier driving the horizontal deflection plates of the tube (Fig. 131). The main sweep generator can be supported by a fast time-base

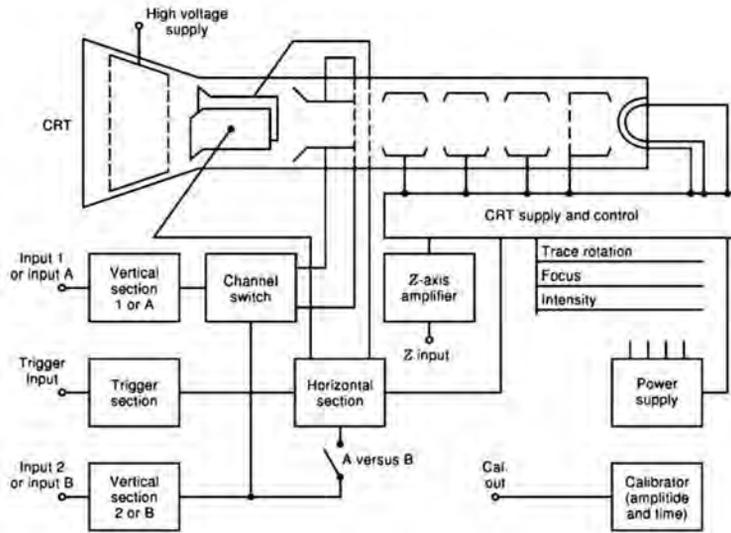

Fig. 129 General diagram of an analog oscilloscope.

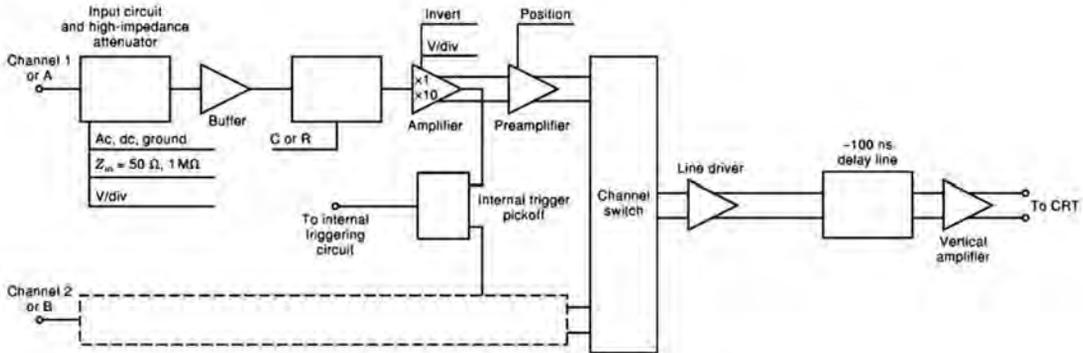

Fig. 130 Vertical channel of an analog oscilloscope.

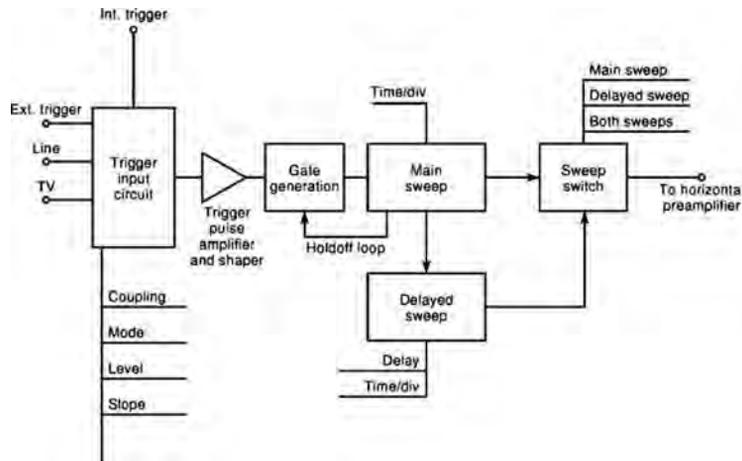

Fig. 131 Horizontal channel of analog oscilloscope.

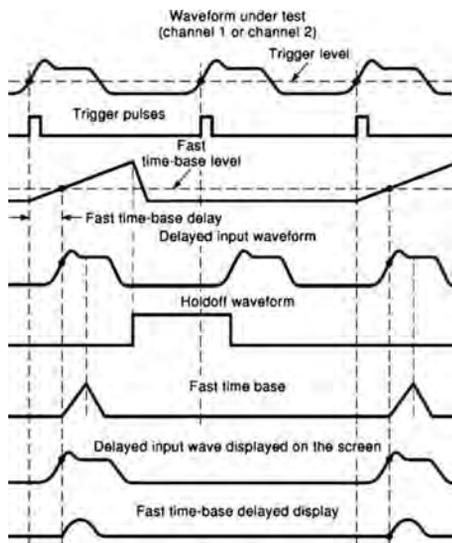

Fig. 132 Waveforms in analog oscilloscope.

unit triggered at a preselected level to expand desired parts of the tested waves. Figure 132 illustrates typical waveforms of analog scopes. Two time bases are activated to show distinguished sections of the signals under test with the help of the fast ramp, which is called the delayed time base. The waves observed on the tube screen are delayed in relation to the input signals due to the action of the delay lines forming parts of the vertical amplifier. In this way the trigger and the time-base circuit delays and nonlinearities

are compensated to create good conditions for tests of the wave leading edges without introducing distortions. Figure 132 also shows internally generated triggering pulses initiated by the input signal of channel 1 or 2.

To stabilize the horizontal wave position on the screen, the trigger level is selected within the frame of the vertical span of the incoming waves. At the same time an auxiliary system, called *holdoff*, has to be adjusted to make the time-base generator insensitive to excessively frequent triggering. If more than one channel is used and a single-trace tube is applied, then a channel switch can direct only one channel to the screen at a time for the duration of the time base, especially at high rates of the time base (alternating mode). At lower time-base rates small segments of the individual channels can be displayed one by one (chopped mode). The waves for both modes of the display are shown in Fig. 133. Multichannel data acquisition allows one to perform basic hardware arithmetic operations on signals, such as addition and subtraction. The process of subtraction, which can disclose a differential signal component, is corrupted by interchannel interference due to the common ground pathways and nonideal channel isolation of the channel switch. Many analog oscilloscopes have internal amplitude calibrators, which help check the scope amplitude calibration and verify or adjust the compensation of the voltage probes.

10.2 Sampling Scopes

Typical real-time analog oscilloscopes have operating bandwidths up to several hundred megahertz. The limits are mainly imposed by the CRT writing speed. One of the means to reduce the speed of observed waves has been the time transformation by means of coherent sampling. The method can be only applied to repetitive waveforms. A basic set of waveforms for a

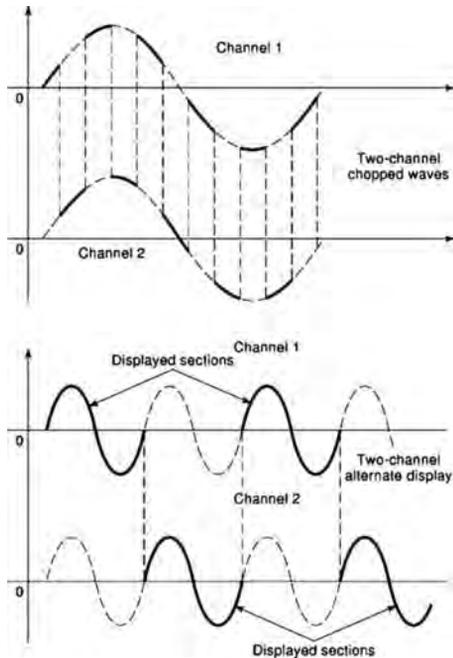

Fig. 133 Modes of display of analog oscilloscope.

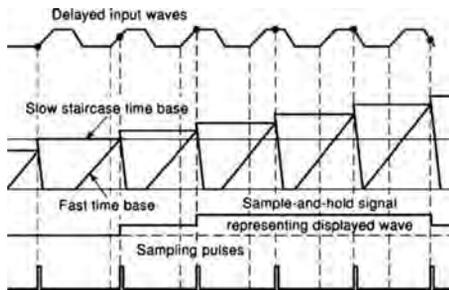

Fig. 134 Time transformation in analog sampling scope.

sampling scope is shown in Fig. 134; the scope block diagram is depicted in Fig. 135. The signal under test applied to the input is delayed by a broadband transmission line, and then sampled by very narrow pulses in a sampling gate. If the repetition frequency is less than several hundred kilohertz, which is the maximum repetition frequency of the trigger circuitry, a single sample is taken from each pulse of a frame defined by the time base. For higher repetition rates the trigger circuits divide the frequency so that every n th one sample is taken from a single pulse of a repetitive wave. When the samples are taken, they are stretched,

amplified and memorized in a sample-and-hold circuit. Later, the samples are applied to low-frequency vertical amplifier driving the tube. The sampling scope system uses a track-and-hold feature that enables the scope to process the small samples formed by the differences between the two consecutive values of the sampled signal. Generation of subsequent sampling pulses is achieved by comparison of two fully synchronized time bases. One of them is a fast time base, and the other is a staircase signal. The horizontal channel provides the timing of all samples. It also delivers trigger signal to the sampling pulse generator and to the time bases. Sampling oscilloscopes can operate up to frequencies above 70 GHz of an equivalent bandwidth, which corresponds to the rise time of 5 ps. Both, vertical and horizontal channels of such, scopes have been digitized and new generations of sampling scopes have been available for the last few years.¹⁷⁹ They are applied not only in the typical scope measurements but also in time domain reflectometry (TDR).

10.3 Digital Scopes

Digital oscilloscopes have overcome many disadvantages of analog scopes, especially the necessity for using long persistence CRTs and delay lines. A digital scope display can be adjusted after wave acquisition and storage. The input circuitry of a typical digital scope does not differ from that of analog scope. After preliminary attenuation or amplification analog signals are sampled and digitized. The digitized samples are stored in a memory. The display receives the reconstructed analog samples of vertical and horizontal information through DACs. The process of data display is delayed and stretched in time, so the samples of the signal are displayed at a slower rate than they are acquired. Three major types of digitizers are applied in digital scopes:

- Real-time digitizers operating at high sampling and conversion rates, which can capture nonperiodic short transient processes.
- Coherent sampling digitizers working in the same way as the sampling oscilloscopes with time transformation described before. The A/D conversion is applied to much slower waves after the sampling and time transformation. In this approach, a pretrigger pulse is required; it is obtained either from the tested signal or from a separate source whose output wave follows the trigger.
- Random interleaved sampling digitizers, which sample repetitive signals in a pseudorandom manner. Amplitude and timing data are digitized and memorized in corresponding memories and later displayed to follow the stored timing sequence.

All three digitizers can equally well acquire periodic signals. In the last two approaches, only a single sample can be taken during the input signal cycle, especially at low frequencies of very short input

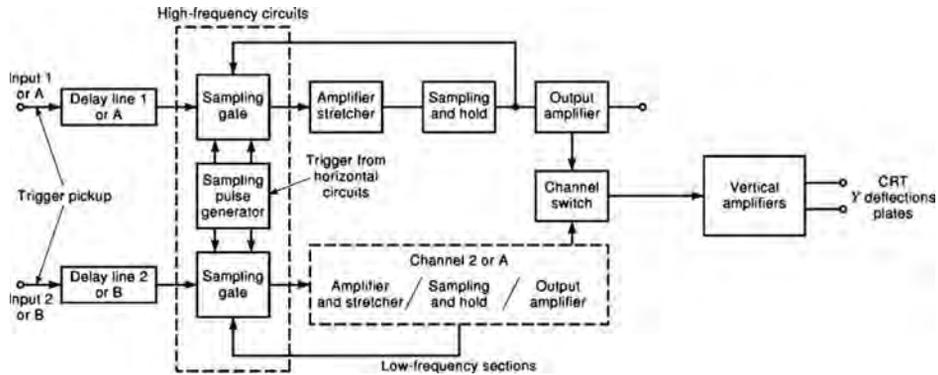

Fig. 135 Vertical system of coherent sampling oscilloscope.

pulses. The real-time signal capture capability of most digital scopes is limited by the maximum sampling rate, which is directly associated with the maximum speed of the analog-to-digital converters. The inherent storage capability of digital scopes, especially the possibility of storing long records of a number of channels, allows for processing the signals applying complex mathematical operation, including Fourier analysis and statistical functions.¹⁸⁰ When the oscilloscope calculates the FFT of the input signal, the frequency spectrum can be displayed separately from the time domain signal image. A typical block diagram of a two-channel digital storage scope DSO is shown in Fig. 136. The channels acquire and digitize the signals independently, and then the digital signals are accumulated and processed according to the chosen function. In the simplest case, the digitized signals are retrieved

from the memory, converted back into their analog forms by the DACs, and displayed. The reduced speed of the signal display processes eliminates the need for high-frequency CRTs. Many scope displays utilize LCD tubes, which are directly controlled by addressing the picture elements (pixels) of a display matrix. Analog scopes with CRTs can update their pictures about 10^5 times per second. Time changes in the signals are then recorded immediately. The display process of a typical digital storage scope is usually a memory reconstruction of the acquired samples taken from many periods, so the entire image can be acquired only 5–10 times per second. High quality of the picture display of analog scopes requires rather high frequency of image updates. Such update frequencies are not available when the signal is not repeated frequently. Some digital storage scopes with high-speed digitizers and

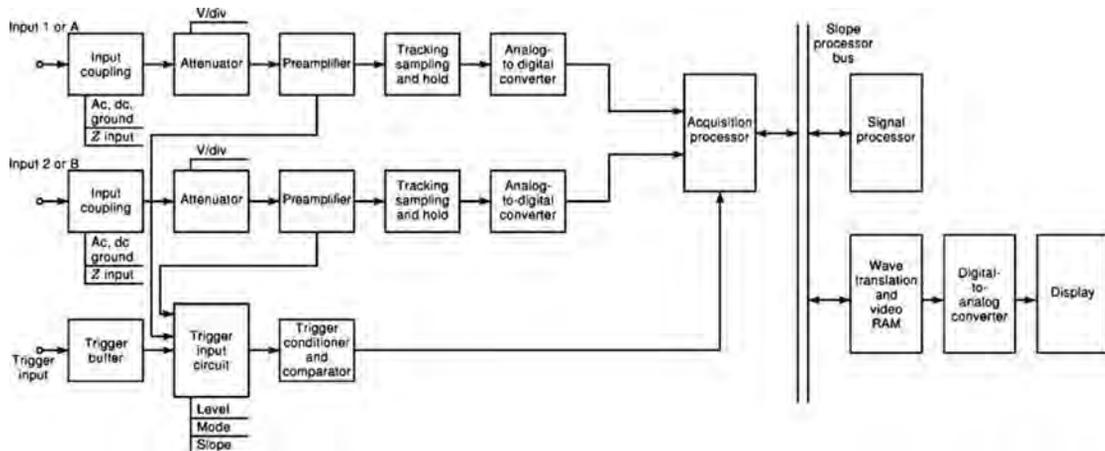

Fig. 136 General block diagram of digital oscilloscope.

processors, and with smart display algorithms, update their displays by creating high-quality analog persistence images over a broad range of signal frequencies. The number of samples displayed on the screen is fixed independently of the time-base settings, which leads to changes of the sampling rates for different time bases. In order to reproduce periodic waves, taking 5–10 samples per period of the highest harmonic is regarded as the minimum to preserve sufficient signal details. The Nyquist sampling rate is too low to reconstruct periodic signals in all cases, especially when the signals are sampled near zero crossings. Major features of the digital storage scopes can be summarized as follows:

- Large amounts of pretrigger information can be acquired without delay lines.
- Single or repetitive waves can be stored permanently.
- Computer or printer interfacing to store or print more data can be easily achieved.
- One may reliably capture unpredictable events.
- One may reliably capture glitches shorter than the resolution time by means of peak detectors.
- Within the memory capacity, there is no dead time between acquired events.
- Measurements can be automated.
- Currently acquired waves can be compared with reference waves.
- Wave tolerance tests are possible, including go-no-go tests.
- Acquired waves can be processed mathematically, including statistical operations.
- Finite resolution and a small number of display sweeps per second can mask the time distribution of waveforms.
- The limited number of samples and the constant sample intensity commonly used in displaying simple repetitive waves can distort composite repetitive signals, including waves of various speeds.

10.4 Technical Parameters and Limitations

This section describes basic parameters of the oscilloscopes to help select the right one for an application. In the selection process, the scope parameters must be related to the waves under test. The major specifications of analog scopes are number of channels, bandwidth, voltage sensitivity, maximum time-base speed, amplitude noise, time jitter, and overall accuracy. From these parameters other scope features can be derived. For digital scopes, the same set of parameters is also important, but maximum sampling rate, vertical and horizontal resolutions, and memory length should be considered.

Number of Channels Common-purpose single-channel scopes are not very popular in measurement

laboratories. If the number of channels is greater than one, the interchannel interference becomes important and a high CMRR is desired. For example, if CMRR = 40 dB, then with one channel receiving a signal of 1 V and the other channel receiving a signal of 10 mV, the lower amplitude channel will measure the amplitude with an error of about 10%, which is well above scope error specifications

Bandwidth The BW is usually defined as the frequency range between the dc and the frequency at which a sinusoidal signal amplitude observed on the screen is reduced 3 dB in relation to the value at dc or low frequencies. The input sinusoidal signal is supplied from a source having very low internal resistance, normally 50 Ω . The bandwidth of an analog scope is primarily determined by the frequency response parameters of its vertical amplification channel, including attenuators and the tube or other display. The magnitude response error introduced by the frequency limitations is shown in Table 32. The frequency response bandwidth relates to an equivalent time domain parameter, namely, the rise time, usually considered as the time the step response changes between 10 and 90% of the steady-state level. For the simplest frequency response approximation, the relationship between the rise time and the bandwidth is as follows:

$$T_B = \frac{0.35}{BW}$$

For instance, for a 100-MHz scope the rise time is 3.5 ns. This leads to time domain measurement error, whose effects can be corrected for using the following expression:

$$T_T = \sqrt{T_B^2 + T_R^2}$$

where T_T = actual rise time
 T_0 = measured rise time
 T_R = scope's own rise time

Table 33 shows the time domain error calculated without corrections.

Both tables suggest that in order to maintain reasonable measurement accuracy, the scope should be at least several times faster than the fastest tested wave. Frequency domain or time domain speed limitations of digital scopes are additionally imposed by the sampler

Table 32 Magnitude Response Error

3.5	10	10.6	6
3.5	20	20.3	1.5

^a BW 100 MHz.

sampling speed and the ADC speed. The sampler includes the sample-and-hold unit, whose sampling pulse width determines the fastest change that can be captured and later converted in the ADC. Majority of digital scopes use flash or parallel ADCs. With ideal sampling pulses, the sampling rate should be several times greater than the expected maximum frequency of the tested signals. The sampling rate also determines the scope horizontal resolution.

Vertical Sensitivity This parameter expresses the scope ability to accommodate small signals as well as large signals within the same space of the screen. Typical ranges of scope sensitivities are between several millivolts per division and 20 V per division. The sensitivity range is a compromise between the user's desired values and the technical limitations imposed by the noise level of the scope amplifier and the maximum available attenuation of high-frequency compensated attenuators.

Amplitude Noise Level The scope noise mainly includes the broadband noise generated by the input stages of the scope and by the source resistance. The observed noise levels are usually on the order of 1 mV. Bandwidth reduction decreases the noise level and allows increasing the scope sensitivity. In digital scopes, the input analog amplifier introduce their noise, thus degrading the resolution of the ADC conversion process. For example, 1 mV noise on a 1-V signal limits the resolution of the conversion to less than 12 bits.

Time Jitter Time jitter, or jitter, is caused by threshold instabilities in triggering and time-base circuits. The jitter is observed on the screen as a spread of vertical parts of the tested signals. In digital scopes, the clock jitter adds its component to this time domain instability.¹⁸¹ The levels of jitter are on the order of picoseconds for fast sampling scopes and on the order of nanoseconds for low-frequency scopes.

Accuracy The inaccuracy of a scope is mainly caused by vertical and horizontal calibration and reading errors. The reading errors of digital scopes, with built-in digital amplitude and time meters, are negligible in comparison with calibration errors of amplifiers, voltage attenuators, and input resistors. The total

amplitude error can reach several percent, but the dc voltage error can be as low as 1%. The time-base errors in digital scopes are comparable with the errors of digital counters, which are below 0.1%,¹⁸² while the time-base errors in analog scopes are usually 2–5%. The process of selecting a scope is primarily determined by the information about the waves under test: their shapes, repetitivity, frequency and amplitude, drift, and speed. Additional conditions that should be considered are the length of the record, possibility of test automation, signal statistics, and wave storage. The scope capabilities and parameters should be also chosen with regard to future applications and affordability.

10.5 Oscilloscope Probes

Almost all standard oscilloscopes use different voltage probes to connect to a circuit or a device under test, chosen to minimize the effects of the scope input impedance and electromagnetic interference. Some probes convert a nonelectrical quantity or another electrical quantity, such as current, into a voltage, which is measured by the scope. Two major types of voltage probes are used. The first type is a passive probe, which yields high input resistance and low input capacitance but introduces significant signal attenuation, usually 10 times. The second type is an active probe, which does not attenuate the signal but provides high input resistance and low input capacitance. Unfortunately, the supply voltage required for active probe devices also introduces undesired noise and offset. Active probes usually employ FETs and broadband operational amplifiers.¹⁸³ A typical voltage probe has two input terminals: a ground terminal and a signal terminal. In many cases, tests of differential signals cannot be done by means of two-channel differential measurement, due to the limitations of the CMRR. For these tests, differential active probes, which have very high CMRR, are recommended.

Passive Probes Passive probes include low-impedance resistive voltage divider probes and compensated high-impedance voltage divider probes. There are also high-impedance probes with a very large voltage division factor, which are used in high-voltage measurements. Figure 137 shows a low-impedance passive probe. This type of probe has very low capacitive loading and wide bandwidth. It can be used in testing low-impedance circuits. High-impedance passive probes are shown in Figs. 138 and 139. In both cases,

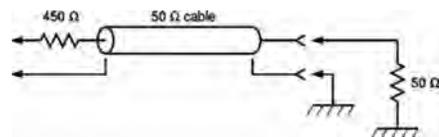

Fig. 137 Low-impedance passive probe.

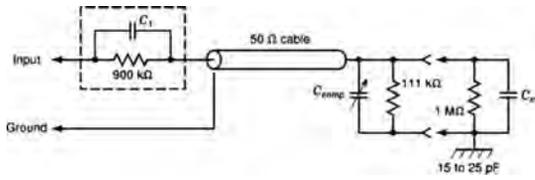

Fig. 138 Passive probe, 1 MΩ input resistance.

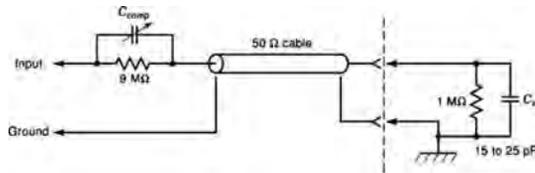

Fig. 139 Passive probe, 10 MΩ input resistance.

the probes require compensation before the measurement process starts. The compensation is performed by observing a standard square wave signal generated by the scope calibrator. The effects of the pulse compensation on the square wave and the sine wave are shown in Fig. 140. High-voltage probes have similar structure to that in Fig. 140. The series resistor is of much higher value and larger physical size, to withstand voltages higher than 500 V. A high-voltage probe circuit is shown in Fig. 141.

The parameters of passive probes are:

- Voltage attenuation (e.g., 10× or 1×)
- Bandwidth for 50-Ω source resistance
- Maximum input voltage (e.g., 500 V)
- Input resistance (e.g., 1 MΩ)
- Input capacitance (e.g., 2 pF)

Active Probes Figure 142 is a diagram of an active probe with a single input. A differential probe is shown in Fig. 143. Both probes have very large input resistance, broadband, and no attenuation. The differential probe also has high CMRR, greater than 60 dB.

10.6 Oscilloscope Measurements

Scopes can measure the following basic quantities:

- Voltage
- Current (with a current probe)
- Frequency and time, including period, time delay, pulse width, and duty factor
- Phase shift
- Rise and fall times
- Amplitude modulation index

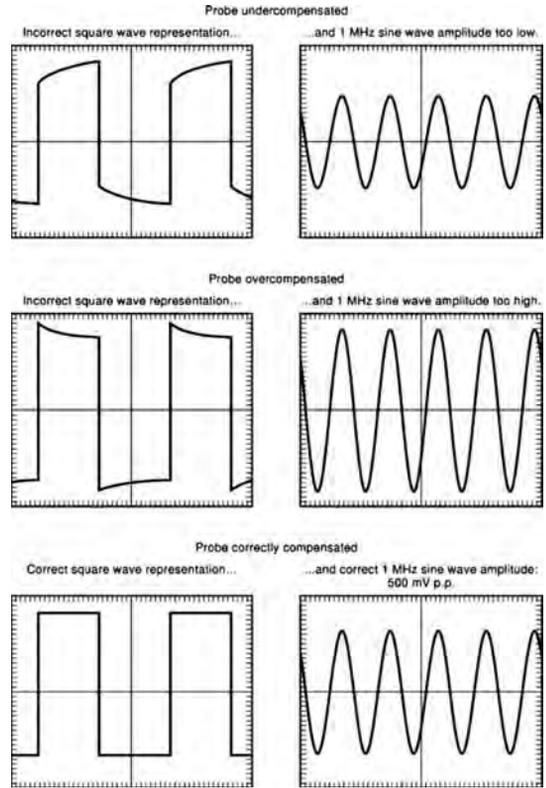

Fig. 140 Compensated probe waveforms.

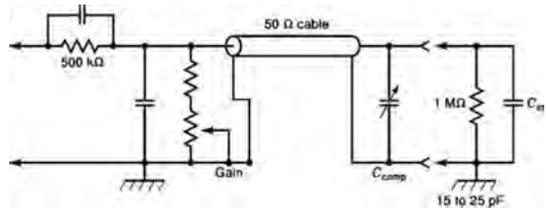

Fig. 141 High-input-resistance high-voltage probe.

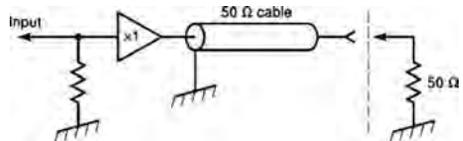

Fig. 142 Diagram of active probe.

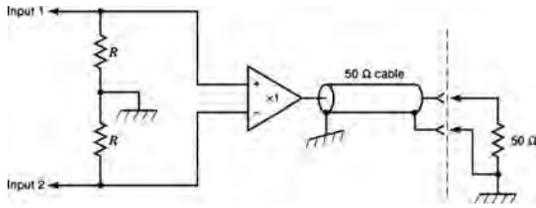

Fig. 143 Differential probe.

- Jitter
- Eye diagram to evaluate quality of communication signals

Voltage Voltage measurements are elementary tests done with oscilloscopes. Direct current voltages are measured by observing the level shift of the horizontal line on the screen when the input of the scope is dc coupled to the source. The screen graticule and the vertical sensitivity setting indicate the amount of shift. Modern scopes have internal digital voltmeters indicating numerical values of the beam position and the positions of the different markers. In older scopes, ac voltages are measured in terms of the voltage differences, which are calculated with the aid of the graticule. In modern scopes, the marked levels are measured digitally and displayed numerically on the screen.

Current Current measurement requires the use of current-to-voltage converting devices, such as Hall effect sensors for dc currents, current transformers clamping sensors for ac currents, or combinations of both. The Hall effect current sensors are supplied from the scope or from a separate power supply, which also incorporates additional amplifiers

Frequency and Time With older scopes, the time domain parameters can be measured using the screen reading in relation to the current time-base setting. Modern scopes, especially digital, have digital readout and they display the time domain parameters with reference markers. Rise and fall times are measured with the help of horizontal levels marked at 10 and 90%. Figure 144 illustrates the way the rise time is evaluated.

Phase Shift The phase shift between two waves is the amount of time, expressed in degrees, that passes between the beginnings or other selected points of the two waves. The phase shift is thus obtained from two time measurements in which the relative position and the period of the waves are found and phase angles are calculated. Another method, which can be used only for coherent sinusoidal signals, involves the XY display mode. One signal is applied to the horizontal

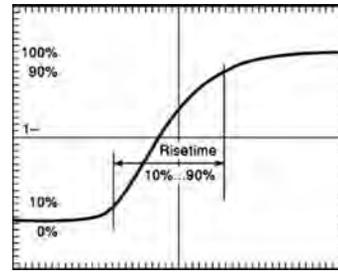

Fig. 144 Measurement of rise time.

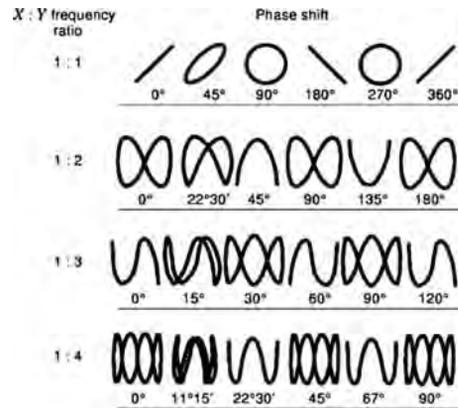

Fig. 145 Phase measurement applying XY display.

channel, the other to the vertical channel. The XY patterns displayed on the screen are called Lissajous graphs, and from the shape of the pattern the phase shift and frequency can be determined. Figure 145 shows different Lissajous patterns.

Amplitude Modulation (AM) Index Figure 146 shows a time domain AM wave displayed on the screen while the external triggering of the scope is synchronized by means of a modulating lower frequency wave. The modulation index is calculated as a ration of M to C . It is also possible to display the XY pattern in which the modulated wave is applied to the scope vertical system, and the modulating signal is applied to the horizontal system. Figure 147 shows a typical AM wave pattern for this method.

Eye Diagram The eye diagram is a very useful visual method, which is often applied in digital communication systems, to evaluate quality of the information data. The vertical channel of the scope displays the demodulated and filtered bipolar symbol stream,

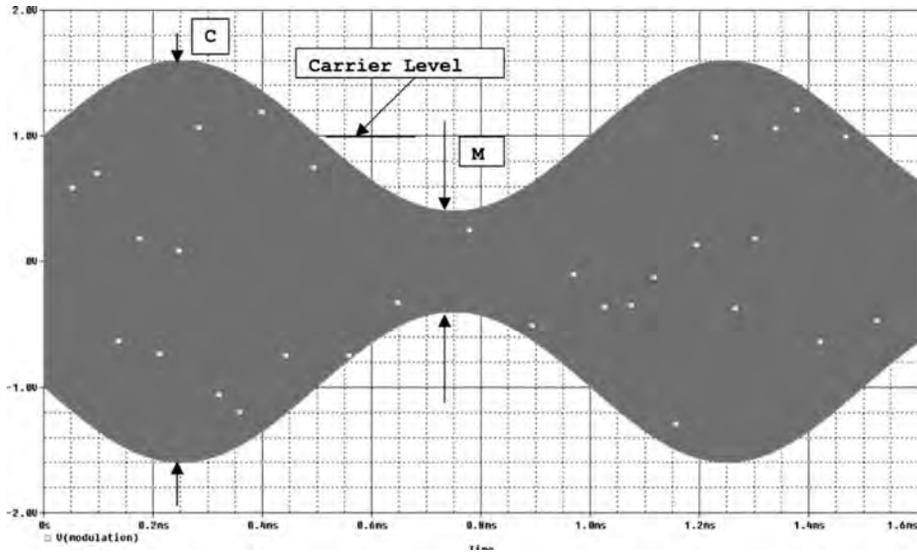

Fig. 146 Time domain measurement of AM depth (index).

but the horizontal channel is triggered at every symbol period or every multiple of the symbol period (Fig. 148). Thanks to the screen persistence the consecutive symbols of various durations can be observed and amplitude and time domain distortions evaluated.

10.7 Programmability of Oscilloscopes

Most modern digital scopes can be controlled by computers. The computer provides more flexibility in storing data and in programming and controlling

experiments. Advance interfacing techniques involve applications of GPIB or IEEE-488 cards and connections controlled by the dedicated software, like VEE of Agilent Technologies or LAB VIEW of National Instruments.^{184,185}

11 POWER DEVICES

Alex Q. Huang and Bo Zhang

11.1 Rectifiers

The semiconductor rectifier¹⁸⁶ was the first semiconductor device developed for power circuit applications. It is a semiconductor device specifically designed to rectify alternating current; that is, to exhibit a very low resistance to current flow in one direction and a very high resistance in the other direction.

$P-i-N$ Rectifier In the past, only $P-i-N$ rectifiers were available for use in power circuits. The first devices were made by using germanium. However, the high leakage current in germanium devices associated with its small energy bandgap (0.66 eV) led to their replacement by silicon $P-i-N$ rectifiers. Since the 1950s, the performance of silicon $P-i-N$ rectifiers has been continually improving due to the optimization of the device structure and lifetime control¹⁸⁷ that is used to adjust the switching speed. The basic $P-i-N$ rectifier structure is shown in Fig. 149. The doping concentration and the thickness of the i region (N^- region) are designed to support the required reverse blocking voltage. In order to support large reverse blocking voltage, it is necessary to use a low doping concentration as well as a large thickness for the i region. In the on state, minority carrier holes are injected from the P^+ anode and electrons injected from the N^+ cathode; they are equal in number to maintain charge neutrality. This phenomenon of injecting a high concentration of holes and electrons into the i region, called conductivity modulation, is an extremely important effect

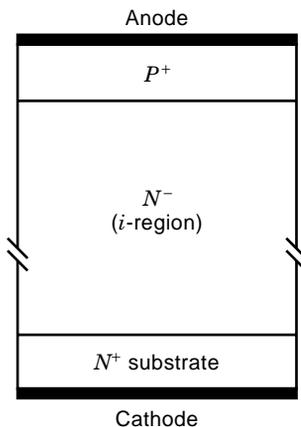

Fig. 149 Basic structure of the $P-i-N$ rectifier. The lightly doped thick i region is designed to support the required reverse voltage. The heavily doped p^+ anode and n^+ cathode inject carriers into the i region to modulate its conductivity during forward conduction.

that allows the transporting of high currents through the $P-i-N$ rectifier with breakdown voltages of up to 5000 V. In the steady-state reverse blocking state, the reverse current is only the leakage current due to minority carrier generation in the depletion region, and the $P-i-N$ rectifier exhibits a very high resistance to current flow.

As described, the injection of a high concentration of minority carriers into the i region can increase the conductivity of the i region. However, the injected carriers also create problems during switching of the $P-i-N$ rectifier. When the voltage across the device reverses polarity, the injected electron-hole population (called stored charge) must be removed before the formation of a depletion region can occur to support the reverse blocking voltage. This leads to a reverse recovery current. The presence of such a reverse recovery transient leads to power dissipation that limits the maximum switching frequency of $P-i-N$ rectifier and degrades the reliability of the applied circuits, an additional concern is the large voltage overshoot caused by the di/dt of the reverse recovery current flowing through the stray inductance in the circuit. When the switching frequency of a power circuit increases, the turn-off di/dt must be increased. It has been found that this causes an increase in both the peak reverse recovery current and the ensuing reverse recovery di/dt . If this reverse recovery di/dt is large, an increase in the breakdown voltage of all the circuit components becomes essential. Raising the breakdown voltage capability causes an increase in the forward voltage drop of power devices, which in turn degrades the system efficiency because of a higher conduction loss. Many methods of lifetime control have been developed to reduce the minority carrier lifetime in the i region to decrease the switching loss of the $P-i-N$ rectifier but they also lead to an increase in the on-state voltage drop. It is therefore customary to perform a tradeoff between on-state and turn-off losses when designing $P-i-N$ rectifiers.

Another drawback of the $P-i-N$ rectifier is the forward voltage overshoot during its turn on. The forward voltage overshoot in a $P-i-N$ rectifier arises from the existence of the high resistance i region. Under steady-state current conduction, the i -region resistance is drastically reduced by hole-electron population injected by the N^+ and the P^+ regions. However, during turn on under high di/dt condition, the current rises at a faster rate than the diffusion of the minority carriers injected from the junction. A high voltage drop develops across the i region for a short period of time until the minority carriers can swamp out the i -region resistance.

Schottky Barrier Diode In order to eliminate the reverse recovery problem associated with $P-i-N$ rectifiers the Schottky barrier diode (SBD), Schottky rectifier was developed in the 1970s. The basic structure of the SBD is shown in Fig. 150. It consists of a metal-semiconductor rectifying contact with

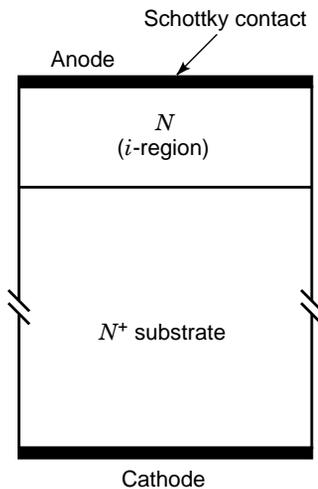

Fig. 150 Basic structure of the Schottky barrier diode. A specially selected anode metalization (such as tungsten, aluminum) forms a Schottky barrier with the lightly doped N region.

an N -region designed to support the required reverse blocking voltage. When a positive bias is applied to the metal with respect to the N -type semiconductor, forward conduction in the SBD occurs by thermal emission of majority carrier electrons across a lowered metal–semiconductor barrier. The on-state voltage drop of the SBD therefore consists of the sum of the voltage drop across the barrier and the ohmic voltage drop across the N region. There is no conductivity modulation of the N region in the SBD structure because the minority carrier injection is negligible. The N region resistance depends on the reverse blocking voltage. For low breakdown voltages (<100 V), the doping concentration of the N region lies between 5×10^{15} and $1 \times 10^{16} \text{ cm}^{-3}$ and its thickness can be made to less than $10 \mu\text{m}$. This leads to a relatively small voltage drop in the N region. For the case of a typical SBD with a reverse breakdown voltage of 50 V and a barrier height of 0.8 V, the forward voltage drop is about 0.554 V at a forward conduction current density of 100 A/cm^2 . This lower forward voltage drop compared to a P – i – N rectifier (whose forward voltage drop at 100 A/cm^2 is about 0.9 V) and its faster switching speed (because of the absence of large reverse recovery current observed in a P – i – N rectifier) make the SBD attractive in low-voltage switching applications.

With the increase of the reverse blocking capability, the forward voltage drop of the SBD will increase rapidly and will approach that of a P – i – N rectifier when the reverse blocking capability is increased to 200 V. In addition, the Schottky rectifier has a larger reverse leakage current, which also increases with

the increase of the temperature, and a soft blocking characteristic. These make the silicon Schottky rectifier generally unacceptable for use in high-voltage applications.

As discussed previously, the silicon Schottky rectifier eliminates the reverse recovery problem that limits its high-frequency application, but the forward voltage drop of the silicon Schottky rectifier increases rapidly with the increase of the reverse blocking capability. A much superior power rectifier can be created by using SBD contact if the resistance of the N region can be reduced while achieving the same blocking capability. An approach for achieving this is to replace silicon with a wide-bandgap semiconductor. Based on this fundamental analysis, it was demonstrated that a gallium arsenide (GaAs) Schottky rectifier has a better forward voltage drop than a silicon P – i – N diode for blocking voltages of up to 500 V.

The mobility of electrons in gallium arsenide at low field is larger than in silicon by a factor of 5.6 . In addition, because of the larger energy bandgap, the critical electric field for breakdown in gallium arsenide is higher than in silicon. These two facts result in a reduction in the specific on resistance (the on resistance per unit area) of the N region by a factor of 13 . For a typical Schottky barrier height of 0.8 V, the gallium arsenide Schottky rectifier are expected to have a lower forward drop than silicon P – i – N rectifier for breakdown voltages of up to about 500 V at a typical operating current density of 100 – 200 A/cm^2 . In this voltage range, the gallium arsenide Schottky rectifier offer a clear advantage over P – i – N rectifier due to faster switching speed because of the absence of the reverse recovery current. The fabrication of gallium arsenide Schottky barrier power rectifier can be accomplished by using aluminum or titanium Schottky barrier contacts. These devices are now commercially available.

An even more promising material for power rectifier is silicon carbide (SiC) because of its much higher critical electric field at breakdown. The on-state voltage drop of the silicon carbide Schottky barrier power rectifier is superior to that of the silicon P – i – N power rectifier for a blocking voltage up to 3000 V. The silicon carbide Schottky barrier power rectifier have also been found to have excellent reverse recovery and reverse bias leakage characteristics even at high operating temperatures. They are likely to replace silicon P – i – N rectifier in high-voltage power electronic circuits in the next decade.

11.2 JBS Rectifiers

With the trend toward lower operating voltages for VLSI chips, there is an increasing demand to reduce the forward voltage drop in rectifiers. The forward voltage drop of a Schottky rectifier can be reduced by decreasing the Schottky barrier height. Unfortunately, a low barrier height results in a severe increase in leakage current and a reduction in maximum operating

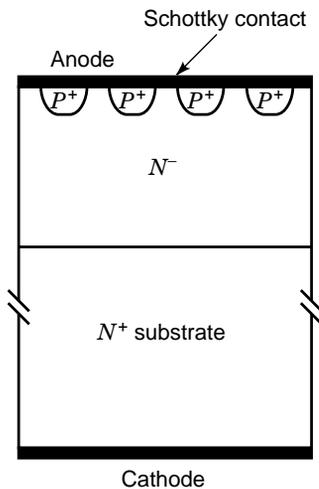

Fig. 151 Cross-sectional view of JBS rectifier structure. The p^+ junction grid is designed so that its depletion layers do not pinch-off under zero and forward bias conditions of the rectifier, but intersect with each other underneath the Schottky contact when the reverse bias exceeds a few volts.

temperature. Further, Schottky power rectifier fabricated with barrier heights of less than 0.7 eV have been found to exhibit an extremely soft breakdown characteristic, which makes them prone to failure.

The junction barrier-controlled Schottky (JBS)¹⁸⁸ rectifier is a Schottky rectifier structure with a $P-N$ junction grid integrated into its N region. A cross section of the JBS structure is provided in Fig. 151. The junction grid is designed so that its depletion layers do not pinch-off under zero and forward bias conditions of the rectifier but intersect with each other under the Schottky contact when the reverse bias exceeds a few volts.

Under reverse blocking states, after the depletion layer pinches off, a potential barrier is formed in the channel between the two grids, and further increase of the applied reverse voltage is supported by it with the depletion layer extending toward the N^+ substrate. Therefore, the potential barrier shields the Schottky contact from the applied voltage. This shielding prevents the Schottky barrier lowering phenomenon and eliminates the large increase in leakage current observed in conventional Schottky rectifiers. During on-state operation, there are multiple conductive channels under the Schottky contact through which current can flow. Because of the suppressed leakage current, the Schottky barrier height used in JBS rectifier can be decreased compared to that of conventional Schottky rectifiers. This has allowed a reduction in the forward voltage drop while maintaining acceptable reverse blocking characteristics. For the same leakage current, the JBS rectifier has been found to provide a

forward voltage of 0.25 V, compared with about 0.5 V for the Schottky rectifier.

In the design of the JBS rectifier the lowest on-state voltage drop can be obtained by making the width of the junction diffusion window as small as possible. This minimizes the dead space below the junction where the current does not flow. The best JBS rectifier characteristics can therefore be expected when submicron lithography is used to pattern the diffusion windows for the P^+ regions.

MPS Rectifiers The merged $P-i-N$ /Schottky (MPS)¹⁸⁹ rectifier has a structure similar to that of the JBS rectifier as shown in Fig. 152. However, the operating physics and applications of the two rectifiers are quite different. In the JBS rectifier there is no injection of minority carrier holes from the $P-N$ junction, and the on-state voltage drop is less than 0.5 V. In the MPS rectifier the N region is designed for supporting a high reverse blocking voltage, and the forward biasing $P-N$ junction becomes necessary in the on state. The forward bias of the $P-N$ junction produces the injection of holes into the N region and results in conductivity modulation in the N region in a manner similar to the $P-i-N$ rectifier which drastically reduces the resistance of the N region to current flow. This also allows larger current flow via the Schottky region due to a lower series resistance. Because of the existence of the Schottky region, the injection level required to reduce the resistance in the MPS is not as large as that observed in the $P-i-N$ rectifier. As a consequence, the stored charge in the MPS rectifier is much smaller than that in the $P-i-N$ rectifier when they have the

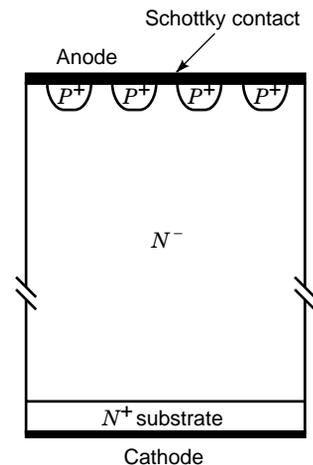

Fig. 152 Basic structure of MPS rectifier. The N^- region is designed to support a high reverse blocking voltage. The purpose of the p^+ region is to enhance the minority carrier injection when the forward voltage is higher than 0.7 V. This p^+ region also reduces the leakage current.

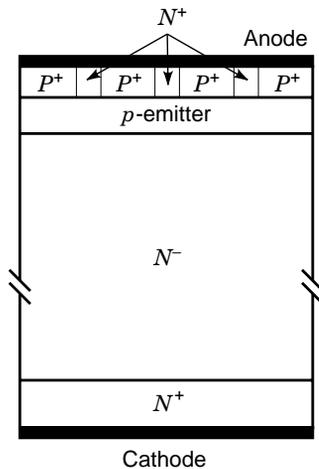

Fig. 153 Basic structure of ESD. Its N^+ short regions reduce the emitter injection efficiency of holes by clamping the peak values of the electron concentration underneath these N^+ regions.

same on-state voltage drop. Consequently, MPS rectifiers have a better reverse recovery characteristic and a superior tradeoff curve between the on state and the turn-off loss than those for $P-i-N$ rectifiers

Emitter Short Diode The emitter short diode (ESD)^{190,191} is an improved $P-i-N$ diode structure proposed for high-voltage and high-speed applications. Figure 153 shows the basic structure of the ESD.

In the ESD structure, additional N^+ short regions are formed on a lightly doped p -emitter layer to reduce the hole injection efficiency and attain asymmetric carrier profile for the N^- region in the on state by control of the junction depth of the N^+ regions. To block a high reverse voltage, a high impurity concentration for the p emitter is needed. However, to reduce emitter injection efficiency, a shallow junction and low impurity concentration for the p emitter are needed. Consequently, the minimum impurity dose of the shallow p emitter should be chosen carefully to block the desired high reverse voltage and avoid the depletion region reaching the N^+ short layers. To reduce the lateral resistance in the p emitter layer under N^+ short regions and avoid the parasitic transistor effect during reverse recovery, the N^+ areas should be formed in a fin pattern.

The ESD reduces the emitter injection efficiency and controls the reverse recovery current behavior by using a shallow p emitter combined with the emitter short structure. It attains half of the reverse recovery current, half of the reverse recovery time, and one-fourth of the reverse charge, when compared to a conventional $P-i-N$ diode. Its leakage current is also as low as a conventional $P-i-N$ diode, even at 125°C.

Synchronous Rectifier With the increasing requirement in applications such as computers for power supplies for even lower supply voltage, the conduction loss in the output rectifier becomes the biggest source of power loss in switching power supplies. Even the commonly used Schottky diodes have a relatively large voltage drop and, hence, a large power loss in such low-output-voltage applications. Consequently, low-voltage MOSFETs, which operate in the third quadrant, with a very low on-state resistance and fast switching speed can be used to replace the diodes in the output stage. Because the gate signal to the low-voltage power MOSFET is provided in synchronism with the drain-source voltage to maintain low on resistance in one direction and blocking state in another direction, the low-voltage power MOSFET in these applications is called a synchronous rectifier (SR).^{186,192,193} Low-voltage power MOSFETs are successfully used as SR, because of their linear $V-I$ characteristic. The conduction loss can therefore be reduced to a very low value by paralleling more MOSFETs. The SR is also fast because it is a majority carrier device.

11.3 Switches

A switch, in semiconductor terms, is a device that has two states for current flow in the same direction—a low-impedance state (ON state) and a high-impedance state (OFF state). Switching between these two states can be controlled by voltage, current, temperature, or light.

Bipolar Power Transistor Bipolar power transistors have been commercially available for more than 30 years. They were favored for low and medium power applications because of their faster switching capability. The rating for bipolar power transistors grew steadily until the end of the 1970s, when power MOSFET started to appear in the market.

Figure 154 shows the cross-sectional view of a bipolar power transistor cell and its circuit symbol. Although the operating physics for bipolar power transistors is essentially the same as that for signal transistors, their characteristics differ because they need to support a high collector voltage in the forward blocking mode. The high voltage capability of the bipolar power transistor is obtained by incorporating a high resistive, thick N^- region into the collector structure. In addition, the base region must be carefully designed to prevent punch-through breakdown. These differences strongly influence the current gain of the device.

Another distinguishing feature of bipolar power transistors is that they operate at relatively high current densities in the saturation region when both the emitter and collector junction are forward biased. This produces high-level injection not only in the base but also in the collector region. The high-level injection results in severe degradation of the current gain. In general, bipolar power transistors have a low current gain at typical operating current levels. Since the

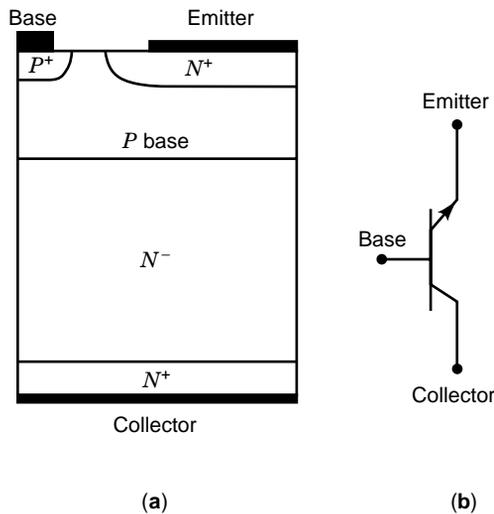

Fig. 154 (a) Cross-sectional view of a bipolar power transistor cell and (b) its circuit symbol.

bipolar power transistor is fundamentally a current-controlled device, with the magnitude of the collector current determined by the base drive current, a low current gain means a bulky and expensive control circuit requiring many discrete components in applications. Consequently, one of the most critical design goals has been to improve the current gain in order to reduce the complexity, size, and weight of the base control circuit. Unfortunately, achieving a high current gain conflict with the achievement of high breakdown voltage. Further, the fall-off in current gain at typical operating current densities due to high injection level leads to a gain of less than 10. The current gain can be improved by using the Darlington power transistor, but this has the disadvantage of considerably increasing the on-state voltage drop.

In addition, the devices are prone to failure due to the second breakdown phenomenon. This occurs because of the affinity for the formation of a local region in the emitter through which the current tends to constrict itself. It appears on the output characteristic of the power bipolar transistor as a precipitous drop in the collector-emitter voltage at large collector currents. As the collector voltage drops, there is a significant increase in the collector current and a substantial increase in the power dissipation. What makes this situation particularly dangerous for the power bipolar transistor is that the dissipation is concentrated in highly localized regions where the local temperature may grow very quickly to unacceptably high values because of the positive feedback relationship between the current and the temperature within the power bipolar transistor. If this situation is not terminated quickly, device destruction results. This positive feedback relationship between the current and the temperature also

means that power bipolar transistors are difficult to parallel. For these reasons, the bipolar power transistor has been displaced by the power MOSFET for high-speed, low-power applications in the 1980s, and for medium-power applications by the IGBT in the 1990s.

Darlington Power Transistor Figure 155 shows the cross-sectional view of a monolithic Darlington power transistor¹⁹³ and its equivalent circuit. In this structure, two transistors have a common collector connection, and the emitter of the drive transistor (T_1) is connected to the base terminal of the output transistor (T_2). The base drive current (I_B) is supplied to the drive transistor. This current turns “on” the transistor T_1 , which then provides the base drive current for transistor T_2 . Consequently, the current gain of the Darlington power transistor, β , is approximately equal to the product of the current gain of the drive transistor (β_1) and the current gain of the output transistor (β_2). That is

$$\beta = \beta_1 \beta_2$$

However, in order to turn on the output transistor T_2 , it is necessary to raise the potential of the collector. Thus, the on-state voltage drop of the Darlington power transistor is higher than that of a single bipolar power transistor.

The Darlington power transistor was the only switching power device with a fast switching speed to deliver several hundred amperes of current and up to 1000 V before the appearance of insulated-gate bipolar transistors (IGBTs). These power Darlington transistors were also called giant transistors (GTRs). Darlington power transistor can be in the form of a monolithic device, such as that shown in Fig. 155; it can also be formed by multichip packaging technique, commonly known as power module.

Thyristor A thyristor is loosely defined as a device having a four-layer $P-N-P-N$ structure, leading to bistable behavior, that can be switched between a high-impedance, low-current OFF state and a low-impedance, high-current ON state. In the past, the thyristor was also commonly called the semiconductor-controlled rectifier or the silicon-controlled rectifier (SCR). The basic structure of the thyristor and its equivalent circuit are illustrated in Fig. 156.

As shown in Fig. 156a, a thyristor consists of four semiconductor layers ($P-N-P-N$). The N^- layer is lightly doped and supports a high voltage when the device is in its blocking state, with junction J_1 or J_2 reverse biased. Thyristors hence offer both forward and reverse blocking capability of comparable magnitude. This makes them well suited for ac circuit applications. Thyristors are now available with ratings of 10 kV and 6 kA. These devices are manufactured from single 10–12.5-cm diameter wafers by using a matured deep diffusion process with gallium and aluminum as dopants. High breakdown voltages are

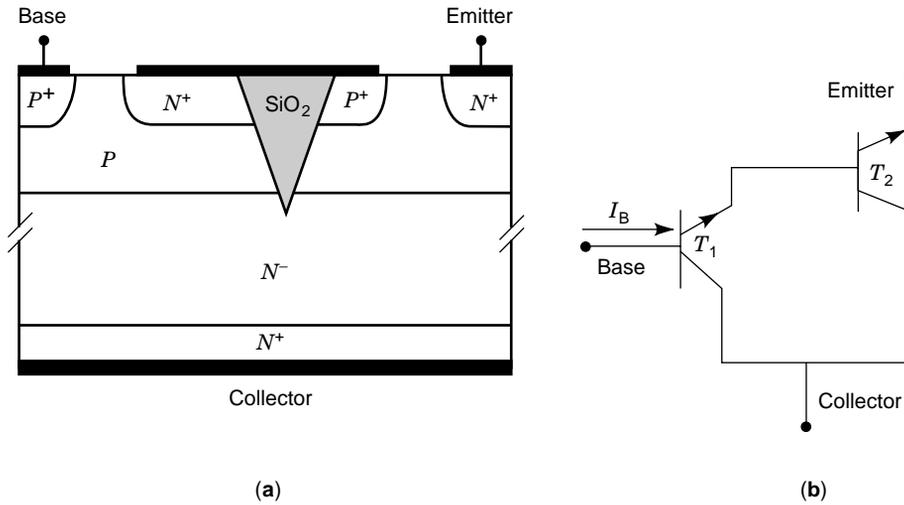

Fig. 155 (a) Cross-sectional view of the monolithic Darlington power transistor and (b) its equivalent circuit.

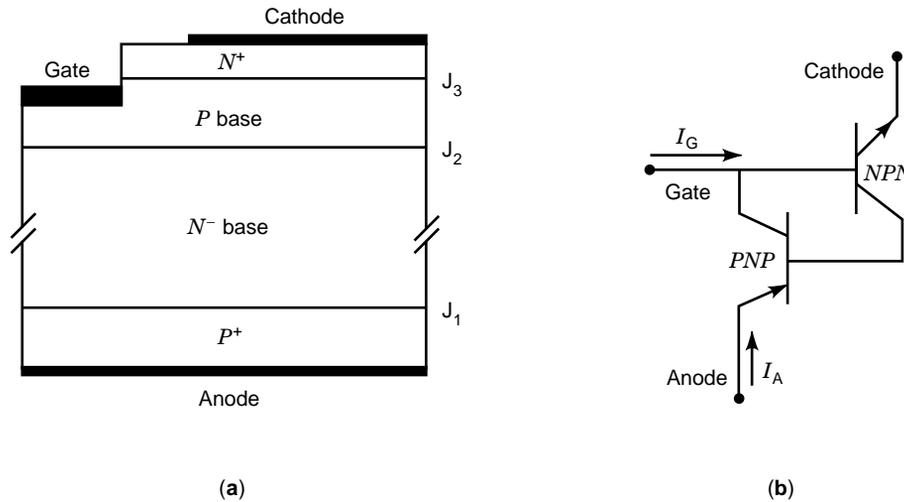

Fig. 156 (a) Basic structure of the thyristor and (b) its equivalent circuit.

realized by using positive and negative bevel etching techniques at the edge of the wafer. An SCR typically only has a few gate fingers so device turn off relies on forced commutation in ac circuits.

From Fig. 156b it is clear that a thyristor can be bisected into a $P-N-P$ and an $N-P-N$ bipolar transistor, with each base connected to the other's collector. Consequently, the anode current I_A can be described by

$$I_A = \frac{\alpha_{NPN} I_G + (I_{co1} + I_{co2})}{1 - (\alpha_{NPN} + \alpha_{PNP})}$$

where α_{NPN} and α_{PNP} are current gains of the $N-P-N$ and the $P-N-P$ bipolar transistors, respectively. I_{co1} and I_{co2} are leakage currents of the $N-P-N$ and the $P-N-P$ bipolar transistors, respectively. In the blocking state, the sum of $\alpha_{NPN} + \alpha_{PNP}$ is much smaller than unity and I_G is zero so that the anode current can be kept quite small. If the sum of $\alpha_{NPN} + \alpha_{PNP}$ approaches unity, the anode current will be arbitrarily large.

For turning on the SCR, a small triggering current is required at the gate. This gate drive current serves to turn on the $N-P-N$ bipolar transistor and

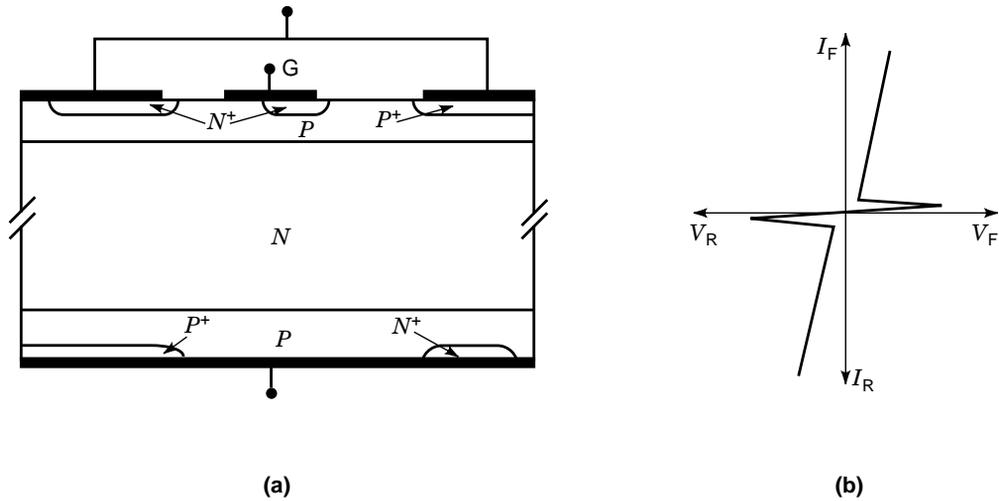

Fig. 157 (a) Basic structure of a TRIAC and (b) its output characteristic.

increases the current gain. Once the current gains of the two transistors within the thyristor structure become sufficiently large, the two transistors can provide the base drive currents for each other and the thyristor enters self-sustaining mode. This mode is referred to as regenerative mode, or as latch-up state.

Because thyristors operate in the latch-up mode, they have very low conduction loss. However, it is difficult to turn off a thyristor. In the case of a conventional thyristor structure, the device is primarily used in ac circuits where the anode voltage periodically reverses to force the current to decrease to zero.

A light-triggered thyristor is a thyristor that can be directly triggered via an optical signal. It is useful for high-power systems, such as the high-voltage direct-current (HVDC) transmission system, because the control system is isolated from the power stage.

TRIAC A TRIAC (triode ac switch)¹⁸⁶ is a semiconductor device with bi-directional voltage blocking capability and bi-directional current conduction capability. Figure 157 shows a basic TRIAC structure with a single control gate electrode and its output characteristic. It is clear that this structure has two back-to-back thyristors integrated monolithically in an antiparallel configuration

GTO Thyristor The gate turn-off (GTO) thyristor is similar to the SCR in device structure but has gate current turn-off capability. Figure 158 shows the vertical cross-sectional view of the GTO. It has the basic $P-N-P-N$ four-layer structure of the SCR. In order to have more efficient gate-controlled turn off, during the on state the base current of the $N-P-N$ bipolar transistor and the collector current of the $P-N-P$ bipolar transistor have to be minimized. This demands that $\alpha_{NP} \gg \alpha_{PN}$. Consequently, in the GTO

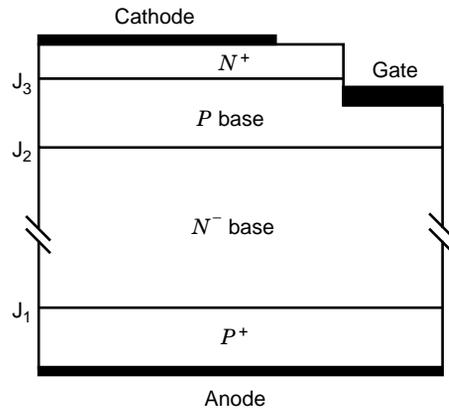

Fig. 158 Vertical cross-sectional view of the GTO structure. Structure of the GTO is similar to that of the thyristor, but it has a much narrower emitter cell width than that of the thyristor so as to improve its gate-controlled turn-off capability.

structure, the thickness of the P base layer is generally somewhat smaller than that in an SCR structure. Another significant difference between a GTO and an SCR is that a lot of gate fingers are placed next to the cathode emitter in an interdigital fashion. The basic goal is to maximize the periphery of the cathode and minimize the distance from the gate to the center of the cathode region.

In the GTO, a negative gate current, I_G , alone is able to turn off the thyristor without forced commutation. A large reverse gate drive current extracts charges from the base region of the upper transistor

and disrupts the self-sustaining current conduction mechanism in the GTO. I_A/I_G is defined as the turn-off gain, β_{off} , where I_A is the anode current. For successful turn off, β_{off} has to satisfy

$$\beta_{\text{off}} \leq \frac{\alpha_{NPN}}{\alpha_{PNP} + \alpha_{NPN} - 1}$$

Typical values for turn-off gain range between 5 and 10.

The main advantage of the GTO thyristor is the elimination of an external circuit for forced commutation, which provides increasing flexibility in circuit applications. Another advantage is a smaller turn-off time and the capability for the higher speed operation compared to that of the SCR. The disadvantage is the large gate currents required for turn on and turn off of the GTO. The GTO is the only commercially available device today with the ability to block 8 kV and control over 6 kA for applications such as traction control. The fabrication process of the GTO is similar to that of the SCR.

The main problem that limits the application of GTOs is that they require a complicated and expensive gate drive to turn off GTOs. Not only is a large negative gate current required but also a high di_G/dt for that negative gate current. The latter is crucial to ensure that each segment in the GTO turns off uniformly. Otherwise, the GTO could be destroyed permanently due to a process called current filamentation, in which a slow gate turn-off current only turns off some of the GTO cells, forcing all of the anode current to crowd around a few cells or even a single cell, hence destroying the device through a very high localized power

dissipation. A large snubber is therefore routinely used in GTO applications to solve this problem.

SIT The static induction transistor (SIT)¹⁹⁴ was introduced in 1972 and began to be produced in the market in the mid-1980s as a switching power device. Several structures of the SIT are shown in Fig. 159. The buried gate structure is the original proposed scheme, while the planar gate structure and the recessed gate structure are more popular. In an SIT structure, the gate and source regions are highly interdigital. Thousands of these basic gate-source cells are connected in parallel to make up a single SIT. The most critical parameters in an SIT are the spacing between gates and the channel doping level. Since most SITs are designed as “normally on” devices, the doping is chosen such that the depletion regions from the gates do not merge, and there exists a narrow neutral channel opening at zero gate bias. The gates in SITs are formed normally by $P-N$ junctions, but the SIT operations can also be generalized to include metal (Schottky) gates, or even metal-insulator-semiconductor (MIS) gates. Normally off SITs are also being fabricated by using very narrow channel design.

The SIT is basically a JFET or MESFET with supershort channel length and with multiple channels connected in parallel. As a result of short channel length, punch-through occurs with high drain bias even if the transistor is originally turned off (static induction is equivalent to punch-through). The output characteristics of a normally on SIT are shown in Fig. 160. These characteristics are quite different from those of a bipolar transistor and are often referred to as

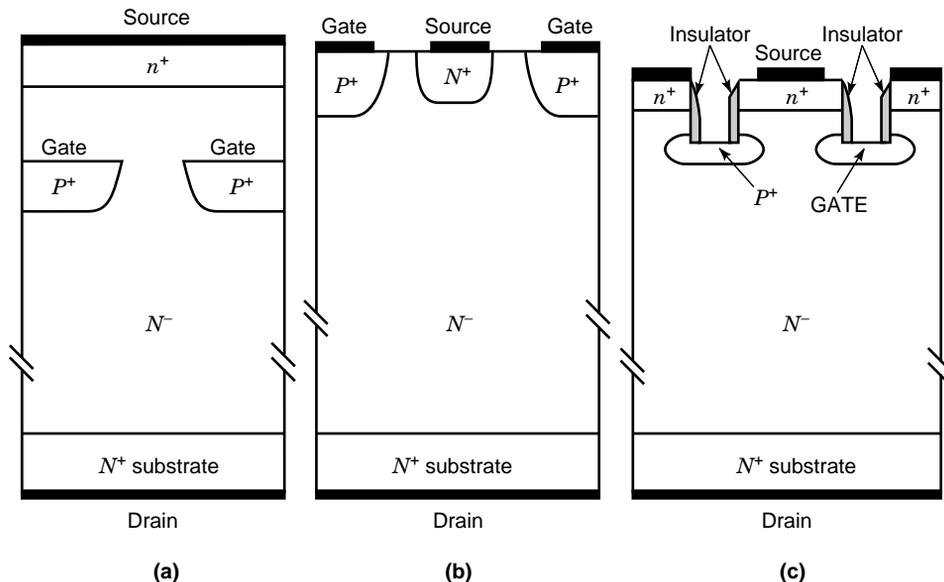

Fig. 159 Structure of SIT with (a) buried gate, (b) planar gate, and (c) recessed gate.

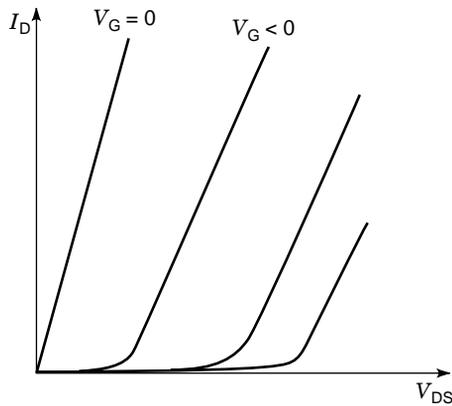

Fig. 160 Output characteristics of the normally on SIT. These I - V curves are very different from those of a bipolar transistor and similar to a triode. The SIT typically conducts current when the gate voltage is zero. This type of device is called a “normally on” device.

triodelike characteristics because of their resemblance to the I - V characteristics of a vacuum triode.

As shown in Fig. 160, when a positive bias is applied to the drain, the normally on SIT is in the on state when the gate-source voltage is zero. The current conduction is adrift in nature and is similar to a JFET. When a reverse bias is applied to the gate, the depletion layers widen, and pinch off the channel. The depletion layers set up a potential barrier to the flow of the drain electron current. As a consequence, there will be no flow of current between drain and source as long as the drain-source voltage is kept small. This is the off state of the SIT. As the drain-to-source bias voltage, V_{DS} , increases, the potential barrier to the drain current flow gets smaller and smaller. When V_{DS} is large enough to suppress the potential barrier set up by the gate-source bias voltage, current begins to flow again and increases with the increase of the V_{DS} .

The main attractiveness of an SIT is the combination of high-voltage and high-speed capability. Its cut-off frequency can be up to 2 GHz.¹⁹⁴ As an audio power amplifier the SIT has low noise, low distortion, and low output impedance. It can be used in high-power oscillators of microwave equipment, such as broadcasting transmitters and microwave ovens. As switching power devices, SITs are limited by their normally on characteristic and because power MOSFETs, developing concurrently with SITs, are superior to SITs in switching power applications due to their fast speed, high input impedance, and normally off characteristic. SITs are also difficult in scaling up to high voltages, not only because the conduction loss will increase but also because a large negative gate bias is needed to block higher voltage. A factor commonly defined as forward-blocking voltage gain is defined as the change of the blocking voltage V_{DS} induced by the change

of V_G for the same drain current. High-voltage SITs typically have a blocking gain of less than 20.

SITH The static induction thyristor (SITH) is also called the field-controlled thyristor (FCT). The SITH was introduced in the mid-1970s with the aim to reduce the conduction loss of high-voltage SITs. Although the SITH is commercially available as a power device, its performance is superseded by the IGBTs.

The structure of the SITH is similar to that of the SIT with a P^+ anode replacing the N^+ drain. The basic structures of the SITH with planar gates, buried gates, and double gates are shown in Figs. 161*a*, *b*, and *c*, respectively. It is clear that the SITH consists of a P - i - N diode with part of the channel surrounded by closely spaced junction grids or gates. There are two types of SITH—normally on SITH and normally off SITH. In the normally on SITH, pinch-off of the channel does not occur with zero gate voltage, and a high current can flow. In the normally off SITH, the depletion regions of the nearby gate merge, and the pinch-off occurs at zero gate voltage. The output characteristics for a normally on SITH are shown in Fig. 162.

In the normally on SITH, at zero gate bias or small positive gate bias, the depletion regions around the gates do not pinch off the gap completely. The current conduction from anode to cathode is similar to that of a P - i - N diode. At a forward-biased voltage V_{AK} , electrons are injected from the cathode and holes are injected from the anode, and they are equal in number to maintain charge neutrality. These excess electrons and holes increase the conductivity of the N^- layer. Note that although the output characteristics are similar in shape to those of the SIT, the P^+ anode can inject holes and enable conductivity modulation, resulting in a lower forward voltage drop or lower on resistance.

With a larger reverse gate bias, the depletion layers extend, pinch-off of the channel is introduced, and a barrier for electrons is formed. This barrier limits the electron supply and becomes the controlling factor for the overall current. Without an ample electron supply, the hole current reduces to leakage generation current and becomes insignificant. The SITH enters the forward blocking state.

In the SITH structure, the channel barrier height can be influenced by the gate voltage as well as by the anode voltage. A large forward anode bias V_{AK} can lower this barrier height. This dependence of the barrier height on the forward anode bias is called static induction. Static induction current is basically a punch-through current due to the thin and small barrier in the direction of current flow.

One useful parameter for the SITH is the forward-blocking voltage gain, which is defined as the change of the blocking voltage V_{AK} induced by the change of V_G for the same anode current. The forward-blocking voltage gain depends on the structure of the gates and the channel doping.

One of the advantages of the SITH when compared with GTOs is its higher speed of operation due to a

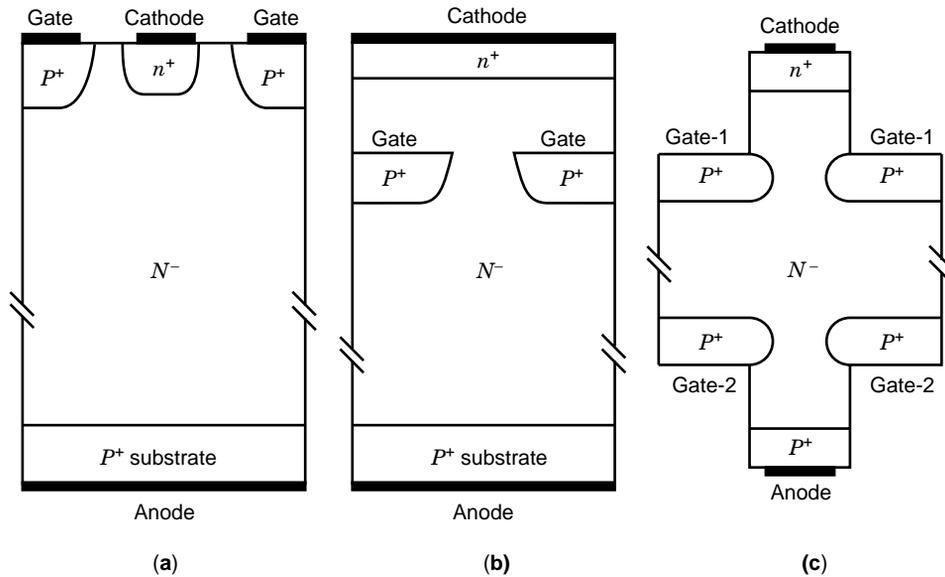

Fig. 161 Structure of SITH with (a) planar gates, (b) buried gates, and (c) double gates.

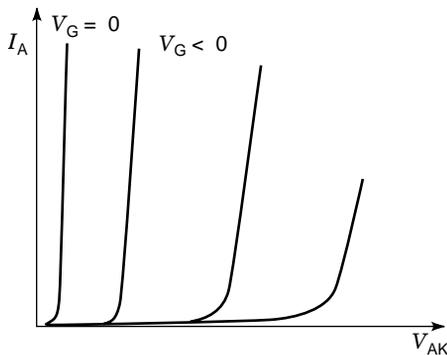

Fig. 162 Output characteristics of normally on SITH.

faster turn-off process. During turn off, the reverse gate bias can extract the excess minority carriers (holes) quickly. The excess electrons, being majority carriers in the N^- region, can be swept away quickly by the drift process. The hole current contributes to an instantaneously large gate current, and a small gate resistance is critical to avoid gate debiasing. An alternate technique to reduce the turn-off time is to reduce the minority carrier lifetime by lifetime control technique. The penalty for using this technique is a larger forward voltage drop.

In the SITH structure, the planar gate structure has a lower gate resistance since a metal contact can be deposited directly over it. This results in a smaller debiasing effect during the turn-off process

when there is a substantial current through the gate. The advantage of the buried gates structure is a higher forward blocking voltage gain resulting from a more efficient use of the cathode area and a more effective gate control of the current. The double-gate SITH is capable of higher speed than the single-gate structure, but it has a more complicated fabrication process.

Because of the fast turn-off capability, SITHs with an operating frequency up to 100 kHz are possible. With a high forward-blocking voltage gain of up to 700, stable operation at high temperature, and large dI/dt and dV/dt capabilities the SITHs have been applied mainly in power source conversion such as ac-to-dc converters, dc-to-ac converters, and chopper circuits. Other applications of the SITH include pulse generation, induction heating, lighting of fluorescent lamps, and driving pulsed lasers.

The main problem for the SITHs is similar to that of the GTOs, in that a large and expensive gate drive circuit has to be provided. Because of the nature of their planar and shallow junction process, the SITHs have not reached the power ratings of GTOs. They are, therefore, seriously challenged by the IGBTs in the medium power range, because IGBTs have many of the SITHs advantages plus a simple control interface owing to their high input impedance.

Power MOSFET Prior to the development of the power metal-oxide-semiconductor field-effect transistors (power MOSFETs), the most favorable device available for high-speed, medium-power switching applications was the power bipolar transistor. But the power bipolar transistors exhibit several fundamental

drawbacks in their operating characteristics, such as that they are current-controlled devices and are difficult to parallel. In order to suppress these performance limitations, the power MOSFET was developed in the 1970s due to the advancement of VLSI technology.

In the power MOSFET, the control signal is applied to a metal (or polysilicon) gate electrode that is separated from the semiconductor surface by an intervening insulator (typically silicon dioxide). Thus, the power MOSFET has a very high input impedance in steady state, and it is classified as a voltage-controlled device that can be controlled using integrated circuits because of the small gate currents that are required to charge and discharge the input gate capacitance. Even during the switching of the devices between the ON and OFF states, the gate current is small at typical operating frequencies of less than 100 kHz because it serves only to charge and discharge the input gate capacitance. When the operating frequency becomes high (>100 kHz), this capacitance current can become significant but it is still possible to integrate the control circuit due to the low gate bias voltages (typically 5–15 V) required to drive the device into its on state with a low forward voltage drop.

In comparison with the bipolar transistor, the power MOSFET is a unipolar device, it therefore has a very fast switching speed due to the absence of minority carrier injection. The switching time for the MOSFET is dictated by the ability to charge and discharge the input capacitance rapidly. This feature is particularly attractive in circuits operating at high frequency, where switching power loss is dominant. Further, the power MOSFET has superior ruggedness and has been found to display an excellent safe-operating area (i.e., they can withstand the simultaneous application of high current and voltage without undergoing destructive failure).

These characteristics of power MOSFETs make them important candidates for many applications such as high-frequency power conversion and lamp ballasts. Three discrete vertical channel power MOSFET structures are described.

VVMOS (VMOS). The vertical V-shaped groove MOSFET (VVMOS or VMOS) was the first commercial structure of power MOSFET developed in the 1970s. The VVMOS structure is shown in Fig. 163. This structure is based on the V-shaped groove by anisotropically etching in a (100) silicon substrate within which the gate is located along the (111) planes extending through the *P* layer. It can be fabricated by first performing an unpatterned *P*-region diffusion followed by the N^+ source region diffusion. A V-shaped groove extending through these diffusions is then formed by using preferential etching with potassium-hydroxide-based solutions. For an aluminum gate VMOS, the gate oxidation layer is grown and the gate electrode is then deposited and patterned. The channel region for this structure is formed along the walls of the V-groove. This structure can therefore

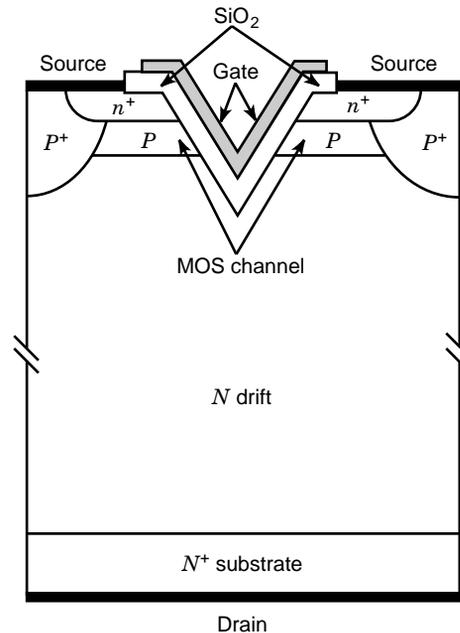

Fig. 163 Cross section of the VVMOS structure. The V-shaped groove is formed by anisotropically etching a (100) silicon substrate. The MOSFET channel region is formed along the walls of the V-groove and can therefore provide short channel length without fine lithography capability. The vertical current flow also maximizes the total current for a given surface area. The drawback of this structure is that a strong electric field peak exists at the V groove corner when a high drain voltage is applied.

provide short channel length without fin lithography capability, and the vertical current flow also maximizes the total current for a given surface area.

For the *N*-channel structure shown, when a positive bias larger than the threshold voltage of the MOSFET is applied to the gate electrode, an inversion layer forms along the V-groove and the channel is turned on. When a positive bias voltage is applied to the drain, electrons flow from the N^+ source via the MOSFET channel into the drift region and are then collected by the N^+ drain. When the gate voltage is lower than the threshold voltage of the MOSFET, the device is in the forward blocking state and can support a high drain voltage across the *P*-body/*N*-drift junction.

Because the gate of the VVMOS is located in the V-groove formed by the preferential etching, there are instabilities in the threshold voltage during manufacturing. In addition, the sharp tip at the bottom of the V-groove creates a high electric field during the forward blocking state, which degrades its breakdown voltage. Furthermore, the mobility of the carrier on a (111) etched slope is somewhat lower. For these reasons, the VVMOS has been displaced by the VDMOS

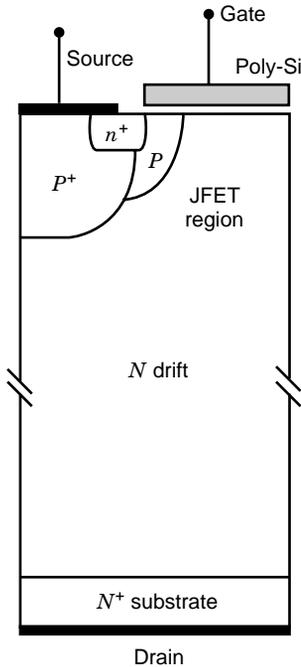

Fig. 164 Cross section of the VDMOS structure. This VDMOS is fabricated by using planar diffusion technology with a refractory gate as a mask. The double-diffusion process forms the channel laterally and enables fabrication of submicrometer channel length without resorting to high-resolution lithography.

structure based on the double-diffusion MOS (DMOS) process.

VDMOS. The vertical double-diffusion MOSFET (VDMOS) is the most popular power MOSFET structure. Figure 164 shows the cross section of one-half of a VDMOS cell structure. This VDMOS is fabricated by using planar diffusion technology with a refractory gate, such as polysilicon, as a mask. The P region and the N^+ source region are diffused through a common window defined by the edge of the polysilicon gate. The name for this device is derived from this *double-diffusion process*. The P region is driven deeper than the N^+ source region, hence defining the surface channel region. This process enables fabrication of a submicrometer channel length without resorting to high-resolution lithography. A commercial VDMOS chip contains millions of such VDMOS cells in parallel, with a common gate control.

For an N -channel VDMOS, the device operates with a positive voltage applied to the drain. When the gate voltage is lower than the threshold voltage of the DMOS, the device can support a high drain voltage across the P -region/ N -drift region junction. The forward blocking capability is determined by the breakdown characteristic

of the P -region/ N -drift junction. The voltage blocking capability of the VDMOS is better than that of the VVMOS because the field distribution in the cell region is essentially one dimensional. When the gate voltage is higher than the threshold voltage of the DMOS, the surface channel is turned on, and electrons will flow from the source via the channel into the drift region and then bend 90° before being collected by the drain.

The conduction loss of the VDMOS is specified by the on resistance. The on resistance is an important device parameter because it determines the maximum current rating. The specific on resistance, defined as the on resistance per unit area, is a preferable parameter in the design of the VDMOS. The on resistance of the VDMOS consists of the N^+ source resistance, the channel resistance, the accumulation layer resistance under the polysilicon gate, the JFET region resistance, the drift region resistance, the substrate resistance, and the contact resistance.

A tradeoff between the forward blocking voltage and the specific on resistance exists for the VDMOS and other unipolar devices such as the SIT. A high forward blocking voltage needs a lightly doped and thick drift region, hence creating a large specific on resistance. This tradeoff relationship can be described by:

$$R_{\text{drift, specific}} = \frac{4BV^2}{\epsilon_s \mu_n E_c^3}$$

where ϵ_s is the dielectric constant of the silicon, μ_n is the electron mobility, BV is the breakdown voltage, and E_c is the critical electric field at avalanche breakdown. Because of this tradeoff, the VDMOS usually are designed to operate at high-voltage, low-current levels or low-voltage, large-current levels.

The forward voltage drop or the on resistance in the VDMOS increases with the increase of temperature; therefore, VDMOSs can be easily paralleled. This characteristic of VDMOSs makes them important candidates for many applications. The VDMOS is a unipolar device; current conduction occurs via transport of majority carriers in the drift region without the minority carrier injection required in bipolar transistor operation. Thus, the VDMOS has a faster switching speed than bipolar transistors. This feature is particularly attractive in circuits operating at high frequencies, where switching power losses are dominant.

UMOS (Trench-Gate MOSFET, UMOSFET). The UMOS structure is shown in Fig. 165. The name for this structure is derived from the U-shaped groove formed in the gate region by using RIE. The fabrication of this structure can be performed by following the same sequence as the VVMOS structure with the V-groove replaced by the U-groove. The U-groove structure has a higher channel density than either the VMOS or DMOS structures, which allows significant reduction in the on resistance of the device. The technology for the fabrication of this structure was derived

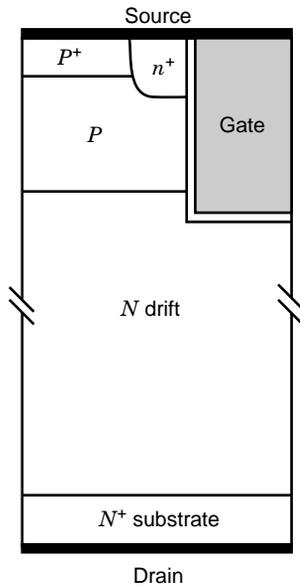

Fig. 165 Cross section of the UMOS structure. A U-shaped gate region is formed by using reactive ion etching (RIE) followed by gate oxidation and polysilicon refill. The UMOSFET has a higher channel density than either the VMOS or DMOS structure, resulting in the lowest on-resistance per unit silicon area.

from the trench etching technique developed for memory cells in DRAMs.

In the UMOS structure, the UMOS cell size can be made relatively small ($6\ \mu\text{m}$) when compared with the DMOS cell ($20\ \mu\text{m}$) for the same design rules. This results in an increase in the channel density (channel width per square centimeter of device area). In the UMOS structure, no JFET region exists. The on-resistance of the UMOS consists of the N^+ source resistance, the channel resistance, the drift region resistance, the N^+ substrate resistance, and the contact resistance. Unlike the DMOS structure, there is no optimum design for the UMOS cell. In this case, it is beneficial to reduce the mesa and trench width as much as possible. As these dimensions become smaller, the channel resistance contribution becomes smaller because the channel density increases. Therefore, the UMOS has the lowest specific on-resistance in power MOSFETs. Using UMOS structure, however, will not reduce the on-resistance of the drift region, hence, UMOS structure is only beneficial for low-voltage power MOSFETs.

Figure 166 shows a modified UMOS structure with a deep trench, which has a very low specific on-resistance approaching the limits for silicon FET performance.¹⁹⁵ In this structure, the trench extends down to the N^+ substrate, and the drift region resistance component of the on-resistance is reduced by the

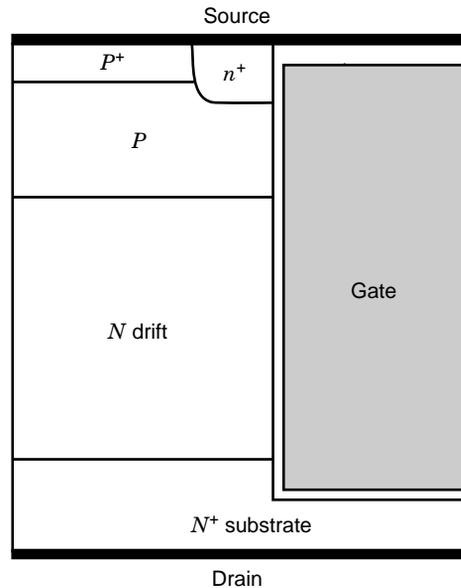

Fig. 166 Cross section of deep-trench UMOS. This structure extends the trench down to the N^+ substrate, and the drift region resistance component of the on-resistance is reduced by the parallel current flow path of an accumulation layer on the sidewall of the trench.

parallel current flow path created by the formation of an accumulation layer on the sidewall of the trench. But it must be noted that the blocking voltage of this structure is limited to less than 30 V by the high electric field created in the gate oxide by the extension of the trench into the N^+ substrate.

Low breakdown voltage power MOSFETs ($<30\ \text{V}$) are also successfully used as synchronous rectifier because their conduction losses can be reduced to even lower than those of the SBDs because of their linear $V-I$ relationships.¹⁹⁰

IGBT The name insulated-gate bipolar transistor (IGBT) comes from its operation based on an internal interaction between an insulated-gate FET (IGFET) and a bipolar transistor. It has also been called previously an IGT (insulated-gate transistor), an IGR (insulated-gate rectifier), a COMFET (conductivity-modulated field-effect transistor), a GEMFET (gain-enhanced MOSFET), a BiFET (bipolar FET), and an injector FET. IGBTs have been successfully used since they were first demonstrated in 1982.

The IGBT is an important power switch used in converters with ratings up to several hundred kilowatts. A cross section of the planar DMOS-technology-based IGBT structure is shown in Fig. 167a. It is clear from Fig. 167a that the IGBT structure is similar to that of the VDMOS from the fabrication point of view. This has made its manufacturing relatively easy

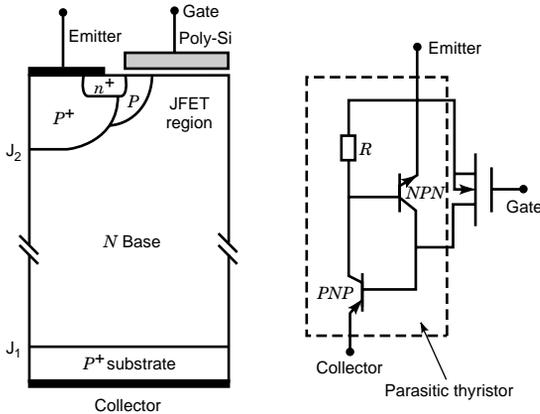

Fig. 167 (a) Cross section of the IGBT structure and (b) its equivalent circuit. The IGBT structure is similar to that of the VDMOS except that a p^+ collector is used to replace the n^+ drain in the VDMOS. This p^+ collector can inject holes into the N base to modulate the conductivity and improve the forward current capability during the forward conduction. The introduction of such p^+ layer results in a vertical $P-N-P$ transistor, which in turn forms a parasitic thyristor with the parasitic $N-P-N$ transistor.

immediately after conception and its power rating has grown at a rapid pace due to the ability to scale up both the current and the blocking voltage.

The equivalent circuit for the IGBT, shown in Fig. 167b consists of a wide-base $P-N-P$ bipolar transistor driven by a short-channel MOSFET. This $P-N-P$ transistor has a long base region, and therefore a very low current gain. A parasitic $N-P-N$ transistor also exists in the IGBT, which forms a parasitic thyristor with the $P-N-P$ transistor. In the IGBT structure, when a positive bias voltage larger than the threshold voltage of the DMOS is applied to the gate electrode, an inversion layer is formed along the P -base surface of the DMOS, and the DMOS channel is turned on. When a positive bias is applied to the collector, electrons flow from the N^+ emitter via the DMOS channel into the N^- region. This provides the base drive current for the wide-base vertical $P-N-P$ transistor in the IGBT structure. Since the emitter junction (J_1) for this bipolar transistor is forward biased, the P^+ substrate injects holes into the N^- base region. When the positive bias on the collector terminal of the IGBT is increased, the injected hole concentration increases and reduces the resistance of the N^- region. Consequently, the IGBT can operate at much higher current densities than the VDMOS even when it is designed to support high blocking voltages.

As long as the gate bias is sufficiently large to produce a strong inversion layer charge of electrons at the N^- base region surface, the IGBT's forward conduction characteristic looks like that of a $P-i-N$ diode. Therefore, the IGBT can also be considered as

a $P-i-N$ diode in series with a MOSFET. However, if the DMOS channel or JFET channel becomes pinched-off and the electron current saturates, the hole current also saturates due to the saturation of the base drive current for the $P-N-P$ transistor. Consequently, the device operates with current saturation in its active region with a gate-controlled output current. This current saturation characteristic is useful for applications in which the device is required to sustain a short-circuit condition.

When the gate voltage is lower than the threshold voltage of the DMOS, the inversion layer cannot sustain and the electron current via the DMOS channel is terminated. The IGBT then operates in the forward blocking mode. A large voltage can then be supported by the reverse-biased P -base/ N -base region junction (J_2). Figure 168 shows the typical output characteristics of the IGBT. Because of the existence of the P^+ collector junction, IGBT also has a reverse blocking capability. Commercial IGBTs, however, are mostly using asymmetric structures, and their reverse blocking voltages are typically very low.

The IGBT was the first commercially successful device based on combining the physics of MOS-gate control with bipolar current conduction. Because of the injection of a high concentration of holes from the P^+ substrate into the N^- drift, the conductivity of the long N^- region is modulated and the IGBT exhibits $P-i-N$ diodelike on-state characteristic with a low forward voltage drop. Thus, the IGBT exhibits excellent current-carrying capability with forward conduction current densities 20 times higher than that of a power MOSFET and 5 times greater than that of a bipolar transistor operating at a current gain of 10. Since the input signal for the IGBT is a voltage applied to the MOS gate, the IGBT has the high input impedance of the power MOSFET and can be classified as a voltage-controlled device. However, unlike the power MOSFET, the switching speed of the IGBT is limited by the time taken to remove the stored charges in the N region due to the injection of holes during on-state current conduction. The turn-off time for the

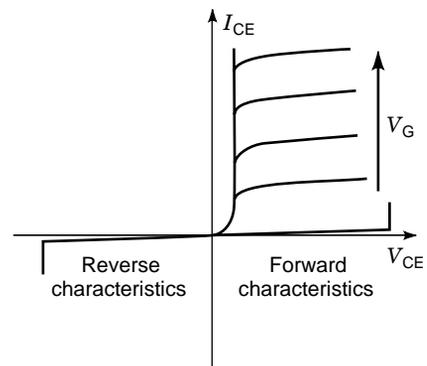

Fig. 168 Output characteristics of the IGBT.

IGBT is dictated by the conduction modulation of the N region and the minority-carrier lifetime. The latter can be controlled by a lifetime control process, such as electron irradiation. Although the lifetime control process can be successful in reducing the turn-off time, it was found that there is a tradeoff between the on-state voltage drop (conduction loss) and the turn-off time (switching loss). A shorter minority-carrier lifetime makes the switching loss of the IGBT lower, but the shorter minority-carrier lifetime also results in a higher conduction loss.

One of the problems encountered when operating the IGBT at high current levels has been the latch-up of the parasitic $P-N-P-N$ thyristor structure inherent in the device structure. Latch-up of this thyristor can occur, causing losses of gate-controlled current conduction. Since the current gains of the $N-P-N$ and $P-N-P$ transistors increase with increasing temperature, the latching current decreases with increasing temperature. This effect is also aggravated by an increase in the resistance of the P base with temperature due to a decrease in the mobility of holes. Many methods have been explored to suppress the latch-up of the parasitic thyristor, such as the use of a deep P^+ diffusion (see p. 454 of Ref. 186), a shallow P^+ diffusion (see p. 456 of Ref. 186), or a self-aligned sidewall diffusion of N^+ emitter.^{196,197} The objective of these methods is to reduce the gain of the parasitic $N-P-N$ transistor to minimal.

Traditionally, IGBTs are fabricated on a lightly doped epitaxial substrate, such as the one shown in Fig. 167a. Because of the difficulty of growing the lightly doped epitaxial layer, the breakdown voltage of this type of IGBT is limited to below 1200 V.

To benefit from such a design, an N buffer layer is normally introduced between the P^+ substrate and the N^- epitaxial layer, so that the whole N^- region can be depleted when the device is blocking the off-state voltage, and the electric field shape inside the N^- region is close to rectangular. This type of design is referred to as punch-through IGBT (PT IGBT), as shown in Fig. 169a. The PT structure allows it to support the same forward blocking voltage with about half the thickness of the N^- base region of the $P-N-P$ transistor, resulting in a greatly improved tradeoff relationship between the forward voltage drop and the turn-off time. Thus, the PT structure together with lifetime control is preferred for IGBTs with forward blocking capabilities of up to 1200 V.

For higher blocking voltages, the thickness of the N -base region becomes too large for cost-effective epitaxial growth. Another type of design, the non-punch-through IGBT (NPT IGBT, as shown in Fig. 169b), is gaining popularity.¹⁹⁸ In the NPT IGBTs, devices are built on an N^- wafer substrate that serves as the N^- base region. The collector is implanted from the backside of the wafer and no field stopping N buffer layer is applied to the NPT IGBT. In this concept, the shape of the electric field is triangular in the forward blocking state, which makes a longer N^- base region necessary to achieve the same breakdown voltage as compared with the PT IGBT. However, the NPT IGBT offers some advantages over the PT IGBT. For instance, the injection efficiency from the collector side can be more easily controlled and devices with voltage ratings as high as 4 kV can be realized. Further, by optimizing the injection efficiency of carriers from the P^+ collector layer and the transport factor of carriers in the N^-

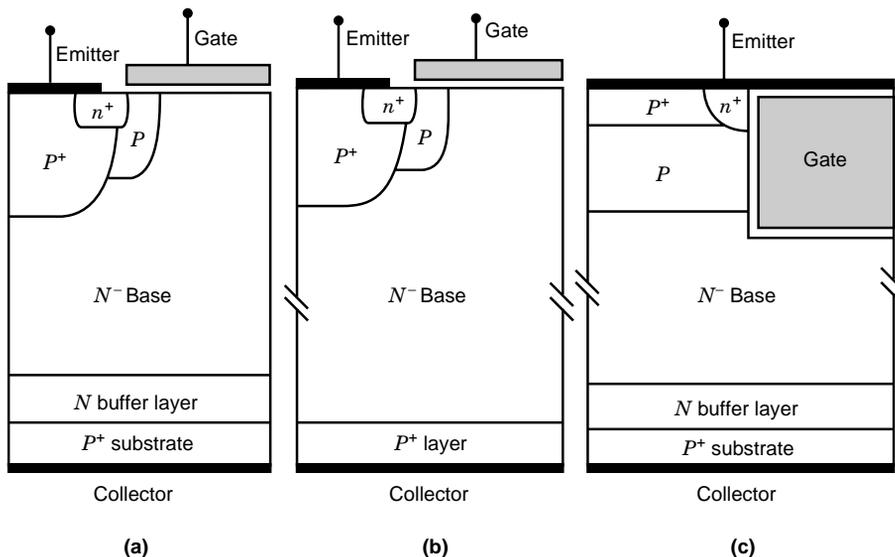

Fig. 169 (a) PT IGBT structure, (b) NPT IGBT structure, and (c) UMOS gate PT IGBT structure.

base, the tradeoff between the forward voltage drop and the turn-off time for the NPT IGBT can be improved to become similar to that of the PT-type IGBT.¹⁹⁹ NPT IGBT is now widely used in high-voltage IGBT design where no lifetime control is used.

Generally speaking, the current tail in the NPT IGBT is longer than the PT IGBT, but the NPT IGBT is more robust than the PT IGBT, particularly under a short-circuit condition.

The trench gate IGBT (trench IGBT, TIGBT, and UMOS gate IGBT) structure²⁰⁰ is shown in Fig. 169c. With the UMOS structure in place of the DMOS gate structure in the IGBT, the channel density is greatly increased and the JFET region between the two adjacent P -base region is eliminated. In addition, the electron-hole concentration is enhanced at the bottom of the trench because an N -type accumulation layer forms. This creates a catenary-type carrier distribution profile in the IGBT that resembles that obtained in a thyristor or P - i - N diode.²⁰¹ These improvements lead to a large reduction in the on-state voltage drop until it approaches that of a P - i - N diode, hence approaching the theoretical limitation of a silicon device. The latching current density of the UMOS IGBT structure is superior to that of the DMOS structure. This is attributed to the improved hole current flow path in the UMOS structure. As shown in Fig. 169c, the hole current flow can take place along a vertical trajectory in the UMOS structure, while in the DMOS structure hole current flow occurs below the N^+ emitter in the lateral direction. The resistance for the hole current that causes the latch-up is determined only by the depth of the N^+ emitter region. A shallow P^+ layer can be used, as shown in the figure to reduce this resistance. As a consequence, the

safe operating area (SOA) of the UMOS IGBT structure is superior to that of the DMOS IGBT structure. Further, because of a very strong percentage of electron current flow in the trench gate IGBT, the turn-off speed of the trench-based IGBT is generally faster than the DMOS-based IGBT. To obtain better trade-off between conduction and switching losses, several improved structures and technologies, such as the carrier injection enhancement,²⁰² local lifetime control by proton irradiation,²⁰³ and p^+/p^- collector region,²⁰⁴ have been proposed for the high-voltage trench IGBT. It can be anticipated that trench gate IGBTs will replace the DMOS IGBT structures in the future.

MCT The MOS-controlled thyristor (MCT)²⁰⁵ is a newer commercially available semiconductor power switch that also combines the physics of MOSFET and bipolar conduction. It is basically a thyristor with two MOSFETs built into the gate structure. One of the two MOSFETs, the ON-FET, is responsible for turning the MCT on, and the other MOSFET, the OFF-FET, is responsible for turning the MCT off. There are two types of MCTs, the N -MCT and the P -MCT, and both combine the low on-state losses and large current-handling capability of a thyristor structure with the advantages of MOSFET-controlled turn on and turn off and relatively fast switching speed. MCTs provide both an easy gate drive, due to the high input impedance of the MOS gate, and a low forward voltage drop, due to the strong conductivity modulation effect of the thyristor structure. They are expected to compete with IGBTs and GTOs in high-power applications.

A cross-sectional view of a single cell of an N -MCT is shown in Fig. 170a. A complete N -MCT is

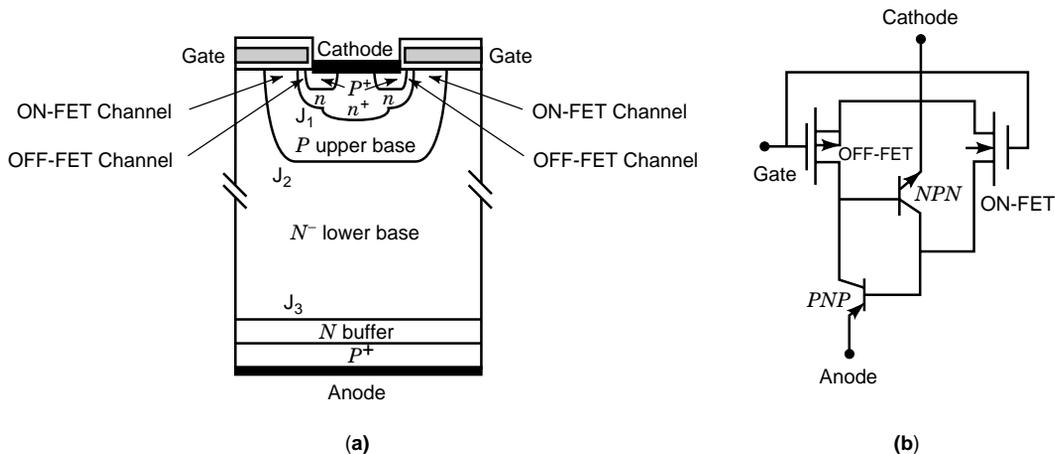

Fig. 170 (a) Cross-sectional view of the MCT cell and (b) its equivalent circuit. The MCT is a five-layer semiconductor device. It is basically a thyristor with two MOSFET channels underneath the gate. One of the two MOSFETs, the ON-FET, is responsible for turning the MCT on, when the gate voltage is positive (such as +15 V), and the other MOSFET, the OFF-FET, is responsible for turning the MCT off, when the gate voltage is negative (such as -15 V).

composed of thousands of these cells fabricated integrally on the same silicon wafer connected in parallel to achieve the desired current rating. The ON-FET density in an MCT can also be adjusted to a suitable percentage of the overall cell density. From Fig. 170, it is clear that the MCT has a four-layer $P-N-P-N$ thyristor structure and a MOS gate controlling both the turn-on and turn-off FETs. When the gate bias is zero or negative, the OFF-FET is turned on to short the upper transistors in the emitter junction. The MCT exhibits a high forward blocking voltage by supporting the voltage across the reverse biased junction J_2 . When a positive bias is applied to the gate electrode, the ON-FET channel turns on and electrons are supplied to the N^- base of the $P-N-P$ transistor. This results in the injection of holes from the P^+ anode into the N^- base region, and they are collected at the reverse-biased junction J_2 . The current in the P upper base created by the collection of holes across junction J_2 acts as the base drive current of the $N-P-N$ transistor, which turns on the $N-P-N$ transistor then triggers the regenerative feedback mechanism between the two coupled transistors within the thyristor structure. The thyristor can therefore be turned on by the application of a positive gate voltage to the MOS electrode.

The MCT can be turned off when a negative bias is applied to the gate electrode because a P channel is formed by the inversion of the N -emitter surface. This provides a path for the flow of holes from the P -base region into the cathode contact that bypasses the N^+ -emitter/ P -base junction. The holes that are flowing into the P -base region when the thyristor was operating in its on state can then be diverted via the P -channel MOSFET into the cathode electrode. This will reduce the current gain of the $N-P-N$ transistor. If the resistance of the P -channel MOSFET is significantly low, a sufficient number of holes are diverted to the cathode by the P -channel MOSFET. The latch-up condition would then be broken and the thyristor would be turned off successfully.

As mentioned previously, there are two types of MCTs, the N -MCT and the P -MCT. The MCT with an N -channel ON-FET is called an N -MCT and the MCT with a P -channel ON-FET is called a P -MCT. A P -MCT can turn off higher currents because of a higher electron mobility in the turn-off N -channel MOSFET compared to that of the N -MCT. Thus, the first two generations of MCTs developed were P -MCTs. On the other hand, applications normally require an N -MCT, because its SOA is larger than the P -MCT's and its bias configuration is compatible with an N -channel IGBT.

An alternative N -MCT structure that uses an N -channel MOSFET for turn off is shown in Fig. 171.²⁰⁶ It has an N -channel OFF-FET and its bias configuration is compatible with an N -channel IGBT. In this N -MCT, a floating ohmic contact (FOC) is used to form the bridge of transferring hole current to electron channel current in the event of device turn-off.

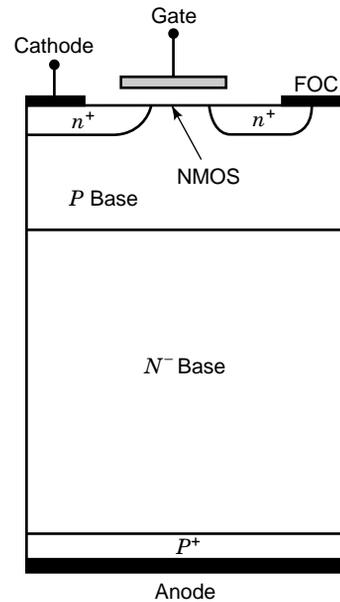

Fig. 171 Cross-sectional view of the N -MCT cell structure. The N -channel MOSFET shorts the upper base via the floating ohmic contact (FOC) to the cathode, resulting in MOS-controlled turn-off.

Figure 172 shows the basic structure of a trench MCT (TMCT) cell based on trench technology.²⁰⁷ The TMCT can have a much smaller cell pitch than its planar counterpart, so it has a much more uniform turn off across the chip. The TMCT has a turn-on-cell–turn-off-cell ratio of 1 without losing silicon area. Thus, the turn-on capability of the TMCT is also expected to be much better than the planar MCT.

Although MCTs combine the advantages of the high input impedance of the MOS gate and the low forward voltage drop of the thyristor, there are some drawbacks limiting the development of the MCT. One is that the MCT has the current filamentation problem during device turn-off that can destroy the device because of internal regenerative action and the negative temperature coefficient for the on-state voltage within the thyristor. Even if a uniform turn-off is possible, the OFF-FET channel resistance will limit the maximum turn-off current and hence the SOA of the MCT. Further, the MCT lacks the ability to saturate the anode current level, making it a fundamentally different device than the IGBT from an application viewpoint. Consequently, a number of new MOS-gated thyristors are currently being developed and studied, and commercialization of some of these newer devices is expected in the future.^{208,209}

Table 34 lists the major electric characteristics of the switches.²¹⁰ These switches are all based on silicon material.

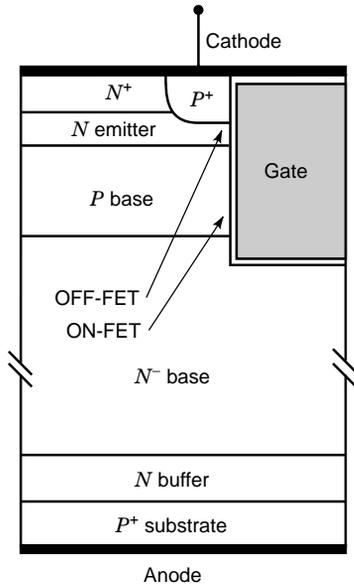

Fig. 172 Basic structure of trench MCT cell.

11.4 Integrable Lateral Power Devices

LDMOS The lateral double-diffusion MOSFET (LDMOS) was one of the first integrable lateral power devices developed and find wide use in power ICs (PICs).^{211,212} A schematic diagram of the cross section

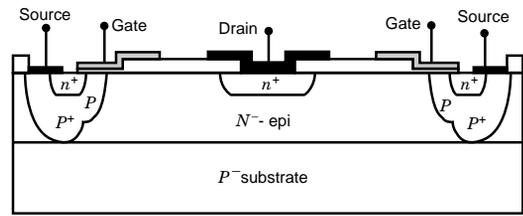

Fig. 173 Cross-sectional view of the RESURF LDMOS. The LDMOS is a lateral version of the VDMOS, with all three electrodes on the substrate surface. There is no need of excessive epitaxial growth and the high voltage is supported laterally. The LDMOS is used mostly in PICs.

of the LDMOS transistor is shown in Fig. 173. The use of the self-aligned double-diffusion process results in a relatively short channel. A lightly doped, thin drift region is used to support a high drain-to-source breakdown voltage. Although the operation mechanism of the LDMOS is the same as that of the VDMOS, the LDMOS has all three electrodes on the substrate surface and there is no need of excessive epitaxial growth. In addition, it is also easily integrated with CMOS circuitry. These reasons make the LDMOS attractive in monolithic PICs, where interconnection between the LDMOS and low-voltage analog and digital ICs can be easily achieved.

Significan efforts have been directed toward increasing the breakdown voltage and reducing the on resistance of the LDMOS. The important parameters related to a required breakdown voltage are the charge

in the drift layer per unit area, the length of the drift region, and the substrate doping density. The use of charge control technology, namely, RESURF (reduced surface field)²¹³ enabled an increase in breakdown voltage or a corresponding reduction in its on resistance per unit area (specific on resistance) by almost a factor of 2.

Figure 173 also illustrates the RESURF principle. As shown in Fig. 173, a thin, lightly doped N^- -type epitaxial layer is located on a P^- substrate. When the total charge in the N^- region between the P^+ source region and the N^+ drain region is large, the surface electric field near the channel reaches the critical electric field before the N^- epitaxial layer is fully depleted. Therefore, the surface-limited breakdown occurs. In the opposite case, when the charge of the N^- epitaxial layer is carefully controlled so that the surface electric field is always lower than that in the bulk, and the superficial N^- layer is fully depleted prior to reaching the critical electric field, the full bulk breakdown value is achieved. The RESURF technology permits realization of lateral power transistors with breakdown voltages of up to 1200 V.²¹⁴

In high-frequency applications, the LDMOS offers the desired high switching speed, in the order of a few tens of nanoseconds, with no significant storage time. This is because current transport occurs solely by majority carriers. As an RF power device (for power amplification not for power conversion), submicrometer channel LDMOS with very small gate-to-source is being used due to its low cost and high efficiency.²¹⁵

LIGBT The lateral insulated-gate bipolar transistor (LIGBT),^{211,212} the lateral version of the IGBT, is another promising integrable power device. Its cross-sectional view is shown in Fig. 174a.

In the LIGBT structure, a lightly doped drift region is also needed to support a high forward blocking voltage. The use of the RESURF technology enabled an

increase in breakdown voltage similar to that of an LDMOS. An N^- -buffer layer is needed in the LIGBT to prevent vertical punch-through breakdown of the vertical $P-N-P$ transistor formed by the P^+ collector and the P^- substrate. The operating mechanism of the LIGBT is similar to that of the IGBT. Because a high concentration of holes is injected from the P^+ collector into the N^- region, the conductivity of the long N^- region is modulated and the LIGBT has a specific on resistance that is lower by about a factor of 5–10 than that of the LDMOS transistor. As a consequence, the LIGBT results in substantial reduction of die size for the same power handling capability in comparison with the LDMOS, which is an important factor in power ICs.

However, during turn off, the minority carriers injected by the P^+ collector at the on state, called the storage charge, reduce the switching speed compared to the LDMOS. Storage charge effect improves the dc performance of the LIGBT, but degrades its switching performance and limits its usefulness at the high operating frequencies. Another disadvantage of the LIGBT is the existence of substrate current due to its bipolar current conduction mechanism, which may cause interference with the neighboring analog and digital ICs.

Similar to the IGBT, the LIGBT can improve its switching speed by lifetime control technique¹⁸⁷ at the expense of higher on resistance. But in the PIC, reducing the switching loss of the LIGBT by lowering the minority-carrier lifetime is difficult because it can also degrade the characteristics of other devices on the chip. An alternative is to use the shorted collector structure, as shown in Fig. 174b, which provides an efficient way to remove excess carriers at turn off, hence reducing the switching loss.²¹⁶

In a shorted collector LIGBT, the device operates like a conventional LDMOS at low drain currents. As

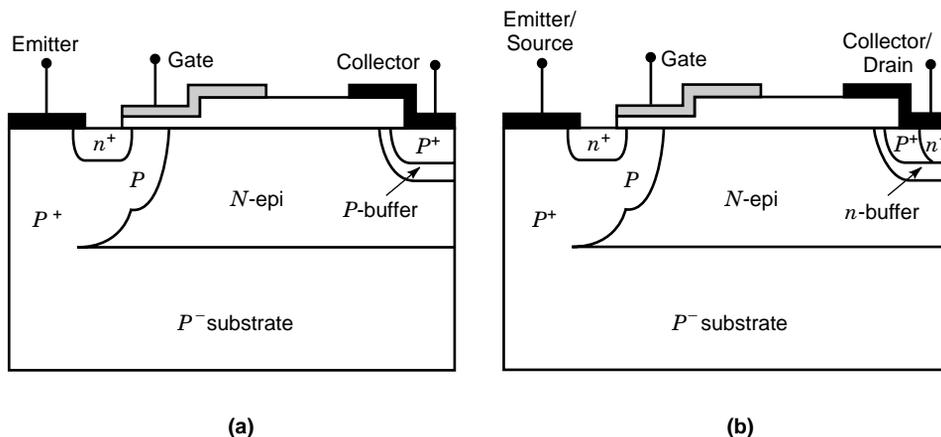

Fig. 174 Cross-sectional view of (a) an LIGBT and (b) a shorted collector LIGBT.

the current increases, the voltage drop across the N -buffer layer resistance underneath the P^+ collector increases, and eventually the P^+ collector becomes forward biased. Holes will then be injected into the N^- -base region from the P^+ collector. As soon as the injected hole density becomes comparable to the N^- -base region doping, conductivity modulation takes place and the on resistance is reduced. Because the P^+ region is shorted to the N^+ region, the emitter efficiency of the P^+ collector is lower than that of the conventional IGBT, and the minority carrier concentration in the N^- -base region is also lower. Further, because the N^- base is connected to the collector contact by the N^+ region, excess electrons can be removed rapidly by the N^+ drain, resulting in a faster turn-off process.

The IGBT is susceptible to latch-up in the same way as the discrete IGBT because of an inherent parasitic $P-N-P-N$ thyristor in the device. At high current levels, sufficient voltage drop occurs across the emitter/body junction and the parasitic $N-P-N$ transistor turns on. The collector current of the $N-P-N$ constitutes the base current of the lateral $P-N-P$ transistor. When the sum of the current gain of the two transistors reaches unity, latch-up occurs and gate control is lost. In the RESURF IGBT, a parasitic vertical $P-N-P$ transistor also exists that diverts some of the hole current into the substrate, and the latch-up threshold is increased. Another method to suppress latch-up is to lower the gain of the $P-N-P$ transistor by using an N -buffer layer. The buffer layer can also be used to limit carrier injection by controlling the collector emitter efficiency. This increases both latch-up current and switching speed and provides a convenient way to trade off speed and forward voltage drop.

Latch-up can be either static, as discussed previously, or dynamic, that is, during switching. Dynamic latch-up occurs because of a rapid increase in the displacement current as well as the change in electron and hole current components near the emitter side. Consequently, the rate at which the device is turned on is critical to dynamic latch-up.

LMCT The lateral MOS-controlled thyristor (LMCT) is another integrable lateral power device, the lateral type of the MCT. The cross-sectional view of an LMCT is shown in Fig. 175.²¹⁷

The LMCT shown in Fig. 175 is built on a P^-/P^+ substrate and has a P -channel DMOS transistor to turn it off and an N -channel lateral MOS transistor to turn it on. An efficient utilization of area is obtained by using the RESURF technique to achieve high breakdown voltage. By controlling the charge in the ion-implanted N -RESURF base layer, it becomes fully depleted at maximum blocking voltage and the breakdown occurs in the bulk at the N -RESURF/ P^- substrate junction (J_2). The N -buffer layer has a higher doping concentration than the N -RESURF layer and is used to prevent punch-through breakdown between the anode and the P^- substrate in the off state.

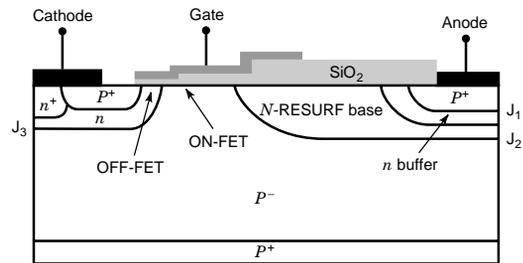

Fig. 175 Cross-sectional view of an LMCT structure.

The LMCT structure turns on by biasing the gate positively with respect to the cathode and turning on the lateral NMOS. Electrons flow into the N -RESURF base layer via the NMOS channel. These electrons form the base current of the $P-N-P$ transistor and turn the anode junction (J_1) on. Because of the $P-N-P-N$ thyristor in the LMCT, at a certain current level, regenerative action takes place and the LMCT latches up. Turn-off is achieved by biasing the gate negatively with respect to the cathode and turning the P -channel DMOS transistor on, which effectively shorts the base-emitter junction (J_3) of the $N-P-N$ transistor and diverts its base current to the cathode contact.

Because the LMCT operates at the latch-up state in its on state, it has much better current-carrying capability than the LDMOS and the IGBT. However, the LMCT has a poorer current turn-off capability. Its maximum controllable turn-off current is limited by the P -channel DMOS transistor's channel resistance. Other variations of the LMCT also exist, which are being studied to improve performance and process compatibility.²¹⁸

11.5 Isolation Technologies for PICs

In order to obtain high performance, low cost, small size, and high reliability of electronic equipment, the development of monolithic PICs has been promoted for several years. For integrating both power devices and low-voltage control ICs on the same silicon substrate, isolating the high- and low-voltage components is essential.

Junction Isolation The junction isolation (JI, or $P-N$ isolation) is the most commonly used isolation technology for PICs. With the junction isolation technique, the silicon islands where the various components are integrated are separated through reverse-biased junctions realized by the diffusion of P regions through the entire depth of the N -type epitaxial layer grown on a P -type substrate (Fig. 176a). This technique is the most widely used because it offers the best compromise between cost and versatility. For thick epitaxial layers, up and down diffusion is used to form the isolation islands (Fig. 176b). Because the isolation diffusion must extend through the entire epitaxial layer

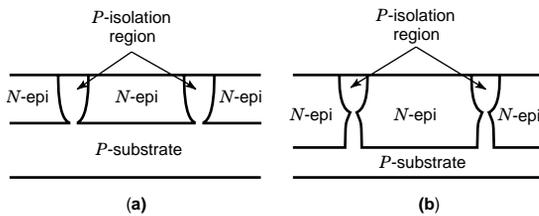

Fig. 176 Junction isolation techniques: (a) down diffusion in thin epitaxial layer and (b) up and down diffusion in thick epitaxial layer.

in the junction isolation, the thickness of the epitaxial layer is limited. However, blocking voltages of up to 1200 V are possible by applying RESURF technique.

The major drawback of junction isolation is that it uses a significant amount of silicon space. Moreover, it introduces an extra $P-N$ junction, which has capacitance and causes leakage current to the substrate. Under unfavorable conditions, JI can also introduce parasitic components such as a $P-N-P$ transistor.

Dielectric Isolation Dielectric isolation (DI) allows the realization of silicon islands completely surrounded by oxide. DI has advantages such as low parasitic capacitance to the substrate, the absence of leakage current, and a reduction in the size of high-voltage components. However, this method requires a more complex and costly manufacturing process. Moreover, since oxide is a poor conductor of heat, it limits the integration of high-power devices.

The conventional dielectric isolation process (epitaxial passivated integrated circuit, EPIC) is shown in Fig. 177. Although EPIC is the dielectric isolation technology for power ICs in mass production, it has a problem with wafer warpage caused by its thick polysilicon layer, which must be solved before the wafer size can be increased and the minimum device patterning size can be lowered. Therefore, many advanced DI technologies are also being developed.

SOI Isolation Technology. The SOI isolation technology is one of the dielectric isolation technologies

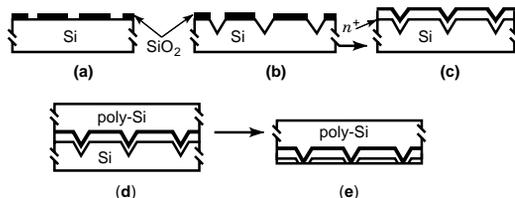

Fig. 177 Fabrication process flow of an EPIC-type wafer: (a) oxidation and photoetching, (b) V-groove etching, (c) N^+ deposition and isolation oxidation, (d) polysilicon epitaxial growth, and (e) grinding and polishing.

developed for ICs aimed at high-speed, high-level integration, and low power consumption. Although the origin of the SOI can be traced back to the 1934 patent of Oscar Heil on MIS structure, it is only in the 1980s that the SOI material became an evolution of the silicon and not an exotic revolutionary material. SOI material has been successfully introduced in production at the begin of the 1990s in some applications where limited volumes of wafer are required. This first IC market helped the SOI development. Among all the techniques proposed in the 1980s to perform the SOI structure, only three are still competing and are serious challengers of standard silicon: SDB (silicon direct bonding),^{21,22} SIMOX (synthesis by implanted oxygen),^{21,19} and smart cut.^{22,20}

Power devices fabricated on an SOI substrate have attracted a lot of attention in the area of smart power integrated circuits. The reason for this is the many advantages offered by SOI over a conventional bulk substrate. V-groove etching, trench, or LOCOS (local oxidation of the silicon) isolation processes between adjacent devices on SOI offer true dielectric isolation and allow simple integration of power and logic devices on the same substrate. It is also possible to achieve significant improvements in breakdown voltage and switching speed with an SOI substrate. These advantages can be attributed to the excellent insulating properties of silicon dioxide in these devices. The buried oxide helps sustain a high electric field, which results in high breakdown voltage, and confine the carriers, which reduces the switching time of minority carrier devices.

On the other hand, the buried oxide underneath the device is also a good thermal insulator. The thermal conductivity of silicon dioxide is only 1.4 W/K · m compared to 140 W/K · m for bulk silicon. This significant difference impedes the dissipation of the heat generated inside the device. Therefore, the temperature rise inside an SOI device can be much higher than that in a bulk device.

In the SOI technologies, the SDB dielectric isolation technology and the SIMOX are promising for high-voltage power IC applications.

SDB Dielectric Isolation Technique. The SDB (silicon direct bonding) dielectric isolation technique, which is also called BESOI (bond and etch back SOI) or DISDB (dielectric isolation by silicon wafer direct bonding) is widely used to prepare starting SOI material. The use of SDB technology has made SOI technology more viable and cost effective. The key process steps are shown in Fig. 178. Starting from two silicon wafers, at least one with an oxide layer on top, these two wafers are bonded together using van der Waals forces. Subsequent annealing increases the mechanical strength of the bonded interface by the chemical reaction which can occur at this interface. One of the substrates is then thinned down to the required thickness from several hundred microns by mechanical grinding and polishing.

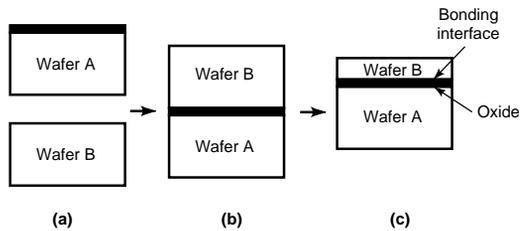

Fig. 178 Fabrication process flow of a SDB wafer: (a) oxidation of slice A, (b) cleaning and bonding, and (c) annealing, then grinding and polishing of wafer B.

The SDB dielectric isolation technique is a promising candidate for power ICs because thick silicon islands, which are required for handling high current and high voltage, can be easily fabricated. The adjacent devices isolation on the SDB wafer can be provided by etching V-grooves, by RIE (reactive ion etching) trench isolation, or even by LOCOS if the SOI layer is thin enough.

The SDB dielectric isolation technique is used not only in the isolation between lateral power devices such as LDMOSs and low-voltage integrated circuits, it is also used in the isolation between vertical power devices such as IGBTs and low-voltage integrated circuits. There are two methods for this application, as shown in Figs. 179 and 180.

Figure 179 shows the process flow of the first method for the SDB wafer to be used in isolating PICs. First, in the SDB wafer, the silicon and oxide film is where the power device is to be formed are removed by wet etching. Then, the etched place is buried with Si epitaxial growth and the lapping and polishing are performed. Next, lateral isolation regions are formed by the conventional steps of groove etching (trench etching or V-groove etching), thermal oxidation for isolation film formation, and refilling the groove with polysilicon.

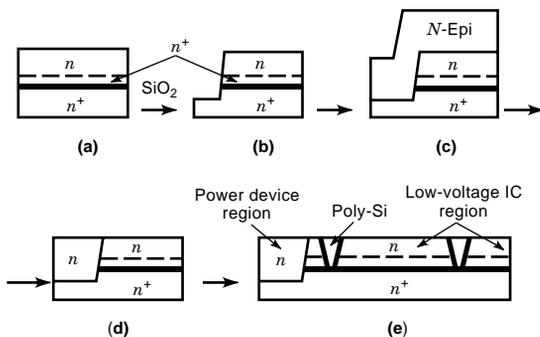

Fig. 179 Method 1 for using SDB in PICs: (a) SDB wafer, (b) silicon and oxide film etching, (c) epitaxial growth, (d) lapping and surface polishing, and (e) lateral isolation.

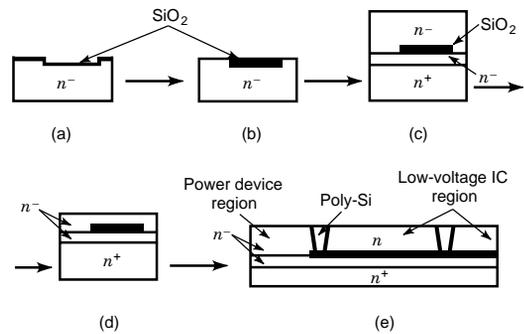

Fig. 180 Method 2 for using SDB in PICs: (a) etching and oxidation, (b) grinding and polishing, (c) bonding, (d) grinding and polishing, and (e) lateral isolation.

Another method is shown in Fig. 180. First, in the wafer A, the region where the low-voltage controlling circuit is formed is masked and etched. After thermal oxidation is carried out to form an isolation film, the wafer is polished until the optically flat Si-SiO₂ coexistent surface is exposed. Then, wafer bonding is performed. After that, the side of the bonded wafer on which devices are fabricated is ground and polished to a thickness of several microns. Finally, lateral isolation regions are formed by conventional steps of groove etching, thermal oxidation for isolation film formation, and refilling of the groove with polysilicon.

SIMOX. The SIMOX (separation by implanted oxygen, or selective implantation with oxygen) technique is considered to be one of the most advanced and promising SOI technologies for high-density CMOS circuits. The key processes of the SIMOX technology are shown in Fig. 181. First, oxygen ions are implanted into the silicon underneath the initial silicon surface. Then, a postimplantation annealing regenerates the crystalline quality of the silicon layer remaining over the oxide. This annealing also drives the chemical reaction that forms the stoichiometric oxide buried in the silicon wafer. Although the ideal annealing conditions are not fully identified yet, it is known that good SIMOX must be annealed at about 1320°C, for 6 h, in argon ambient containing 1% of oxygen.

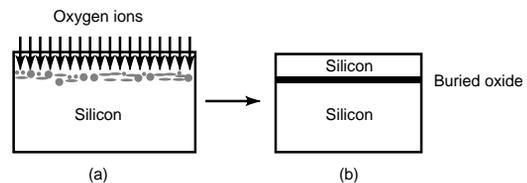

Fig. 181 Fabrication process of SIMOX wafer: (a) oxygen ion implantation and (b) high-temperature annealing.

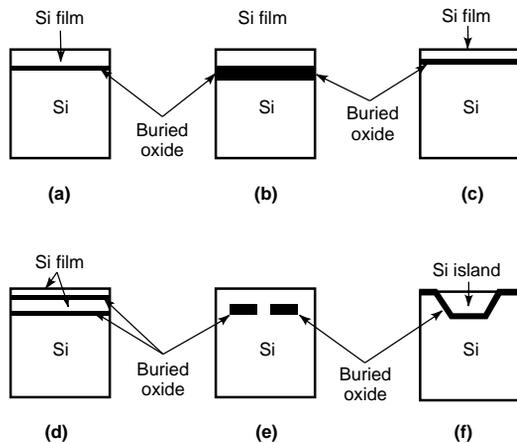

Fig. 182 Various types of SIMOX structure: (a) thin BOX, (b) thick BOX, (c) thin Si film, (d) double SIMOX, (e) interrupted BOX, and (f) totally isolated island SIMOX.

A number of SIMOX variants have been explored, as shown in Fig. 182. The thin or thick buried oxide (BOX) can be fabricated by using a lower implanted dose or a higher implanted dose. The thin and thick silicon film over the BOX can be obtained by using lower implanted energy or higher implanted energy. The double SIMOX structure is fabricated by two sequential oxygen implants. The thicker silicon layer can be achieved by using epitaxy technology. The interrupted BOX and the totally isolated island SIMOX can be processed by masked implantation.

The main disadvantage of the SIMOX technology is the need of $>1300^{\circ}\text{C}$ annealing, which could be a limitation for the 300-mm wafers.

The SIMOX technology is also considered to be one of the most promising dielectric isolation technologies for PICs. Figure 183 shows a PIC using SIMOX technology. As shown in Fig. 183, the wafer can be

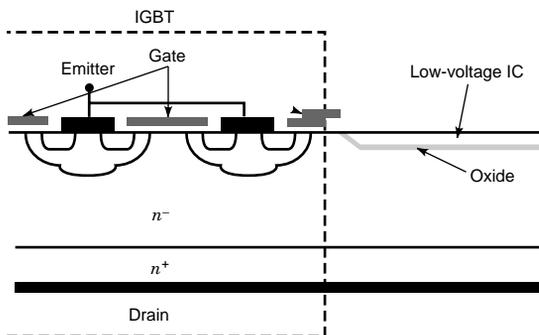

Fig. 183 One possible way of using SIMOX technology in PIC.

selectively implanted with oxygen ions and forms local dielectric isolation. This local SIMOX technology with the epitaxy and the trench technology offers the unique opportunity to integrate monolithic devices with vertical current pathlike VDMOS or IGBT with lateral low-voltage control circuits by means of rather standard VLSI process steps. In contrast to other dielectric isolation technologies, no “exotic” process steps like selective epitaxy or mechanical back-lapping and surface polishing are necessary. Further, since the SIMOX technology involves forming a local buried oxide layer, improved smart power discrete devices are possible using SIMOX technology and they are being studied and developed.

SPSDB Technique. The single-silicon polysilicon direct bonding (SPSDB) technique,^{221–223} which is also called laminated dielectric isolation (LDI or laminated DI) is a new SDB isolation method used for power ICs. Figure 184 shows the cross-sectional view of the SPSDB wafer. The SPSDB wafer has inverse V-groove isolation regions with a narrow isolation width of about $5\ \mu\text{m}$, which is independent of breakdown voltage. Consequently, the SPSDB technique has a very high packing density. Further, the SPSDB wafer has a simple fabrication process and is suited to mass production. Furthermore, the same design rules as those for the EPIC DI wafer can be utilized.

The process of the SPSDB is based on those of the EPIC and the SDB. Similar to the process of the conventional EPIC, first the $\langle 100 \rangle$ silicon wafer is oxide-masked and the V-grooves are etched with a preferential etching solution like KOH. When the grooves are completed, the etching stops automatically. The wafer is then oxidized and subsequently covered with a polysilicon layer about $80\ \mu\text{m}$ thick. Next, the polysilicon layer is lapped and polished to about $10\ \mu\text{m}$ thickness. The polished wafer is treated with $\text{NH}_4\text{OH}-\text{H}_2\text{O}_2$ solution at 70°C , rinsed with deionized water, and dried using a spin dryer. Then, a single-crystal silicon wafer is placed onto the polished polysilicon surface. These wafers are bonded at 1100°C for 2 h in an oxidizing atmosphere. Finally, the slice is inverted and the original single-crystal substrate is lapped and polished until the silicon islands are isolated from each other.

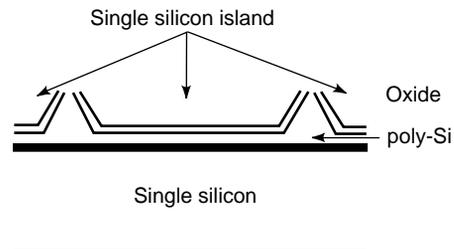

Fig. 184 Cross-sectional view of SPSDB wafer.

The SPSDB wafer has an unchanging warpage height during high-temperature heat treatments and has a high bonding strength comparable to that of the thermal oxidizing layer interface.

11.6 SiC-Based Power Devices

In recent years, silicon carbide (SiC) has received increased attention as a potential material for power devices operating at high temperatures, high power levels, and high frequencies due to its unique material properties.^{224,225} Silicon carbide has a bandgap about three times wider than that of silicon (3.0 eV for 6H-SiC and 3.25 eV for 4H-SiC), high avalanche breakdown electric field of $2\text{--}4 \times 10^6$ V/cm, high saturated electron drift velocity of 2×10^7 cm/s, and high thermal conductivity of 4.9 W/cm \cdot K. The high breakdown electric field allows the use of much higher doping and thinner layers for a given blocking voltage than silicon devices, resulting in much lower specific on-resistance for unipolar devices. Further, high thermal conductivity and high saturated electron drift velocity also make SiC especially attractive in the power device arena.

With the arrival of commercial single-crystal substrates of 6H- and 4H-SiC and the ability to grow high-quality SiC epitaxial layers, the silicon carbide process has developed rapidly and the fabrication of power devices has become viable.

Among the SiC substrates, the two SiC polytypes 6H and 4H are having the biggest impact on power devices. Although the 6H-SiC has the best single-crystal quality of the established polytypes, the 4H-SiC is more attractive for power devices than the 6H-SiC. The reason for this is that the electron mobility in the 4H-SiC is two times that of the 6H-SiC in the direction perpendicular to the c axis and almost 10 times that of the 6H-SiC in the direction parallel to the c axis.

Compared with silicon and gallium arsenide materials, SiC has a lower mobility in the inversion layer and very small diffusion rates for dopants. These factors are limiting the pace of SiC power device development.

Schottky and $P\text{-}i\text{-}N$ Junction Diodes High-voltage SiC Schottky rectifier are already commercially available. Figure 185 shows the cross-sectional view of a SiC Schottky barrier diode (SBD, or Schottky diode) with high-resistance edge termination. This structure consists of an N^+ -doped substrate with backside ohmic contact, a lightly doped epitaxial layer, and a topside Schottky contact with a high-resistance termination. The Schottky diode is fabricated by evaporating a high work function metal, such as titanium, nickel, or gold, onto the lightly doped epitaxial layer to form the Schottky contact and by depositing a metal onto the back of the N^+ substrate to form the back ohmic contact. The high resistivity edge termination is achieved by implanting argon, which damages the exposed semiconductor to create a high-resistance

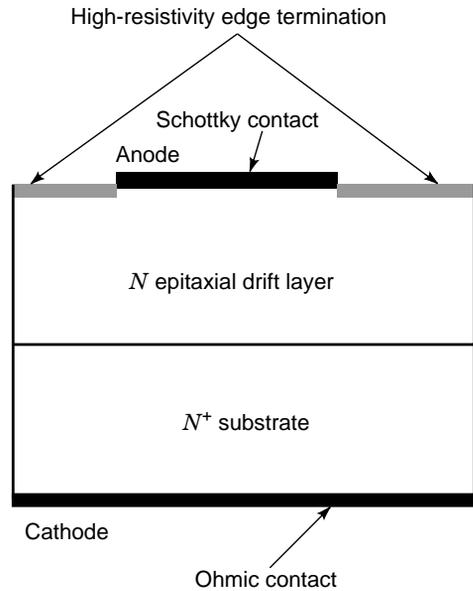

Fig. 185 Cross-sectional view of SiC Schottky diode with high-resistivity edge termination. The SiC Schottky diode consists of an N^+ -doped substrate with backside ohmic contact, a lightly doped N epitaxial layer, and a topside Schottky contact surrounded by a high-resistance termination.

region. This process is self-aligned to the Schottky contact because the Schottky metal acts as a mask preventing damage under the contact.²²⁶

Because of the higher breakdown electric field, the epitaxial layer of the SiC SBD can have a higher doping and thinner drift layer at the same blocking capability when compared with that of a gallium arsenide (GaAs) SBD and Si SBD. The specific on-resistance of a 1000-V 4H-SiC SBD is 15 times lower than that of a 1000-V GaAs SBD and over 200 times lower than that of a 1000-V silicon SBD. However, due to the high electron mobility of the GaAs material, a GaAs SBD has a lower specific on-resistance than an SiC SBD at block voltages lower than 200 V.

SBDs have also been found to have excellent reverse recovery and reverse bias leakage characteristics even at high operating temperatures. They are likely to replace silicon $P\text{-}i\text{-}N$ rectifier in high-voltage power electronic circuits.

A somewhat more complex device is a SiC $P\text{-}i\text{-}N$ diode, as shown in Fig. 186.²²⁷ A high concentration N^+ SiC epitaxial layer is grown on the N^+ SiC wafer, and then an N -type epitaxial drift region and a high concentration P^+ thin epitaxial layer are grown. A mesa edge termination is formed by using RIE technology to block reverse voltage. This etching process was self-aligned in that the aluminum etch mask also acts as the top contact to the P^+ layer in the device.

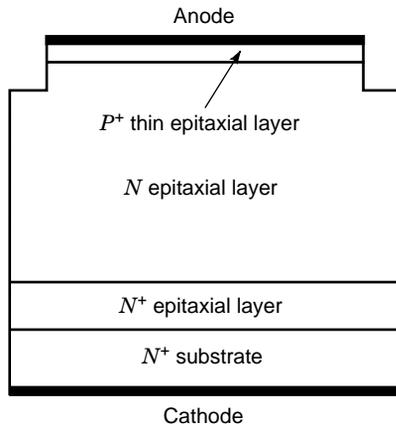

Fig. 186 Cross-sectional view of SiC $P-i-N$ diode. In the SiC $P-i-N$ diode structure, a high concentration N^+ SiC epitaxial layer is grown on the N^+ SiC wafer, and then an N -type epitaxial drift region and a high concentration P^+ thin epitaxial layer are grown. A mesa edge termination is formed by using RIE technology to block reverse voltage.

Thyristors For very high voltage (5–10 kV) applications, such as traction control and high-voltage dc transmission, silicon bipolar devices have much lower on-state losses than silicon unipolar devices. The same is expected to be true for SiC bipolar devices. At these very high voltages, a single SiC thyristor could replace a stack of silicon thyristors and thereby achieve a lower forward voltage drop.²²⁸ In addition it is expected that properly designed SiC bipolar devices, which take advantage of the high breakdown field of SiC, will have lower voltage drops than silicon bipolar devices. The most promising SiC thyristor structure to date has been an $N-P-N-P$ device in 4H-SiC, as shown in Fig. 187. This structure utilized a mesa structure, with all of the doping being done in situ during epitaxy. The device periphery was terminated using an RIE mesa.

MOSFET SiC vertical power MOSFETs have a strong advantage over those made in silicon because the drift layer may use a 10 times higher doping level and one-tenth the thickness for a given breakdown voltage because of the much higher breakdown electric field of the SiC material. Ultimately, this could translate into specific on resistances as low as 1/300th that of an equivalent Si device. Because dopant diffusion rates in SiC material are very small, the UMOS process was considered to be the most suitable for making SiC power MOSFETs because the UMOS process can rely on epitaxy to form the channel region.²²⁹

The cross-sectional view of an SiC UMOSFET structure is shown in Fig. 188. An N^- epitaxial drift layer is grown on the N^+ substrate, and then a P -type channel layer is grown. N^+ source regions are formed by using implantation into the P -type channel layer.

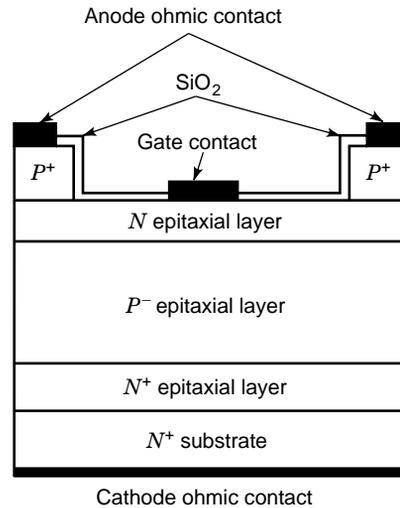

Fig. 187 Cross-sectional view of the SiC $N-P-N-P$ thyristor. In the SiC thyristor structure, epitaxy is used to grow all semiconductor layers. The RIE is used to define the gate contact. Because an N^+ substrate is used, the resulting thyristor is a p -type thyristor.

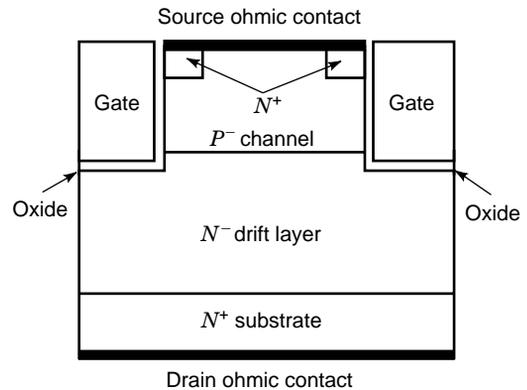

Fig. 188 Cross-sectional view of SiC UMOSFET. An N^- epitaxial drift layer is grown on the N^+ substrate, and then a P -type channel layer is epitaxially grown. N^+ source regions are formed by using implantation into the P -type channel layer. RIE is used to form the trenches on either side of p -type layer.

RIE is used to form the trenches on either side of the P -type layer. After the gate oxide (SiO_2) is grown and annealed, ohmic contacts are formed on the source and drain areas. Finally, the gate metal and interconnect metal are defined. During operation, current flow from the N^+ source contacts through an inversion channel layer to the N^- drift layer and they are collected by

the N^+ drain. The current flow from source to drain is controlled by the voltage on the gate electrode.

It was found, however, that there is a high electric field at the corners of the trenches, which restricts the breakdown voltage of the UMOSET far lower than its theoretical breakdown voltage. Further, the side-wall inversion channel mobilities in the SiC UMOSET are lower than those in planar SiC MOSFETs, which leads to a severe increase in the on resistance of the device. A planar high-voltage SiC MOSFET using double implants has also been reported,²³⁰ which avoids both of these problems by forming the inversion channel on the silicon. Shown in Fig. 189, the DMOS structure is formed by using multiple energy boron and nitrogen implants. Both implants are activated simultaneously at 1600°C for 30 min in an argon ambient. Then, the wafer is thermally oxidized to obtain the gate oxide, and the polysilicon is deposited or aluminum is thermally evaporated to form the gate electrode.

6H-SiC UMOSET IGBT has also been experimentally demonstrated.²²⁹ Its structure is similar to that of the SiC UMOSET MOSFET, shown in Fig. 188, except that a p^+ collector substrate is used to replace the n^+ substrate of the MOSFET. The SiC IGBT has better forward conduction capability than that of the SiC MOSFET at high blocking voltage (>1000 V) and high operating temperature (>200°C) due to the conductivity modulation.

SIT Although the SiC SIT (static induction transistor) has a structure resembling that of the UMOSET, as shown in Fig. 190,²³¹ the operation mechanism is significantly different. The SiC SIT is a vertical device with an ohmic source contact on the top and an ohmic drain contact on the back of the wafer. Between the

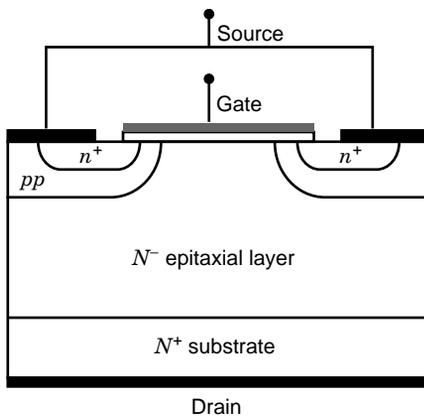

Fig. 189 Structure of planar SiC MOSFET. An N^- epitaxial drift layer is first grown on the N^+ substrate. The DMOS structure is formed by using multiple high-energy boron (p region) and nitrogen implants (n region).

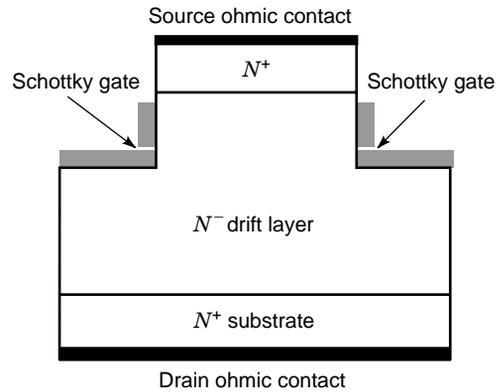

Fig. 190 Cross-sectional view of SiC SIT. An N^- epitaxial drift layer is grown on the N^+ substrate, and then an N^+ layer is grown. Trenches are etched to define the channel region, and Schottky gate contacts are formed in the bottom and along the sidewalls of the trench.

N^+ source and N^+ drain regions is an N^- epitaxial drift layer whose doping is one of the factors that determines the device breakdown voltage and pinch-off voltage. Trenches are etched to define the channel region, and Schottky gate contacts are formed in the bottom and along the side walls of the trench. Majority carriers flow from the source contact to the drain contact through the N^- channel region. By applying a negative voltage to the gate contact, the current flow can be modulated and even decreased to zero when depletion regions under each gate contact meet in the middle of the channel.

The SiC SIT is ideally suited to high-power microwave devices owing to the remarkable transport properties, very high breakdown field strength, and thermal conductivity of SiC. The SiC SIT is being developed as a discrete power microwave transistor for operation at frequencies up to S-band.

RF MESFET The cross-sectional view of an RF SiC MESFET is shown in Fig. 191.²³² This device is a lateral device with both source and drain contacts on the top surface of the wafer. The MESFET epitaxial structure consists of an undoped P -buffer layer, N^- type channel layer, and N^+ contact layer. The majority of carriers flow laterally from source to drain, confined to the N^- channel by the P^- buffer layer and controlled by the Schottky gate electrode.

For RF SiC LDMOS, GaAs MESFET, and SiC MESFET, the device parameters that are important in different power densities are low field electron mobility, breakdown electric field, and electron saturation velocity. At a doping density of $1 \times 10^{17} \text{ cm}^{-3}$ the electron mobility of 4H-SiC is $560 \text{ cm}^2/\text{V} \cdot \text{s}$, which is slightly lower than that of Si ($800 \text{ cm}^2/\text{V} \cdot \text{s}$) and significantly lower than that of GaAs ($4900 \text{ cm}^2/\text{V} \cdot \text{s}$). On the

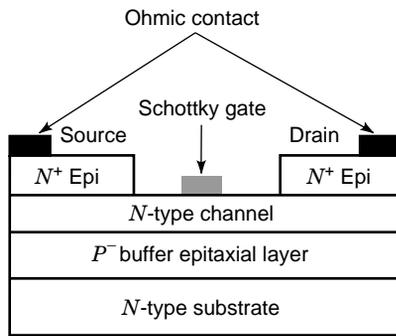

Fig. 191 Cross-sectional view of RF SiC MESFET. In the SiC RF MESFET structure, all semiconductor layers are epitaxially grown. The RIE is used to define the Schottky gate.

other hand, the breakdown electric field of 4H-SiC is about 10 times that of Si and GaAs, and the saturated drift velocity is 2 times that of Si and GaAs. Consequently, at low voltages, GaAs MESFETs, which have the highest electron mobility, have the highest power density. The higher power density of SiC MESFETs is only achieved at drain voltages higher than those normally used with either Si or GaAs devices.

RF JFET High-frequency SiC JFETs are of interest for high-temperature RF applications because a much lower gate leakage current can be obtained with a $P-N$ junction at high temperature than with a Schottky gate.²³³ The cross-section of a SiC RF JFET (shown in Fig. 192) is similar to that of the RF MESFET, except a P^+ SiC epitaxial region with an ohmic contact on top is used in place of a Schottky contact,

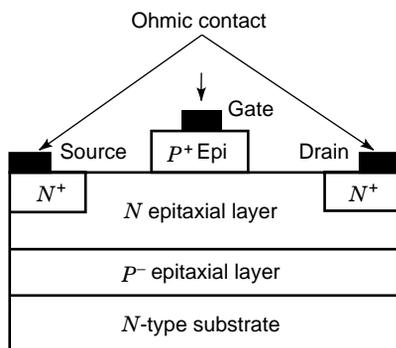

Fig. 192 Cross-sectional view of SiC JFET. In the SiC RF JFET structure, a p^- epitaxial layer is grown on the N -type substrate, and then an N -type epitaxial layer and high concentration P^+ epitaxial layer are grown. The P^+ mesa is formed by using RIE technology and N^+ source and drain regions are formed by using ion implantation.

and ion-implanted N^+ source and drain contact regions are used in place of the N^+ epitaxial region.

1 INTRODUCTION

Radiation is the transfer of energy through space without requiring any intervening medium; for example, the energy reaching Earth from the sun is classified as radiation.

The majority of this is in the form of electromagnetic waves, which have a wide range of frequencies. Of this, a relatively narrow frequency band between 4×10^{14} and 8×10^{14} Hz is capable of stimulating the visual system; this is light. Our attention will be directed primarily toward the visible part of the spectrum, but most of the principles are valid in other parts of the spectrum.

Electromagnetic radiation propagates through empty space with velocity c , which is one of the fundamental

constants of nature; its approximate value is $2.998 \dots \times 10^8$ m/s. This velocity is independent of frequency. In any material medium, the velocity of propagation v is less than c ; the ratio $c/v \equiv n$ is called the *index of refraction* of the medium. The velocity v (and therefore n) depends upon the frequency of the radiation; this variation of velocity (or index) with frequency is known as dispersion.

The simplest wave to discuss is one in which some physical quantity varies sinusoidally with time at any point in space and this variation propagates with velocity v . Such a wave is represented by an equation of the form

$$b = A \sin \frac{2\pi}{\lambda}(x \pm vt) \quad (1)$$

where b represents the value of the quantity at position x and at time t and A is the maximum value of b and is called the *amplitude* of the wave. This equation represents a *plane wave*, that is, the quantity b is constant over a plane surface perpendicular to the x axis. The minus sign gives a wave propagating in the positive x direction; the plus sign gives a wave propagating in the negative x direction. The wavelength λ represents the smallest, nonzero distance for which $b(x + \lambda) = b(x)$ for all x ; alternately, λ may be defined as the distance between adjacent crests of the wave. See Fig. 1, which is a plot of b as a function of x for some fixed t . Equation (1) is meaningful for all values of x and t ; in this sense, it represents a wave of infinite extent in time and space. We can also define the period T of the wave as the time required to execute one cycle, or the smallest, nonzero, time for which $b(t + T) = b(t)$. Frequency ν is the reciprocal of the period; for period in seconds, the frequency unit is the hertz. Equation (1) is called a monochromatic wave since it contains only one frequency. These quantities are interrelated as follows:

$$\nu = \lambda\nu = \frac{\lambda}{T} \quad \text{or} \quad \lambda = \nu T$$

As the radiation passes from one medium to another, such as from glass to air, the frequency remains constant, but the velocity and wavelength change.

No real wave extends indefinitely in time but must begin and end; real waves cannot be monochromatic in the strictest interpretation of the term.

The methods of Fourier analysis enable us to construct a finite wave train as a sum of appropriately selected infinite wave trains of the proper phase. The amplitude as a function of time in the finite wave train and the amplitude as a function of frequency for the infinite components form a Fourier transform pair. Although the details in each case will depend upon the manner in which the wave builds up initially and dies away at the end, some "rule-of-thumb" statements are often helpful. These are:

$$\frac{\Delta\nu}{\bar{\nu}} \approx \frac{\bar{T}}{\Delta t} \approx \frac{\bar{\lambda}}{\nu\Delta t} \approx \frac{\Delta\lambda}{\lambda}$$

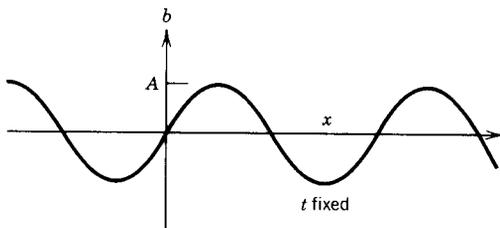

Fig. 1 Simple harmonic wave of the form $y = A \sin(2\pi/\lambda)(x - vt)$. Plot is for fixed $t = 0$. Over time, disturbance moves to right.

where Δt is the duration of the wave train; $\Delta\nu$ is the frequency spread of the infinite or monochromatic components making up the wave train; $\bar{\nu}$, \bar{T} , and $\bar{\lambda}$ are the average frequency, period, and wavelength of the finite wave. These are rule-of-thumb or *order-of-magnitude* statements. A wave for which $\Delta\nu \ll \bar{\nu}$ is properly called *quasi-monochromatic* but is frequently called *monochromatic*. For many classical (i.e., prelaser) light sources, $\Delta\nu/\bar{\nu} \approx 10^{-5}$ and the wave is, for most practical purposes, monochromatic. Sunlight, on the other hand, has a very broad spectral range ($\Delta\nu$ comparable to $\bar{\nu}$) and may be described equally well as a series of randomly spaced short pulses or a broad spectrum of randomly phased monochromatic waves. The two descriptions are equally valid and interchangeable.

As already mentioned, light is electromagnetic radiation. The quantities described by Eq. (1) are electric and magnetic field \mathbf{E} and \mathbf{B} . These two fields each obey Eq. (1) and are in phase with each other. They are perpendicular to each other in space and each is perpendicular to the direction of propagation. This is illustrated in Fig. 2, which shows \mathbf{E} in the y direction and \mathbf{B} in the z direction for a wave propagated in the positive x direction. Here, \mathbf{E} , \mathbf{B} , and v form a right-handed orthogonal system so that in order to have a wave propagated in the negative x direction, either \mathbf{E} or \mathbf{B} must be reversed.

Within the constraint that it remain in a plane perpendicular to the direction of propagation, \mathbf{E} may have any direction. Usually the direction of \mathbf{E} changes in a random way, and the light is called unpolarized. If the direction of \mathbf{E} remains constant, the light is called linearly polarized. Also, \mathbf{B} is always perpendicular to \mathbf{E} .

Theoretical considerations indicate that in vacuum $c = (\mu_0\epsilon_0)^{-1/2}$, which experiment confirms. Theory also predicts that in a medium $v = (\mu\epsilon)^{-1/2}$ or $n = (\mu\epsilon/\mu_0\epsilon_0)^{1/2}$. Here μ and ϵ are the permeability and permittivity of the medium; μ_0 and ϵ_0 are the corresponding quantities for vacuum. The prediction for the velocity in a real medium cannot be experimentally confirmed since μ and ϵ are frequency dependent and at optical frequencies the only available measurements are the measurements of n or v ; there are no direct measurements of μ and ϵ . The velocity v in Eq. (1) is the phase velocity. For a finite wave train or pulse, the envelope of the pulse moves forward with the *group velocity* U . The value of U may be expressed in a variety of forms, including

$$U = \frac{c}{(d/d\nu)(n\nu)} = \frac{c}{n} \left(1 + \frac{\lambda}{n} \frac{dn}{d\lambda} \right) \quad (2)$$

For common transparent materials, $dn/d\lambda < 0$ and $U < v$. In nondispersive media (e.g., vacuum), $U = v$; λ is the wavelength in the medium.

One common aspect of wave propagation, as observed with water waves, is the tendency of the

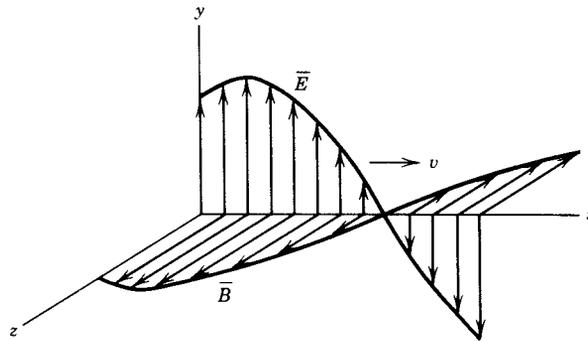

Fig. 2 Electromagnetic wave, where \mathbf{E} , \mathbf{B} , and v form right-handed orthogonal system as shown. Plot is for some fixed time; wave moves to right; E_y and B_z have maximum values for same value of x .

wave to spread into the shadow region behind barriers. This phenomenon is known as diffraction. Light also exhibits diffraction, but the effects are much smaller than for water waves because the wavelengths of light waves are so small ($\sim 5 \times 10^{-7}$ m). Diffraction effects are important if we attempt to pass light through openings only a few wavelengths wide or to focus the light into a very small spot. Otherwise, we may describe the light in terms of “rays” that represent the direction of energy flow and coincide with the direction of propagation. In a homogeneous isotropic medium, the rays are straight. That part of optics that may be treated by tracing rays is called geometric optics.

2 GEOMETRIC OPTICS

If a ray of light strikes a boundary separating two homogeneous isotropic media such as air and glass (see Fig. 3), a simple wave calculation will show and experiment will confirm the following statements:

1. The incident ray will be partially reflected at the boundary and partially transmitted (refracted) into the second medium.
2. The incident ray, the reflected ray, the refracted ray, and the normal to the surface (erected at the point of incidence) are coplanar.
3. The angle of reflection θ' is equal to the angle of incidence θ ; these angles are measured between the surface normal and the rays, as shown in Fig. 3.
4. The angle of refraction ϕ and the angle of incidence θ are related by the following equation, which is known as Snell's law:

$$\frac{\sin \theta}{\sin \phi} = \frac{v_1}{v_2} = \frac{n_2}{n_1} \tag{3}$$

where v_1 and v_2 are the velocities of propagation in medium 1 and medium 2 and n_1 and n_2 are the indices of refraction.

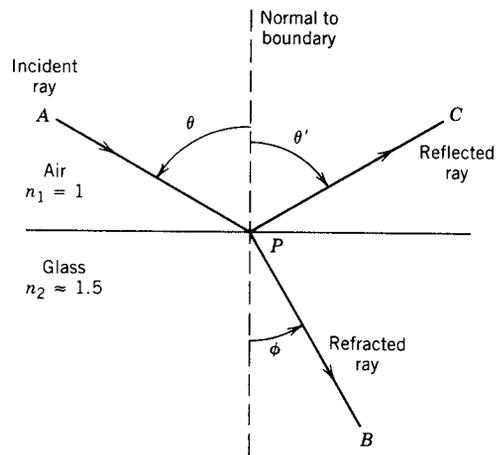

Fig. 3 Refraction at plane boundary separating two media with different indices of refraction. According to Snell's law, $n_1 \sin \theta = n_2 \sin \phi$. In the special case for which θ_B satisfies condition $\tan \theta_B = n_2/n_1$, reflected light is linearly polarized.

These statements can be proven without postulating that the light wave is electromagnetic. However, one must recognize the electromagnetic nature of the wave in order to calculate the fraction of the light that is reflected or transmitted. The path of light is reversible; that is, light will travel from B to A along the same path BPA .

It is a straightforward exercise in calculus to show that if A and B (of Fig. 3) are fixed points, one in each medium, and if P is an arbitrary point on the boundary, then the location of P that minimizes the propagation time from A to P to B is the same location of P for which Snell's law is satisfied. Also, for A and C as fixed points in the same medium, the choice of P that produces a minimum of $AP + PC$ is the same P for which $\theta = \theta'$. These are examples of Fermat's

principle, which states that the path of an actual ray from one point to another is a path for which the transit time is stationary. By *stationary* we mean that the derivative of the transit time with respect to small changes in the path (such as small changes in the location of P) must be zero.

For a ray such as APB in Fig. 3, which passes through more than one medium, it is convenient to define the *optical pathlength* from A to B as $n_1 AP + n_2 PB$, or in case the ray passes through many media, the optical pathlength is $\sum_i l_i n_i$, where l_i is the pathlength in medium i and n_i is the index of medium i . The optical pathlength between two points A and B is the distance in vacuum that light could travel during the time required to propagate from A to B through the intervening media.

Snell's law and the law of reflection are sufficient to explain the image-forming properties of lenses and mirrors. We first turn our attention to lenses and to the case in which the same medium (air) is on both sides of the lens. The lens will have spherical surfaces and rotational symmetry about some line called the axis; distances are measured along and perpendicular to this axis. The following results are usually derived using small-angle approximations, $\sin \alpha \approx \alpha \approx \tan \alpha$, and are called *paraxial calculations*. Consider first a ray that is parallel to the axis at a distance h above the axis (see Fig. 4). Upon passing through the lens, the ray will be refracted according to Snell's law and cross the axis at the point F in the figure. For a good lens, the point F is independent of h ; it is called the focal point of the lens. As the ray passes through F , it has a slope of u ; in the figure u is negative. The ratio $h/(-u)$ is the focal length f . For a thin lens, f is the distance from the lens to F , where F is the second (or back) focal point. There is another point, F' , in front

of the lens called the first (or front) focal point. Any ray that passes through F' (with slope u) and strikes the lens will be refracted to be parallel to the axis (at height h). The front focal length, $h/u \equiv f'$, will be equal to f provided there is the same medium on both sides of the lens. For a thin lens in air

$$\frac{1}{f'} = \frac{1}{f} = (n - 1) \left(\frac{1}{r_1} - \frac{1}{r_2} \right) \quad (4)$$

where n is the index of refraction of the lens material and r_1 and r_2 are the radii of curvature of the first and second surfaces of the lens; r_1 and r_2 are considered positive (negative) if the center of curvature of the surface is to the right or downstream (left or upstream) relative to the surface; and $1/f$ is the power of the lens. In Fig. 4, r_1 is positive and r_2 is negative; for this lens, the focal length f is positive. This lens is *convergent*.

Figure 5 shows the application of these definitions to a *negative*, or *divergent*, lens. In this case, r_1 is negative and r_2 is positive, making f negative. Notice that F , the *second* focal point, is to the left of the lens; the refracted ray does not pass through F but must be extended backward to intersect the axis (at F). In Fig. 5b, the incident ray is headed toward F' , the *first* focal point, but is refracted by the lens to be parallel to the axis.

For both positive and negative lenses, a ray that crosses the axis at the center of the lens continues undeviated into the region beyond. This is called a *chief ray*.

It follows from Eq. (4) that positive, or convergent, lenses are thicker on axis than at the edge, whereas negative, or divergent, lenses are thinner on axis than at the edge. They may have a variety of shapes, as illustrated in Fig. 6.

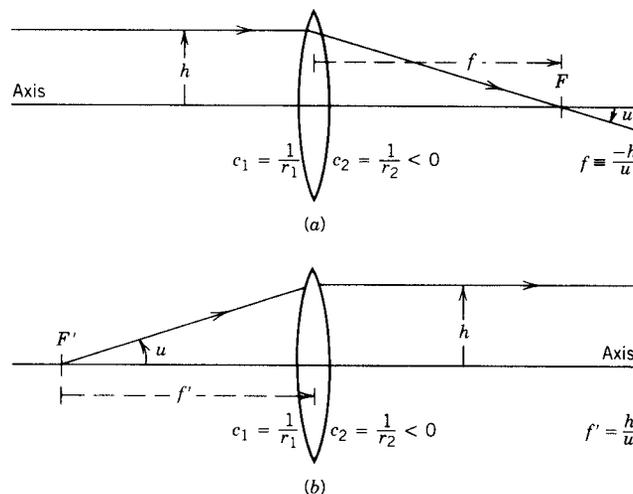

Fig. 4 Two focal points of *positive* lens. In (a) F is second (or back) focal point. In (b) F' is first (or front) focal point. For lens shown, r_1 (radius of curvature of front surface) is positive; r_2 (radius of curvature of second surface) is negative.

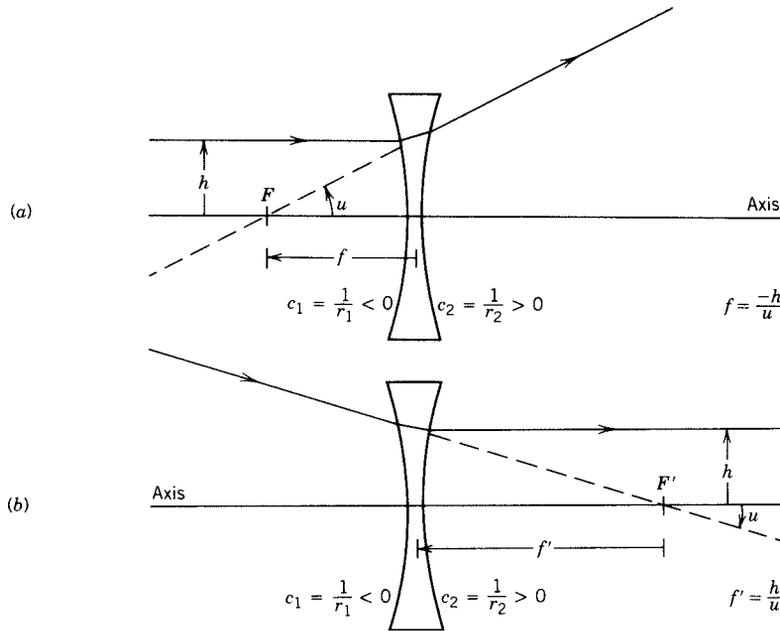

Fig. 5 Two focal points of negative lens. In (a) F , the second focal point, is in front of lens. In (b) F' , first focal point, is behind lens. For lens shown, r_1 is negative and r_2 is positive.

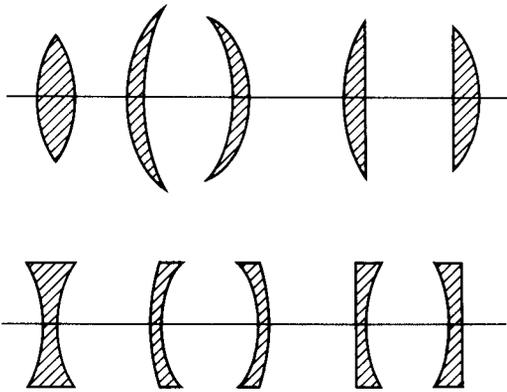

Fig. 6 Variety of positive lenses (upper group) and negative lenses (lower group).

Figure 7 shows a positive lens forming an image of point A at point B . All rays from A that pass through the lens converge to B , but only three are shown. It is assumed that the locations of F and F' are known; rays 1 and 3 are drawn to satisfy the definition of these points. Ray 2 passes undeviated through the center of the lens. The image is inverted and the lateral magnification m is defined as y'/y or $B'B/A'A$; it is negative in the cases shown, indicating an inverted

image. The image is real since the rays actually arrive at point B .

It is simple to calculate the image position by the equation

$$xx' = f^2 \tag{5}$$

where x is the distance from the object to the first focal point; it is taken as positive if (as shown in Fig. 7) the object-to-focal-point direction is the same as the direction of the light propagation. On the image side x' is the distance from the second focal point to the image; it is positive in Fig. 7. From Eq. (5), we see that x and x' always have the same sign. Since the product xx' is constant, moving the object to the right (toward F') moves the image to the right (away from F). The lateral magnification m is given as

$$m \equiv \frac{y'}{y} = -\frac{f}{x} = -\frac{x'}{f} \tag{6}$$

Another pair of equations may be used

$$\frac{1}{p} + \frac{1}{q} = \frac{1}{f} \quad \text{and} \quad m = -\frac{q}{p} \tag{7}$$

where p is the distance from the object to the lens and q is the distance from the lens to the image; they are considered positive if they are in the same

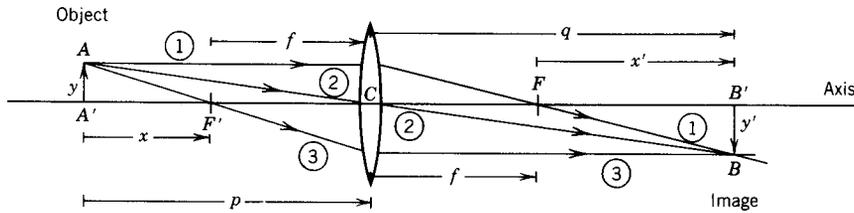

Fig. 7 Image formation by positive lens, illustrating quantities that appear in Eqs. (5)–(7). Also shown are three rays easily used in graphical ray tracing.

direction as the light propagation. In Fig. 7, both p and q are positive. Equation (7) is very convenient for use with thin lenses. For thick lenses or lenses consisting of several elements, it is not obvious what point (or points) in the lens should be used for measuring p and q . By reversing the rays, A becomes the image of B , and A and B are said to be conjugate points.

Figure 8 shows the corresponding situation for a negative lens. Here the first focal point F' is to the right of the lens and the second focal point F is to the left of the lens. Ray 1 is parallel to the axis until it strikes the lens and is refracted along a line that appears to have come from F . Ray 3 is headed for F' but is refracted to be parallel to the axis. Ray 2 passes straight through the center of the lens. These rays do not intersect anywhere to the right of the lens but if extended backward appear to have intersected at B . Only ray 2 actually passes through B . Point B is a *virtual* image of A (in contrast to the real image formed in Fig. 7). Equations (5) and (6) or Eq. (7) work for this case, but notice the following: f is negative; x is measured from A' to F' as before, but F' is to the right of the lens; x' is measured from F to B' , but F is to the left of the lens; p is positive; Eq. (7) gives a negative value for q , indicating that B' is to the left of the lens and therefore virtual; m is positive but less than 1, so the image is upright or erect and smaller than the object.

Equations (5)–(7) may be used to establish the information in Table 1.

The *focal length* of a thin positive lens may be calculated from Eq. (4) if the curvatures and the index of the glass are known. It may also be measured in the laboratory by setting up on an optical bench an experiment similar to Fig. 7, measuring the appropriate distances and calculating f . A small luminous source, such as the filament of an unfrosted lightbulb, might serve as a suitable object. A ground glass screen is used to locate the image. Negative lenses cannot be measured in this way because the image in Fig. 8 is virtual and virtual images cannot be caught upon a screen. There are two ways around this problem.

Two thin lenses of focal lengths f_1 and f_2 when placed in contact are equivalent to a single lens of focal length f_c , given by the equation

$$\frac{1}{f_c} = \frac{1}{f_1} + \frac{1}{f_2} \quad (8)$$

If f_1 is a negative lens under test, it may be combined with a positive lens of known focal length f_2 . If $f_2 < |f_1|$, then the combined focal length f_c will be positive and can be measured by the experiment of Fig. 7; f_1 is then calculated from Eq. (8).

An alternate method is shown in Fig. 9. A positive lens is used to form a real image at $A'A$; its position is determined and recorded by observing the image on

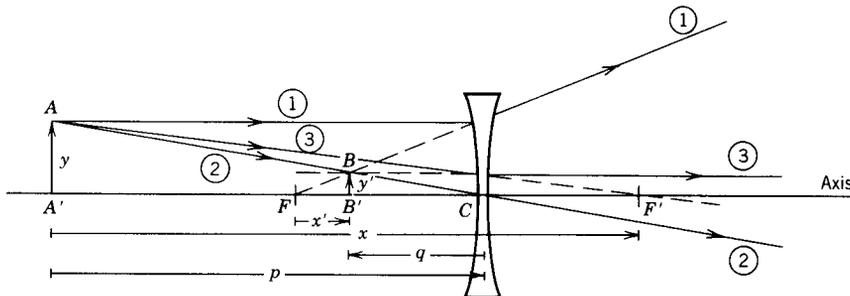

Fig. 8 Image formation by negative lens illustrating quantities from (5)–(7). Also shown are the rays easily used in graphical ray tracing.

Table 1 Images Formed by Thin Lenses

Lens	Object Position		Image Position		Nature of Image
Positive, or convex, $f > 0$	$x = \infty$	$p = \infty$	$x' = 0$	$q = f$	Real
	$\infty > x > f$	$\infty > p > 2f$	$0 < x' < f$	$f < q < 2f$	Real, inverted, $ m < 1$
	$x = f$	$p = 2f$	$x' = f$	$q = 2f$	Real, inverted, $ m = 1$
	$f > x > 0$	$2f > p > f$	$f < x' < \infty$	$2f < q < \infty$	Real, inverted, $ m > 1$
	$0 > x > -f$	$f > p > 0$	$-\infty < x' < -f$	$-\infty < q < 0$	Virtual, erect, $ m > 1$
Negative, or concave, $f < 0$	$x = \infty$	$p = \infty$	$x' = 0$	$q = f = - f $	Virtual
	$\infty > x > -f$	$\infty > p > 0$	$0 < x' < -f$	$f < q < 0$	Virtual, erect, $ m < 1$

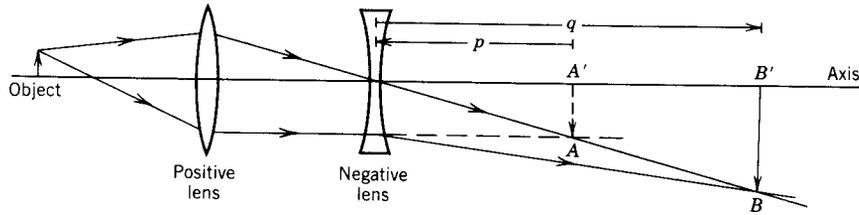

Fig. 9 Measuring focal length of negative lens using image AA' formed by positive lens as virtual object for negative lens (p is negative).

a screen. Being careful not to move the object or the positive lens, the negative lens to be measured is placed between the positive lens and the image $A'A$. The image now has a new location, $B'B$, which may be adjusted to some convenient position by moving the negative lens to the left or right. The initial image $A'A$ is the object for the negative lens; it is called a *virtual object* because the light is intercepted by the negative lens before it reaches point A . The distance from object to lens, p , is negative since it points upstream. The image distance q is the distance from the negative lens to the image $B'B$; in the figure it is positive (i.e., downstream). The focal length f of the negative lens may be calculated from Eq. (7) and the values of p and q just obtained.

A *spherical mirror*, concave toward the light source, forms images and behaves in many ways as a positive

lens. There is, however, only one focal point F (see Fig. 10). A ray that is initially parallel to the axis is reflected to pass through F . A ray that passes through F before striking the mirror will be parallel to the axis after reflection. A ray that passes through the center of curvature C will strike the mirror normally and be reflected back on itself. These three rays are shown in the figure starting from A and intersecting at B , which is the image of A . The focal point F is midway between the center of curvature and the mirror surface.

Equations (5)–(7) may be used to calculate image locations and magnification. The focal length of a concave mirror is positive. The downstream direction is always positive, but this reverses when the rays reflect from the mirror. In Fig. 10, rays from the object that have not reached the mirror (called rays

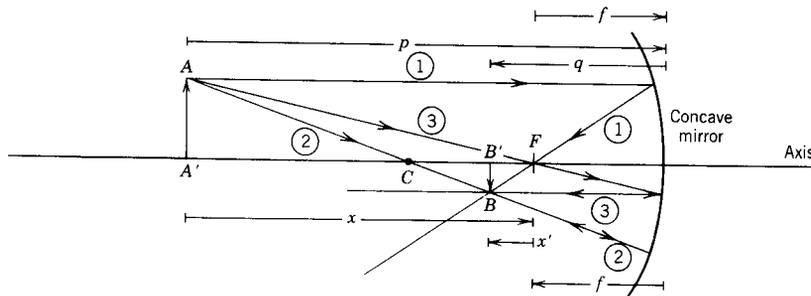

Fig. 10 Image formation by concave mirror. Focal point F is halfway between center of curvature C and mirror surface.

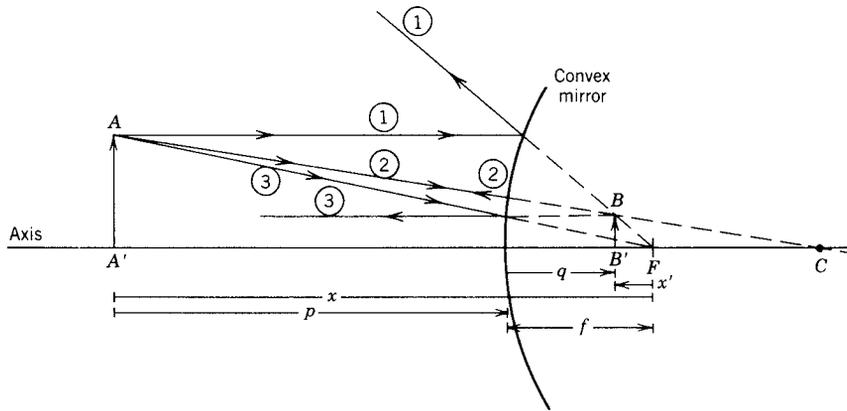

Fig. 11 Image formation by convex mirror.

in object space) are downstream to the right, so this is the positive direction for p and x . Rays that have been reflected from the mirror (called rays in image space) are downstream to the left, so right to left is the positive direction for q and x' , which locate the image. In the figure, x , x' , p , and q are all positive.

A mirror that is *convex* toward the light source is similar to a negative lens. The focal point is behind the mirror surface and $|f| = \frac{1}{2}|r|$, where r is the radius of curvature. Image formation for this case is illustrated in Fig. 11. In the equations, f is negative; x and p are in object space and positive in the figure. Distances x' and q are part of image space where downstream is to the left, so x' is positive and q is negative in the figure.

2.1 Aberrations

In first-order optical calculations, it is found that all the rays from a point object that pass through the optical system converge upon the image point. If the object lies in a plane that is perpendicular to the axis of the system, the image will lie in a plane perpendicular to the axis of the system and be similar in shape to the object.

If we abandon first-order approximations ($\sin \theta \approx \theta$) and use more accurate calculations, we discover that the preceding statements are not true. The differences between the actual behavior of the optical system and the ideal (or first-order) behavior are called *aberrations*, which are generally classified as follows.

2.2 Chromatic Aberration

According to Eq. (4), the focal length of a lens depends upon the index of refraction of the glass from which it was made. Since the index is wavelength (or frequency) dependent, the focal length is also wavelength dependent. This is *chromatic aberration*. Usually the focal length is longer for red light than for blue light. By combining two lens elements (such as a positive

lens of crown glass and a negative lens of flint glass), it is possible to create a "doublet" that has the same focal length for two specific wavelengths, such as a wavelength in the red and a wavelength in the blue. It will then have nearly the same focal length for the intervening wavelengths. Such a doublet is said to be *achromatic*. Objectives for small telescopes are usually of this design.

2.3 Spherical Aberration

See Fig. 4a. If the point F at which the ray crosses the axis depends upon h , the lens has spherical aberration. For the simple lens shown, F moves slightly toward the lens as h increases. Likewise, in Figs. 7 and 10, all the rays from A' do not cross the axis at B' ; rather, the crossing point depends to some extent upon height (or off-axis distance) at which the ray strikes the lens or mirror.

Spherical aberration and chromatic aberration exist for source and image points that are on axis or off axis. The following aberrations do not exist for object and image points on axis; they exist only for off-axis points and increase in magnitude as the object and image points are more off axis.

A lens is said to exhibit *field curvature* if the image of an off-axis point does not lie upon the paraxial image plane but departs from that plane by a distance proportional to the square of the angle off axis.

For *astigmatism*, the image of an off-axis point consists of two short line segments. These two line segments are at different distances from the lens. One line segment (called the sagittal image) is directed radially outward from the axis; the other (called the tangential image) is perpendicular to the radial line through its center. If a lens suffering from astigmatism is used to image an object consisting of radial lines and concentric circles, they will not be sharply imaged on the same plane. The radial lines will be imaged at the sagittal position; the concentric circles will be

imaged at the tangential position. Midway between these two images is the position of “least confusion.” The separation between the sagittal and tangential lines is a measure of astigmatism; it increases with the square of the angle off axis.

For a lens with *coma*, an image of a point source is formed at the paraxially predicted position by the rays that pass through the central portion of the lens (Fig. 12). Rays that pass through the lens at some fixed distance from the axis (i.e., through a circular zone) do not come to the paraxial image point. Instead, they intersect the image plane in a circle, the center of which is displaced from the paraxial image point by twice its radius. The image of a point produced by all the rays through the lens is a bright spot at the expected location with a 60° flare extending from it. It resembles a comet (hence the name *coma*). The size of the coma pattern increases linearly with angle off axis.

A lens with *distortion* produces a plane image of a plane object, and the rays that pass through the lens all reach the image point, but the image of an extended object (such as a square) is not the same shape as the object. Instead of having constant magnification m so that

$$y' = my$$

there is an additional term to give

$$y' = my + Cy^3$$

The second term on the right is small compared with the first term, but y'/y is no longer independent of y .

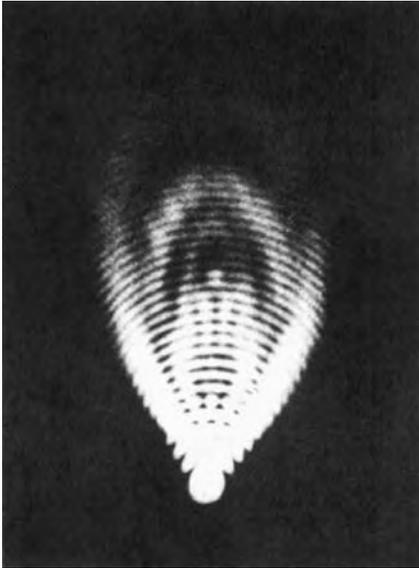

Fig. 12 Image of point source as formed by lens with coma. (Photograph by David Dutton.)

In case $m < 0$ (real images) and positive C , we find that $|y'/y|$ decreases as $|y|$ increases; the image of a square has a barrel shape. Conversely, a lens for which C is negative images a square into a figure resembling a pin cushion.

The monochromatic aberrations (spherical, astigmatism, coma, field curvature, and distortion) can be calculated using third-order approximations, that is, approximations consistent with $\sin \theta \approx \theta - \frac{1}{6}\theta^3$. These are called Seidel, or third-order, aberrations. In third-order calculations there exist only the aberrations listed in the preceding (and linear combinations of them). We have also assumed the lens has rotational symmetry about its axis.

Most practical lenses consist of several elements or components, each of which is a simple lens. The lens designer reduces the aberrations by adjusting the following: (a) the distribution of the power among the elements; (b) the shapes, thicknesses, and spacings of the elements; (c) the position of the stop (or limiting aperture); and (d) the choice of glass in each element. Usually it is not possible to minimize all of the aberrations, and the designer must know the application for which the lens is intended and make some judgment about the relative importance of the various aberrations. A lens that is optimally corrected for one pair of conjugate points will not be optimally corrected for another pair of conjugate points; for this reason the tube length of a compound microscope is important (and has been standardized).

A few lenses have been produced in which one or more elements are made of inhomogeneous glass that contains a deliberately introduced gradient of the index of refraction. This is a recent method of controlling the aberrations.

The “ray” description of image formation by lenses and mirrors, which has occupied our attention in the previous sections, takes no account of the wave nature of light. We now recognize several situations in which the wave properties of light are important; these are part of a field known as *physical optics*.

3 PHYSICAL OPTICS

We set up the experiment diagrammed in Fig. 13. A source of light L is placed behind a slit S_0 on axis. Light from S_0 passes through two slits S_1 and S_2 in an opaque screen and continues on to a viewing screen. The slits S_1 and S_2 are symmetrically located about the axis at $\pm a/2$. The point P is an arbitrary point on the viewing screen at a distance y from the axis, R is the distance from S_0 to the slits S_1 and S_2 , and D is the distance from these slits to the viewing screen. In a typical laboratory experiment, a would be in the range 0.5–1.0 mm and R and D in the range 50–100 cm. The three slits should be less than 0.1 mm wide.

The path difference Δ for the two possible paths is

$$\Delta \equiv S_0S_2P - S_0S_1P = S_2P - S_1P = \frac{ay}{D} \quad (9)$$

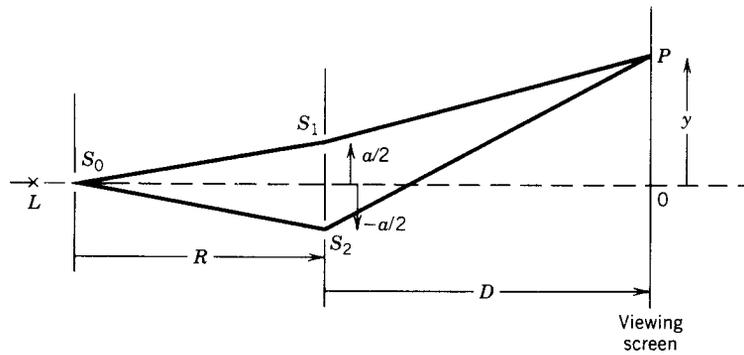

Fig. 13 Young's double-slit interference experiment. Light from the source slit S_0 passes through slits S_1 and S_2 and continues on to viewing screen. Interference pattern is formed on viewing screen. Intensity at point P depends upon path difference for two possible paths.

The light reaching P by way of S_2 is out of phase with the light reaching P by way of S_1 . The phase difference δ is

$$\delta = \frac{2\pi}{\lambda} \Delta = \frac{2\pi}{\lambda} \frac{ay}{D} \quad (10)$$

Depending upon the value of δ , the two waves will interfere at P either constructively or destructively.

If the slits S_1 and S_2 are of equal width so that they contribute equally to the irradiance at P , then the irradiance at P is I_p :

$$I_p = 4I_0 \cos^2 \frac{\delta}{2} = 2I_0(1 + \cos \delta) \quad (11)$$

where I_0 is the irradiance that would be produced at P by light from only one slit. From Eqs. (10) and (11), we see that I_p will have maxima at values of y given by

$$y = \frac{m\lambda D}{a} \quad (12)$$

where $m = 0, \pm 1, \pm 2, \pm 3, \dots$; m is the order number or order of interference. Halfway between each pair of consecutive maxima is a minimum at which $I_p = 0$.

This pattern of fluctuating irradiance is called a pattern of *interference fringes*, or a *fringe pattern*.

The minima in the fringe pattern are not always zero. In this case, we define the fringe contrast or visibility V as

$$V = \frac{I_{\max} - I_{\min}}{I_{\max} + I_{\min}} \quad (13)$$

where I_{\max} and I_{\min} are the maximum and minimum values of I_p . For the fringe pattern described by Eq. (11), $V = 1$; this is its maximum possible value. The case $V = 0$ corresponds to uniform irradiance, that is, no fringe pattern, or $I_{\min} = I_{\max}$.

If the two slits do not contribute equally to the irradiance at P , the fringe visibility will be reduced. Let I_1 represent the irradiance at P due to slit S_1 and I_2 the irradiance due to S_2 ; then Eq. (11) becomes

$$I_p = I_1 + I_2 + 2\sqrt{I_1 I_2} \cos \delta \quad (14)$$

giving a fringe pattern with visibility

$$V = \frac{2\sqrt{I_1 I_2}}{I_1 + I_2} \quad (15)$$

If we keep S_1 and S_2 of equal width so that they contribute equally to the irradiance at P , the fringe visibility will be reduced if we increase the width of the source slit S_0 . If S_0 is centered on axis and has width w , the fringe pattern is described by

$$I_p = 2I_0(1 + V \cos \delta) \quad (16)$$

where the fringe visibility V is

$$V = \frac{\sin \beta}{\beta} \quad \text{where} \quad \beta = \frac{\pi wa}{\lambda R} \quad (17)$$

The visibility V decreases from 1 (for very small values of w) to zero for $\beta = \pi$ or $w = \lambda R/a$. The visibility as a function of w is often identified with γ , the degree of coherence of the light emerging from slits S_1 and S_2 . Here, γ is the normalized cross-correlation function of the waves emerging from the two slits. Loosely speaking, $|\gamma|$ represents the reliability with which the phase at S_2 could be predicted from a hypothetical determination of the phase at S_1 . If β lies in the range $\pi < \beta < 2\pi$, the value of V (or γ) is negative. For the specific case $w = 1.4\lambda R/a$ or $\beta = 4.4$, we obtain from (17) that $V = -0.2$ or $\gamma = -0.2$. Fringes of contrast 0.2 are not very good but are easily

recognizable. The negative value of γ indicates that there is a minimum rather than a maximum at the axial point ($y = 0$) of the viewing screen. The waves emerging from S_1 and S_2 are poorly phase correlated (only 0.2), and the most probable phase difference is 180° (minus sign). Since the separation of S_1 and S_2 is perpendicular to the direction of propagation, this is called spatial coherence.

Figure 14 illustrates the irradiance profile for fringe patterns with three different values of V .

Another interference experiment is illustrated in Fig. 15. A broad source of light is used to illuminate two partially reflecting mirrors M_1 and M_2 . The reflected light is viewed by the eye; in order to have both illumination and viewing directions nearly normal to the mirrors M_1 and M_2 , a third mirror, M_0 , is inserted as shown. Here, M_0 is partially reflecting and partially transmitting.

In order to have interference effects, the two rays must be coherent. Since the source is broad, we have coherence only between rays reflected from M_1 at A_1 and from M_2 at A_2 , where points S , A_1 , and A_2 lie on a straight line, where S is an arbitrary point of source. The light reflected at A_1 will be reflected at B_1 into the eye by mirror M_0 . Light reflected at A_2 reaches the eye by a similar path. In order for an interference pattern to be seen, both of these rays must enter the eye. Interference will take place where these rays intersect on the retina of the eye, but the eye (or the brain) will interpret this as an interference at P , the intersection

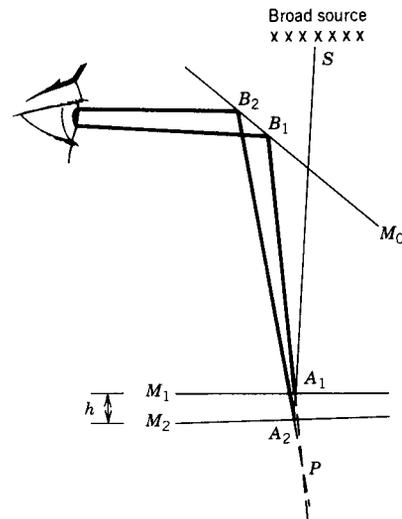

Fig. 15 Interference produced by light reflected from thin wedge. Effect may be observed in oil slick or in soap bubble.

point of lines A_1B_1 and A_2B_2 . Interference such as this is observed in an oil film on wet pavement or sometimes in a soap bubble.

Both rays must enter the pupil of the eye; in order to obtain this, the mirrors M_1 and M_2 must be nearly parallel and either h (the separation of the mirrors) must be small or the ray SA_1 must be at near normal incidence. The mirror M_0 permits near normal illumination and viewing.

The path difference and therefore the phase difference between the two rays will be determined by the mirror separation h at the point A_1 . If the space between the mirrors M_1 and M_2 is slightly wedged or if the mirrors are not exactly plane, then the locus of a maximum (or a minimum) in the fringe pattern represents the locus of points of constant h . A change from one bright (or dark) fringe to the next bright (or dark) fringe corresponds to a change of h by one-half wavelength.

Fringes of good contrast [corresponding to Eq. (11)] are obtained if the illumination is nearly monochromatic, if h is small, and if the two reflecting surfaces M_1 and M_2 have small but equal reflectances. The last condition ensures that the two rays A_1B_1 and A_2B_2 are of nearly equal irradiance. A clean glass surface in air reflects 4% and would serve very well as M_1 or M_2 .

If the mirror M_2 is moved away from M_1 so as to increase h , this serves to introduce a time delay in the ray A_2B_2 relative to A_1B_1 . If air separates the mirrors M_1 and M_2 , the time delay τ is given by

$$\tau = \frac{2h}{c} \tag{18}$$

As h (and therefore τ) is increased, the fringe visibility gradually decreases, indicating a decrease in

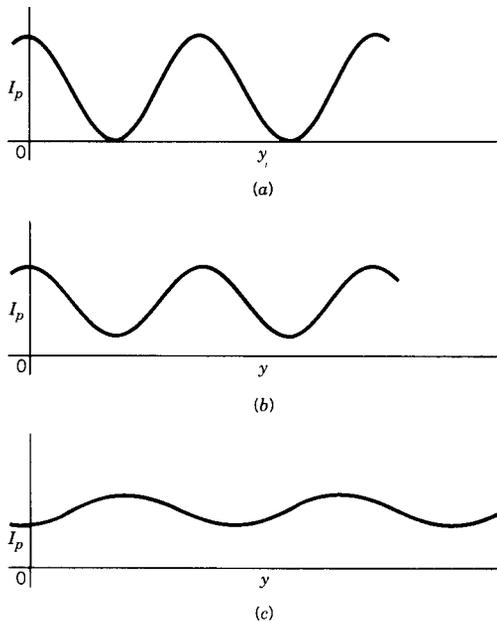

Fig. 14 Plots of I_p vs. y for fringes with different visibility V : (a) $V = 1.0$; (b) $V = 0.5$; (c) $V = -0.2$.

the coherence between the two waves or rays. In this case, the coherence decreases due to a time difference between the rays and is called temporal coherence. If a dispersive medium separates the two mirrors, the time delay should be calculated using the group velocity [U of Eq. (2)] instead of c . The largest value of τ for which fringes of reasonable visibility can be observed is called τ_c , the coherence time of the source; $c\tau_c$ is called the coherence length; τ_c is the same as Δt in the discussion following Eq. (1).

Aside from the interference fringes produced in Young's experiment (Fig. 13), there is another aspect of the experiment that is contrary to the ideas of ray optics. If light reaches P by two paths S_0S_1P and S_0S_2P , then at least one (and usually both) of these paths must be bent. This ability of light to bend into regions that geometrical optics would call shadow regions is known as *diffraction*. Diffraction is a property of all wave propagation.

Practical diffraction problems can be solved by the Huygens-Fresnel method. The method is outlined in Fig. 16. Light from a small source S_0 spreads out to pass through an aperture A in an opaque screen. A wave front (surface of constant phase) reaches the aperture and is transmitted through the open part but is blocked by the opaque portion of the screen. Each elemental area on the transmitted wave front acts as a secondary source radiating spherical waves into the region to the right of A . To calculate the disturbance (i.e., electric field) at P , an arbitrary point on the viewing screen, we must sum (i.e., integrate) the contributions due to all the elemental areas of the aperture. The summation process must take into account the fact that the disturbances reaching P from the various elemental areas of the aperture are not in phase at P because contributions from the various elemental areas have traveled unequal distances from S_0 to P . Mathematically this is written

$$U(P) = -\frac{iA}{2\lambda} \iint_A \frac{e^{ik(r_1+r_2)}}{r_1r_2} dS \quad (19)$$

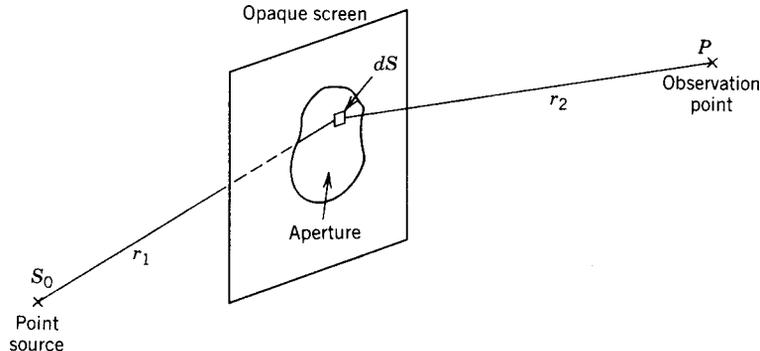

Fig. 16 Geometry of general diffraction problem. Here, S_0 is point source of light; disturbance at P calculated using Eq. (9) where r_1 and r_2 are distances illustrated.

where $U(P)$ is the disturbance at P ; dS is an element of area in the aperture; $k = 2\pi/\lambda$; and r_1 and r_2 are distances from S_0 to dS and from dS to P . The integration is over the open aperture. In many practical cases, the product r_1r_2 in the denominator may be considered as a constant during the integration. The values of r_1 and r_2 in the exponent may not be considered as constant because the exponential is periodic and k is large; A is the open area of the aperture. (We have also assumed that r_1 and r_2 are nearly perpendicular to the plane of the opaque screen.) A complex quantity, $U(P)$ represents the amplitude and phase of the disturbance at P . The irradiance at P , $I(P) = |U(P)|^2 = U(P)U^*(P)$, where $U^*(P)$ is the complex conjugate of $U(P)$.

The integral in Eq. (19) is generally difficult to evaluate, but results are available for some simple cases.

If the aperture is a slit with length much larger than its width, we can consider this as a two-dimensional problem (as illustrated in Fig. 17), ignoring the dimension along the length of the slit. The point source may be replaced by S_0 , a narrow slit (or line) source provided this is parallel to the diffracting slit S_1 ; use of the slit source rather than a point source will noticeably increase the irradiance on the viewing screen.

In discussing this problem, we take as axis the line from the source S_0 through the center of the diffracting slit S_1 ; it intersects the viewing screen at O . The slit S_1 is of width w and is symmetrically located about the axis so that the two edges D and D' of the slit are at $\pm \frac{1}{2}w$ from the axis. The distance S_0DO is larger than the axial distance S_0O , and on the assumption that $w \ll a$ or $w \ll b$, the difference is

$$K \equiv S_0DO - S_0O = \frac{a+b}{2ab} \left(\frac{w}{2}\right)^2 \quad (20)$$

where a and b are the distances from source to diffracting slit and from diffracting slit to viewing screen, as shown in Fig. 17.

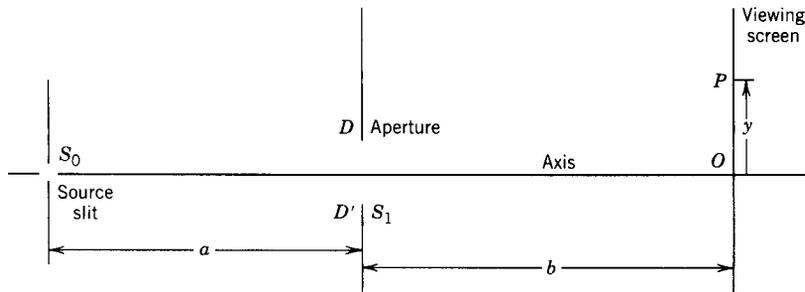

Fig. 17 Geometric quantities used in calculating diffraction pattern produced by slit.

Some generality may be achieved by replacing w by the dimensionless parameter u :

$$u = w \sqrt{\frac{2(a+b)}{ab\lambda}} \quad (21)$$

and replacing y (the distance along the viewing screen from the axis to the point of observation P) by the dimensionless variable v :

$$v = y \sqrt{\frac{2a}{\lambda b(a+b)}} \quad (22)$$

With these changes $K = \frac{1}{16}u^2\lambda$.

Figure 18 shows the irradiance at P as a function of v for several values of the parameter u . In each case, the edge of the geometrical shadow is indicated by vertical lines.

Notice that for the larger values of u , the curves have several maxima and minima and that there is very little irradiance outside the geometrical shadow region. For the smaller values of u (e.g., $u = 1.5, 0.5$), the curves show less structure and for values of $u < 1$ spread out well beyond the geometrical shadow region.

The experiment of Fig. 17 may be repeated using a point source and a small circular aperture in place of the slit. The observed diffraction pattern on the viewing screen will have circular symmetry and the minima will be deeper than those observed with the slit. For $u > 1$, most of the light will be within the region of

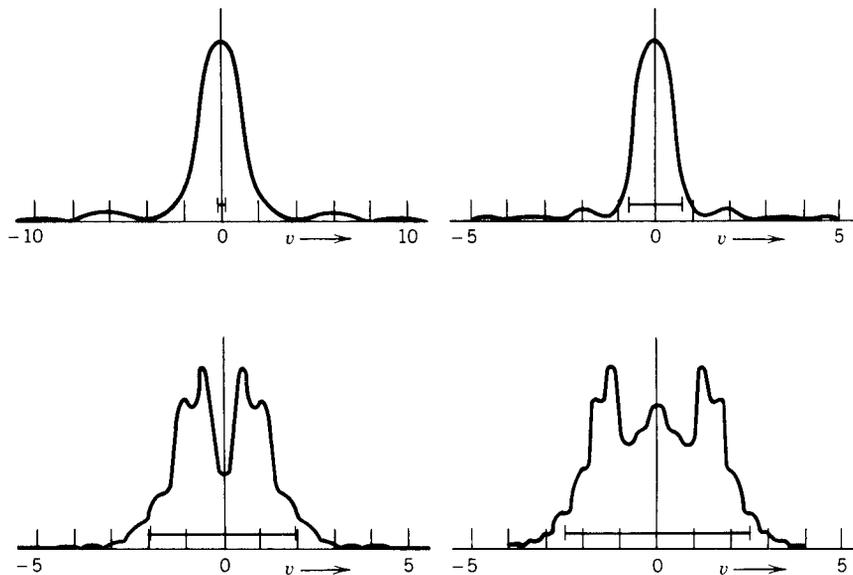

Fig. 18 Diffraction patterns of four slits of different widths. Each figure is plot of irradiance at P as function of v . (a) For narrow slit, $u = 0.5$. Other figures are for successively wider slits: (b) $u = 1.5$; (c) $u = 3.8$; (d) $u = 5.0$. In each case geometrically predicted width is indicated by horizontal line segment just above v axis.

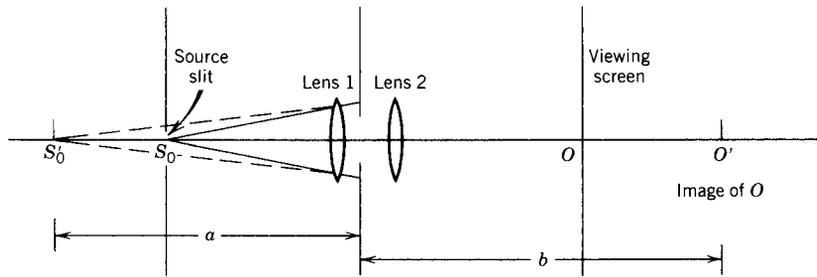

Fig. 19 Effect of using lenses in diffraction experiment. Source distance measured from S'_0 , image formed by lens 1 of real source slit. Screen distance is measured to O' , image formed by lens 2 of actual viewing screen.

the geometrical shadow; and for $u < 1$, the light will spread out into the shadow region.

Diffraction problems are generally divided into two classes, known as *Fresnel diffraction* and *Fraunhofer diffraction*. Fresnel diffraction, or near-field diffraction, covers the cases for which u [of Eq. (21)] is larger than 1. Fraunhofer (or far-field) diffraction covers the cases for which $u < 1$. For a given aperture and wavelength, you can move from the Fresnel to the Fraunhofer region by increasing the distances a and b .

A lens may be placed on each side of the aperture as indicated in Fig. 19. Lens 1 forms an image of the source S_0 at S'_0 and lens 2 images point O of the viewing screen to O' . In this situation, the distance a is measured from S'_0 to the aperture and b is measured from the aperture to O' . If S_0 is at the front focal point of lens 1 and the viewing screen is at the second focal plane of lens 2, then a and b are infinite and $u = 0$ independent of the aperture size. Fraunhofer diffraction calculations assume that the preceding conditions are satisfied and some mathematical simplification results therefrom. Even though the calculations are for the $u = 0$ case, the results are good approximations to any case for which $u \leq 1$. The irradiance distribution for the Fraunhofer diffraction pattern of a slit is

$$I(y) = I_0 \left(\frac{\sin \beta}{\beta} \right)^2 \quad (23)$$

In this equation, I_0 is the irradiance on axis; $I(y)$ is the irradiance at P that is at a distance y from the axis; $\beta = (\pi w y)/(\lambda f)$. Here w is the slit width and f is the focal length of lens 2. Figure 20a is a plot of Eq. (23); notice that it has a large central maximum with small secondary maxima on each side. The irradiance is zero at $\beta = \pi, 2\pi, \dots$. Notice the similarity between this figure and the $u = 0.5$ case of Fig. 18.

For a circular aperture and a point source on axis, the Fraunhofer diffraction pattern will have circular symmetry. Calculations show that the irradiance $I(r)$

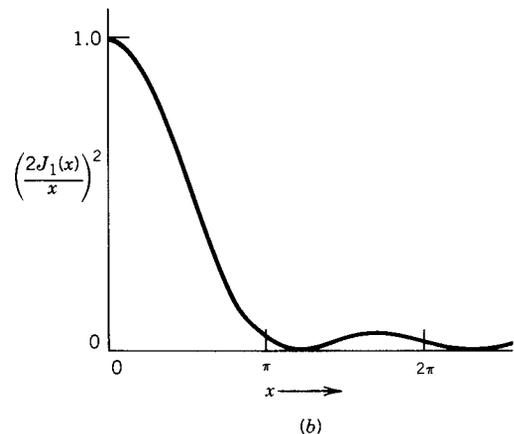

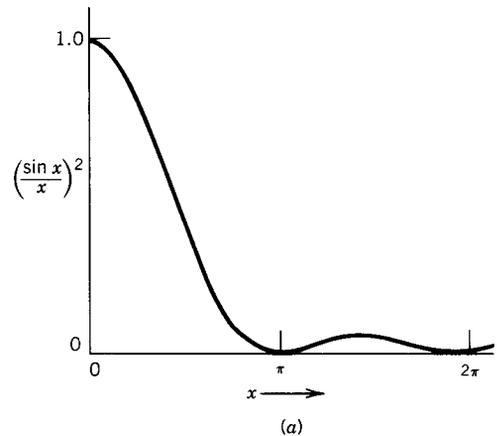

Fig. 20 (a) Function $(\sin x/x)^2$ as function of x . This is Fraunhofer diffraction pattern of single slit. (Pattern is symmetrical about $x = 0$.) (b) Function $[2J_1(x)/x]^2$ as function of x . This is Fraunhofer diffraction pattern of circular aperture. (Pattern has rotational symmetry about axis.)

at a distance r from the axis in the rear focal plane of lens 2 is given by

$$I(r) = I_0 \left(\frac{2J_1(x)}{x} \right)^2 \quad (24)$$

where J_1 is the first-order Bessel function and $x = (\pi w r)/(\lambda f)$. In this case w represents the diameter of the circular aperture. Figure 20b is a plot of Eq. (24). The pattern has rotational symmetry about the $x = 0$ axis. For the circular aperture the zeros of irradiance are not quite equally spaced, occurring at $x = 1.220\pi, 2.23\pi, 3.328\pi, \dots$. The first dark ring is at $r = 1.22\lambda f/w$. Of all the optical power that passes through the aperture, 84% is focused inside this first dark ring, forming what is known as the Airy disk.

For many optical instruments (e.g., telescopes and cameras), the light enters through a circular aperture and the image of a distant point source such as a star is not a bright point but an Airy disk that has the size just discussed. It follows that two separate sources will not be recognized as separate (we say they will not be “resolved”) unless their images are separated by a distance at least equal to the radius of the Airy disk. The angular separation θ of two just resolved stars is

$$\theta = 1.22 \frac{\lambda}{w} \quad (25)$$

As a rule of thumb the 1.22 is often ignored.

Photographers often express the size of the camera aperture in terms of the f number, which we represent as $F^\#$. It is defined as $F^\# = f/w$. In terms of the f number, the diameter d of the Airy disk is

$$d = 2 \frac{1.22\lambda f}{w} = 2.44\lambda F^\# \quad (26)$$

Using a typical value of $\lambda = 0.55 \mu\text{m}$, we obtain

$$d = 1.33 F^\# \quad (\mu\text{m})$$

The diameter of the Airy disk (in micrometers) is about equal to (or 33% larger than) the f number used. This assumes the lens has no aberrations; the performance of such a lens is said to be *diffraction limited*.

Microscopists generally speak of the *numerical aperture* (NA) of the microscope:

$$\text{NA} \equiv n \sin i \quad (27)$$

where i is the half angle of the cone of light that enters the microscope from the object (see Fig. 21) and n is the index of refraction of the region between the object and the microscope objective. Usually $n = 1.0$, but in oil immersion microscopes, n is the index of the oil that fill the space between the object and the lens.

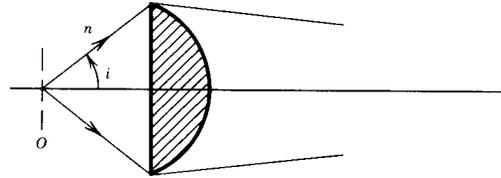

Fig. 21 Numerical aperture (NA) of microscope objective defined as $\text{NA} = n \sin i$. Here i is half-angle of cone of light entering objective from object O; n is index of refraction of medium between object and objective.

Microscopes generally cover a small field of view and are diffraction limited. The separation s of two just resolved points is

$$s = \frac{\lambda}{2n \sin i} = \frac{\lambda}{2(\text{NA})} \quad (28)$$

where λ is the wavelength in a vacuum.

Equation (24) describes the irradiance as a function of r , the distance off axis, in a plane through the rear focal point and perpendicular to the axis. The *irradiance on axis* as a function of x , the distance to the right of the focal point, is given by

$$I(x) = I_0 \left(\frac{f}{f+x} \right)^2 \left(\frac{\sin(U_N/4)}{U_N/4} \right)^2 \quad (29)$$

where I_0 is the irradiance at $x = 0$ and

$$U_N \equiv 2\pi N \frac{x}{f+x} \quad (30)$$

and $N \equiv w^2/(4\lambda f)$. See Fig. 22 for a sketch of this experiment. An examination of Eq. (29) shows that the maximum value of $I(x)$ is not at $x = 0$ but is shifted toward the lens (i.e., to negative x) by the amount Δf given by

$$\frac{\Delta f}{f} = - \frac{1}{1 + N^2\pi^2/12} \quad (31)$$

This shift is insignificant unless N is small ($N < 10$), which corresponds to a very large $F^\#$ or a very small cone angle in the converging light beam.

In spite of the shift just calculated, if one is given a fixed aperture size w with a distant fixed object on which it is required to produce maximum irradiance and the available variable is the focal length of the lens (or the curvature of the wave front emerging from the lens), the optimum choice is to select the lens for which the distant object will be at the center of curvature of the emerging wave front.

A beam with *Gaussian* irradiance profile that is, a beam for which

$$I_p(r) = I_0 e^{-r^2/w^2} \quad (32)$$

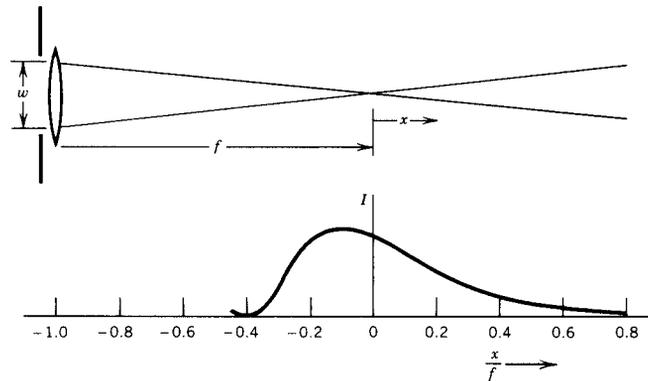

Fig. 22 Position of maximum irradiance shifted toward lens from geometrical focal point. Effect becomes significant only if w^2 is comparable to $4\lambda f$ or less. Lower curve of irradiance vs. x/f : $N = w^2/4\lambda f = 3$.

is unusual in the sense that as it propagates, the irradiance profile remains Gaussian. The curvature of the wave front and the width w will vary as the beam propagates, but it will remain of the form given by Eq. (32), that is, it will remain Gaussian.

A *diffraction grating* may be used in spectroscopy to measure the wavelength of light or to study the distribution of optical power throughout the spectrum.

In its simplest form, the diffraction grating is an opaque screen in which a large number N of transparent slits have been made. The slits should be parallel, evenly spaced, and of the same width. We represent the width of each slit by w and the center-to-center spacing of adjacent slits by d . (Since gratings are routinely produced with d in the range of 3–5 μm and sometimes even smaller, their production requires great care and skill.)

The grating is used in Fraunhofer diffraction, as shown in Fig. 23. This device is called a spectroscope. Light enters the collimator through slit S_0 , which is at the front focal point of lens L_c . Parallel rays strike the grating G ; the diffracted light is viewed through the telescope, which is focused for infinity. The telescope consists of an objective L_t and an eyepiece E_p . The light is incident upon the grating at angle θ and is viewed from the direction ϕ ; both of these angles are measured from the normal to the plane of the grating and with a sign convention that makes both angles positive in Fig. 23. Since w and d are only a few times the wavelength of light, the diffraction angles will be so large that we cannot use small-angle approximations for $\sin\theta$ and $\sin\phi$.

A calculation applying Eq. (19) to this problem gives

$$I = I_0 \frac{\sin^2 \beta}{\beta^2} \frac{\sin^2 N\gamma}{\sin^2 \gamma} \quad (33)$$

where

$$\beta = \frac{\pi w}{\lambda} (\sin\theta + \sin\phi) \quad (34a)$$

and

$$\gamma = \frac{\pi d}{\lambda} (\sin\theta + \sin\phi) \quad (34b)$$

Equation (33) contains two factors, one of which depends upon β and therefore w ; the other depends upon γ and therefore d . Here, I_0 is a normalizing factor and is equal to the value of I when $\theta = -\phi$ (i.e., the straight-through irradiance).

The factor involving γ has maxima (equal to N^2) when $\gamma = m\pi$, where $m = 0, \pm 1, \pm 2, \dots$. By way of Eq. (34b), this corresponds to maxima of I when

$$m\lambda = d(\sin\theta + \sin\phi) \quad (35)$$

The integer m is called the *order number*.

For large values of N , these maxima of I are very sharp (or narrow) functions of θ and ϕ . If γ changes from the value $m\pi$, which produces a maximum, by the amount $\pm\Delta\gamma = \pi/N$, the factor goes to zero. For good commercially available gratings, N may be in the range from 10^4 to 10^5 and $\Delta\gamma$ is correspondingly quite small.

If the source slit of the spectrometer (Fig. 23) is illuminated with monochromatic light and if d is known and θ and ϕ can be measured, then Eq. (35) enables us to calculate the wavelength λ . Conversely, if λ is known, we can calculate the grating space d . If the source slit of the spectrometer is sufficiently narrow, the half width $\Delta\phi$ of the image line may be calculated from Eq. (34b) using $\Delta\gamma = \pi/N$. Two spectral lines of wavelength λ and $\lambda + \Delta\lambda$ are said to be just resolved (Rayleigh criterion) when their angular separation has this value of $\Delta\phi$. It can be shown that

$$\frac{\lambda}{\Delta\lambda} = \frac{\gamma}{\Delta\gamma} = mN \quad (36)$$

The ratio $\lambda/\Delta\lambda$ is known as the resolving power of the grating.

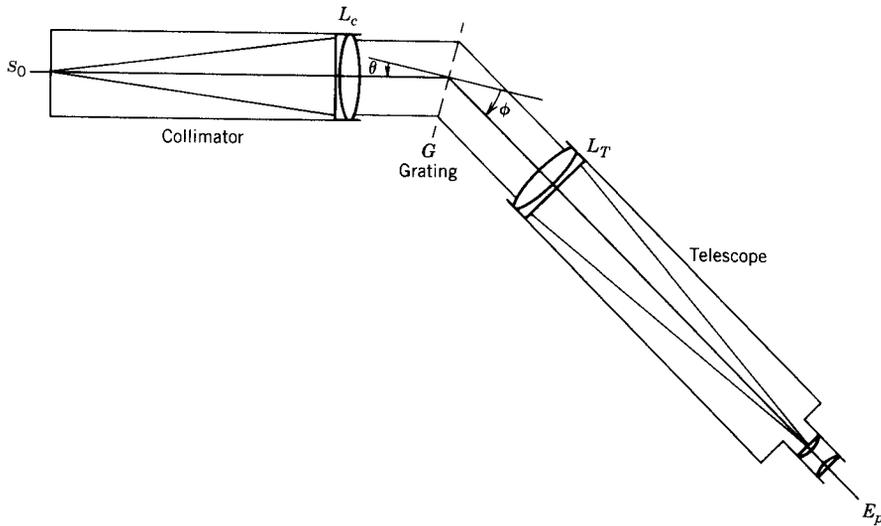

Fig. 23 Use of grating in spectroscopy. If grating space is known, measurement of angles θ and ϕ provides sufficient information to calculate λ , wavelength of light.

If the source of light contains several colors, the deviation $|\theta + \phi|$ of the light will, in any given order, be larger in the red than in the blue.

In Eq. (33), the factor involving β is the same factor found in Eq. (23); it describes the diffraction pattern of a single slit of width w . It does not alter the value of ϕ for any of the maxima, but it determines the relative irradiance of the various orders. For example, if we make $w = \frac{1}{2}d$, then the orders $m = \pm 2, \pm 4, \dots$ will be missing because the zeros of this factor fall at the same values of ϕ as the even-numbered maxima given by Eq. (35).

The grating need not be composed of alternate opaque and transparent lines. It may be everywhere transparent but have a thickness variation that is periodic with period d in one dimension. One surface of such a grating would represent a small-scale copy of a sheet of corrugated steel. Alternately, the grating might be a transparent, uniformly thick sheet in which the index of refraction is a periodic function of one dimension with period d . In all these cases, Eqs. (34) and (35) are still valid, but the factor involving β has to be changed to represent the diffraction pattern of one period of the grating structure.

If the tool that cuts the grooves or lines on the grating is deliberately shaped to increase the irradiance in some order (say, order $m = 1$) at the expense of the irradiance in other orders (such as $m = 0, -1$), the resulting grating is said to be "blazed." In measuring weak spectral lines, this is desirable.

In Fraunhofer diffraction, the *amplitude distribution* in the observation plane is the Fourier transform of the *amplitude transmittance function* of the aperture (with a suitable scaling factor, which is wavelength

dependent). Irradiance is proportional to the square of the amplitude. With this information, many Fraunhofer diffraction patterns are predictable.

3.1 Holography

Interference and diffraction form the basis of holography. Consider Fig. 24. A photographic plate P that is to become a hologram is exposed to two coherent beams of monochromatic light O and R that strike the

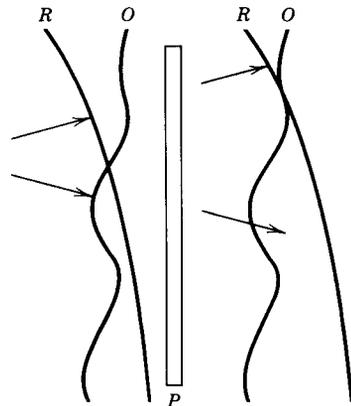

Fig. 24 Process of holography. Hologram is formed when photographic plate P records interference pattern produced by two overlapping wave fronts O and R . If plate is processed, returned to its original position, and illuminated by *one* wave front (e.g., R), diffraction will reproduce copy of other wave front (i.e., O).

plate from different directions. A wave front for each beam is sketched in the figure. An interference pattern is formed on the plate. The fringe pattern formed will be irregular in shape and spacing unless *both* wave fronts have some simple form, such as plane, spherical, or cylindrical. The photographic plate is exposed to this interference pattern for a suitable time and is then processed in the darkroom in the usual way. The photographic density as a function of position on the plate is a record of the irradiance in the interference pattern. The photographic plate is now a hologram. In some respects it resembles a grating, but the lines are unequally spaced and distorted as a means of carrying information about the shape of the two wave fronts.

If the hologram is now replaced in its original position (as in Fig. 24) and illuminated from the left by *either* of the beams (*O* or *R*), then to the right of *P* there will be observed both beams (*O* and *R*) as if they had been propagated through a window at *P*. This process is called wave front reconstruction. The reconstructed wave front will correspond in direction to the first-order beam from a diffraction grating, but the irregular spacing and distortion of the lines will cause the wave front to duplicate, in amplitude distribution and phase, the wave front used to produce the hologram. There will usually be a third beam, called the conjugate beam, corresponding to order -1 of the grating. In some cases the form of the conjugate beam is easily predicted.

It is customary for one wave, *R* (called the reference wave), to be of some simple form, such as plane or spherical, that can be easily reproduced for use in the reconstruction process. The other wave, *O*, is from some object to be recorded; it carries information about the object and usually has rapid spatial variations of amplitude and phase. If such a complicated wave were used as the reference wave, then in the reconstruction process, the hologram would have to be repositioned very accurately. (Error from the exposure position must be small compared to the spatial scale of the amplitude and phase variations in the wave front.)

The preceding statements may be derived from the interference and diffraction equations. Let us look at a simple example as illustrated in Fig. 25*a*. A coherent, monochromatic beam of light such as an expanded laser beam falls upon an object (represented by a mug) and upon a polished steel ball. The light reflects from the ball provides a spherical wave front at the photographic plate *P*; this is the reference wave. Light is also scattered by the object and reaches the plate *P* as a very irregular object wave front carrying information about the object.

The plate is processed in the darkroom and becomes a hologram. This hologram is returned to its original position and is illuminated by light reflected by the ball, which is also in its original position. An eye looking through the hologram will see the object at its former position even though it has been removed. The hologram and the reference wave have reconstructed

the object wave front. This reconstructed object wave front has entered the eye and produced therein the same image that would have been produced by the original object wave front. The eye is using only that part of the hologram that is between the eye pupil and the reconstructed image. By moving the eye so as to look through a different part of the hologram, the observer sees the image from a different perspective and thereby observes that the image is three dimensional.

In this case, the conjugate wave gives rise to a conjugate image, as shown in Fig. 25*b*. It may be seen by looking through the hologram. In this case, both the image and the conjugate image are virtual. Real images may be obtained at these same positions if the reconstructing reference wave is replaced by its "conjugate," a spherical wave that strikes the hologram from the left and is converging toward *B*.

If the reference wave is plane, then the image in the reconstruction is a duplicate of the object and is virtual. In this case, the conjugate image is real and located on the opposite side of the hologram from the object position. The conjugate reference wave is a wave of the same curvature as the reference wave but propagating in the reverse direction. In this case, it is plane and produces a real image with virtual conjugate image.

The hologram is a photographic record of an interference pattern. The average fringe space *d* is given by

$$d = \frac{\lambda}{\sin \theta} \quad (37)$$

where θ is the angle between the reference and object beams; see Fig. 25. It is necessary that the photographic emulsion (or whatever recording medium is used) be able to resolve lines of this spacing.

The recording system is very sensitive to vibration. The relative motion of one wavelength of light of the various parts during exposure will reduce the contrast of the interference pattern to nearly zero and make the "hologram" useless. It is usually necessary to isolate the hologram-recording system from building vibrations.

By using reasonably large values of θ ($\approx 30^\circ$), it is possible to make the fringe spacing much less than the thickness of the photographic emulsion. In this case, the hologram has some of the properties of a blazed grating; that is, the reconstructed image is much brighter than the reconstructed conjugate image. It also makes the reconstructing angle of incidence more critical.

The main advantage of holography is its ability to record and reproduce the phase distribution in a wave front. Other recording methods record only the irradiance distribution.

4 LIGHT SOURCES

If we consider the light sources that we encounter in our daily lives, these would probably include

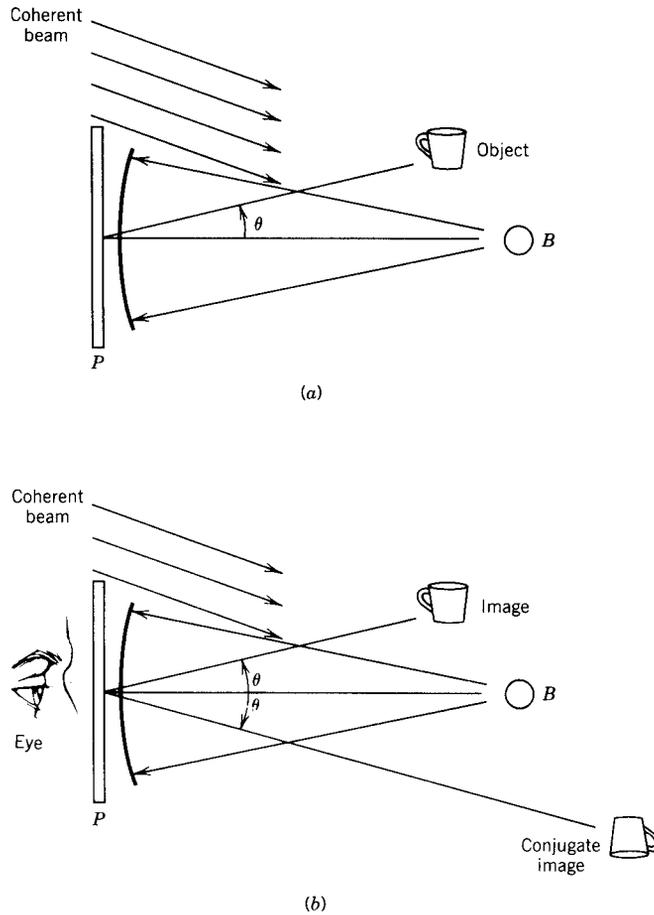

Fig. 25 Simple hologram experiment. Hologram is produced with arrangement of upper figure. Light reflected from polished steel ball *B* forms reference wave. Object wave is light scattered diffusely by object. In lower figure, object has been removed; reference wave falls on hologram. Eye, looking through hologram, sees image of object in its original position; conjugate image is also seen.

(a) tungsten filament lamps and fluorescent lamps used to illuminate our homes and workplaces (b) mercury or sodium arcs frequently used for highway lighting, and (c) in recent years, lasers, which have become fairly common but must be used with caution.

The tungsten filament lamp is the most common example of light sources that are solids and produce light because they are hot (i.e., incandescent). The oil lamp of years past also belongs in this class, producing light because small specks of carbon (i.e., soot) are heated to incandescence by the flame.

Discussion of these sources usually begins with a consideration of *blackbody radiation*. This is because the radiation of light from a blackbody is understood from a theoretical view and provides a standard of comparison for other sources of radiation. The subject is treated in many textbooks of thermodynamics or

modern physics. We shall be content to summarize the major results of the theory.

A blackbody is an object that absorbs all the radiation that falls upon it. In order to remain in thermal equilibrium with its surroundings, it must also emit radiation. A laboratory blackbody would consist of a cavity, the walls of which are maintained at some temperature *T*. There is thermal equilibrium between the walls and the radiation in the cavity except for a small hole in one wall that allows radiation to enter and leave the cavity. This hole is black in the sense that any radiation that enters the cavity through the hole has a negligible chance of finding its way back out. If the area of the hole is only a small part of the total wall area of the cavity, then the radiation escaping from the cavity through the hole is blackbody radiation at temperature *T*. The properties of this radiation are

independent of the shape of the cavity and the material of which the walls are made. It is also assumed that the cavity is filled with a transparent medium of index of refraction $n = 1.0$.

Experimental investigations support the following theoretically derived equations that describe the radiation emitted from a blackbody:

$$\frac{d\Phi}{dA} \equiv M = \sigma T^4 \quad (38)$$

This is known as the Stefan–Boltzmann law, where M is the total radiant flux Φ per unit area (watts per square meters) emitted by the blackbody, T is the temperature (degrees Kelvin), σ is the Stefan–Boltzmann constant, which has the value $5.67 \times 10^{-8} \text{ W/m}^2 \text{ K}^4$. Here, M is called the *radiant exitance*.

It is also customary to define the radiance L , which is the radiant flux (or power) per unit solid angle per unit *projected* area. In Fig. 26, the solid angle $d\Omega$, in steradians, is defined as dA_2/r^2 , where the area dA_2 is perpendicular to r and dA_1 is an element of area of the source (blackbody in our present discussion) but projected area means apparent area as seen from the direction θ ; so projected area is $dA_1 \cos \theta$:

$$L \equiv \frac{d^2\Phi}{d\Omega dA_1 \cos \theta} \quad (39)$$

A source for which L is independent of θ is called a Lambertian source; it looks equally “bright” from all viewing directions. A blackbody is a Lambertian source; some other sources are approximately Lambertian. For a Lambertian source that radiates into a hemisphere,

$$M = \pi L \quad (40)$$

The spectral distribution of blackbody radiation is described by the Planck radiation law, which may be

written in either of two forms. The first form is

$$L(\nu) = \frac{2h\nu^3}{c^2} \frac{1}{e^{h\nu/kT} - 1} \quad (41)$$

where $L(\nu) \Delta\nu$ is the radiance in the spectral region between frequencies ν and $\nu + \Delta\nu$; h is Planck's constant and k is the Boltzmann constant.

If the spectral distribution is to be given in terms of wavelength, then Eq. (41) may be converted to

$$L(\lambda) = \frac{2hc^2}{\lambda^5} \frac{1}{e^{hc/\lambda kT} - 1} \quad (42)$$

Here $L(\lambda) \Delta\lambda$ is the radiance in the spectral region between wavelengths λ and $\lambda + \Delta\lambda$. The velocity of light in free space is represented by c .

If we divide both sides of the preceding equation by T^5 , we see that $L(\lambda)/T^5$ depends upon λ and T only through the product λT . We can therefore plot a single graph of $L(\lambda)T^{-5}$ versus λT , which will serve for all wavelengths and temperatures. Figure 27 is such a plot.

The maximum value of $L(\lambda)T^{-5}$ is 4.095×10^{-6} if $L(\lambda) \Delta\lambda$ is in watts per square meter per steradian and $\Delta\lambda$ is measured in meters. The maximum occurs at $\lambda T = 2.898 \times 10^{-3} \text{ m K}$. The radiance $L = \int_0^\infty L(\lambda) d\lambda = \int_0^\infty L(\nu) d\nu$.

The surfaces of real solid objects are not black since they absorb only a fraction α of the radiation that falls upon them. The unabsorbed radiation will be reflected or scattered or, if the object is not too thick, transmitted. The fraction absorbed, α , will be a function of wavelength, temperature, and angle of incidence θ .

Heated solids radiate, but the spectral radiance $L(\lambda)$ is less than that of a blackbody at the same

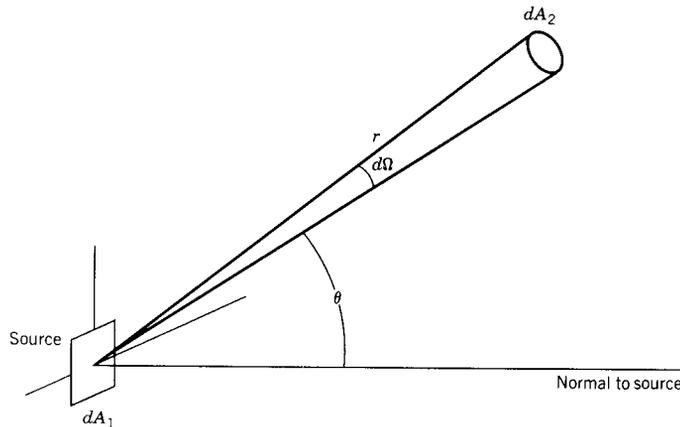

Fig. 26 Geometric quantities used in defining radiance L .

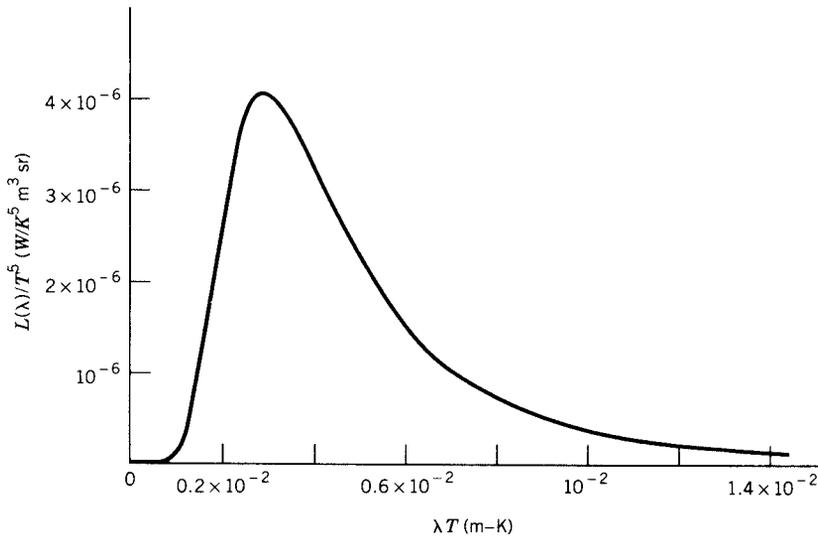

Fig. 27 Blackbody spectral distribution curve $L(\lambda)/T^5$ vs. λT . Power in watts; all lengths (including λ) in meters, and temperatures are degrees Kelvin. Curve has maximum value of 4.095×10^{-6} at $\lambda T = 2.898 \times 10^{-3}$.

temperature. The emissivity of the material, $\epsilon(\lambda)$, is the ratio of the radiance $L(\lambda)$ for the material at hand to the radiance $[L(\lambda)]_{BB}$ of a blackbody at the same temperature; $\epsilon(\lambda)$ is not only a function of wavelength but depends also upon the temperature and the angle of viewing, θ . For given temperature, wavelength, and angle

$$\epsilon(\lambda, \theta, T) = \alpha(\lambda, \theta, T) \tag{43}$$

Solids for which $\epsilon(\lambda)$ varies slowly over the spectral range are known as *gray bodies*. For example, the emissivity of tungsten at 2500 K varies in the visible spectrum from about 0.49 in the blue to about 0.40 in the red. It is considered a gray body. As a function of temperature, the value of $\epsilon(\lambda)$ of tungsten at $\lambda = 800$ nm is 0.414 for $T = 2000$ K and 0.396 for $T = 3000$ K.

Radiation from the sun closely resembles, in spectral distribution, radiation from a blackbody at 6500 K. Selective absorption by the atmosphere removes the ultraviolet ($\lambda < 350$ nm) and various regions of the infrared so that the sunlight reaching Earth is different from blackbody radiation.

If light passes through an optical system, we can measure the radiance L_1 before it enters the system and also measure L_2 after it leaves the optical system. [Recall the definition of L as given by Eq. (39).] It can be shown that if there are no losses (e.g., by absorption or by reflection at surfaces), then

$$\frac{L_1}{n_1^2} = \frac{L_2}{n_2^2} \tag{44}$$

where n_1 and n_2 are the indices of refraction of the medium before and the medium after the optical system. In many cases, the same medium (e.g., air) exists on both sides of the optical system; in these cases $L_2 = L_1$. If there are losses in the system, then L_2 will be less than the value given by this calculation.

Consider the situation presented in Fig. 28. A source S of area dA is imaged by an optical system to S' , which may serve as an apparent source for the region to the right of S' . The radiance of the beam to the left of the lens is L_1 ; neglecting losses and assuming air on both sides of the lens, the radiance to the right of the lens (both left and right of the image S') is $L_2 = L_1$. This is true only within the solid angle subtended by the lens at the image S' . Outside this solid angle L_2 is zero since no light reaches S' from the region beyond the circumference of the lens. As a secondary source, S' has radiance equal to L_1 out to this limiting angle and zero radiance for larger angles. No passive optical system can produce $L_2 > L_1$.

The irradiance (incident power per unit area) onto S' is E , given by

$$E = \frac{d\phi}{dA} = \int L_2 \cos \theta \, d\Omega$$

where the integration is over the solid angle subtended at S' by the lens. This is the same irradiance that would be produced at S' if the source S filled the exit pupil of the lens. The value of E depends upon the solid angle subtended. In photography, the solid angle is usually represented through the f number [see Eq. (26)] so that irradiance is proportional to $(F^\#)^{-2}$.

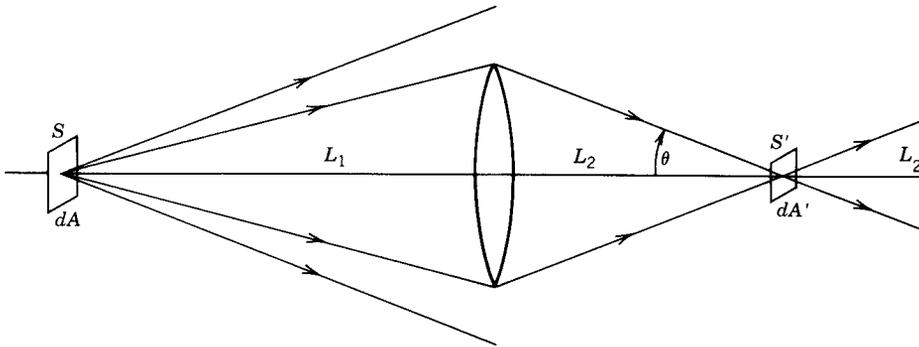

Fig. 28 Neglecting losses in lens, $L_2 = n_2^2 L_1 / n_1^2$. Assuming there is no diffusing screen at image position S' , L_2 remains the same to right of image; L_2 cannot be greater than L_1 if $n_2 = n_1$.

If one were to place a small luminous source, such as the filament of a small lightbulb, at S and then place the pupil of his eye at S' while looking back at the lens, he would see the exit pupil of the lens entirely filled with light. Only if the pupil of the eye is located at S' will the exit pupil be entirely filled with light.

5 LASERS

In gases, the intermolecular spacing is generally so large that the molecules radiate independently of each other, and the spectrum produced is a line structure for monatomic molecules or a band structure of fine lines for polyatomic molecules. We comment briefly about the atomic (or monatomic) case. As an example, sodium vapor may be observed to emit light by introducing a little salt (NaCl) into a bunsen flame alternatively, radiation from sodium vapor may be observed from the sodium arcs, which are widely used for highway lighting.

In the heat of the bunsen flame, the salt dissociates into sodium and chlorine atoms. Most of these atoms are in their lowest energy (or "ground") state. The atoms can, however, be put into more energetic (or "excited") states; the energy of the excited states is specific depending upon the atom. The number of atoms per unit volume, N_1 , in the excited state and the number of atoms per unit volume, N_0 , in the ground state will be in the ratio

$$\frac{N_1}{N_0} = e^{-\Delta E/kT} \quad (45)$$

where ΔE is the energy difference between an atom in the excited state and an atom in the ground state, T is the temperature (in Kelvin), and k is the Boltzmann constant. Clearly $N_1 < N_0$. The atom will have several excited states, each with its own ΔE , and there will be an equation similar to (45) for each state. The atoms in the more energetic states are said to be thermally excited. An excited atom may give up its excess energy

in the form of light and return to the ground state. The frequency and wavelength of the emitted light are given by the equation

$$h\nu = \frac{hc}{\lambda} = \Delta E \quad (46)$$

This bundle of light energy is called a *photon* or a *quantum*. Since each atom (e.g., sodium, potassium, mercury, and hydrogen) is characterized by its own set of excited states, it is also characterized by its own set of spectral lines.

In the case of the sodium arc lamp and other gaseous discharge lamps, the atomic excitations take place by inelastic collisions of the atoms with the moving electrons or ions that make up the electric current. Equation (45) is no longer an adequate description of the ratio N_1/N_0 , but in most cases it remains true that $N_1 \ll N_0$; that is, only a small fraction of the atoms are excited.

If there are N_1 excited atoms per unit volume, there will be a rate of spontaneous return to the ground state. That rate will be

$$\frac{dN_1}{dt} = -A_{01}N_1 \quad (47)$$

where A_{01} is a constant determined by the nature of the two states. Aside from the value of this constant, the rate of spontaneous return depends only upon N_1 . Each atom that returns from the excited state to the ground state emits one quantum of light.

If light of the resonant frequency [i.e., the frequency given by Eq. (46)] passes through the gas, some of the atoms in the ground state will absorb a quantum and be excited into the more energetic state. This process is called absorption, and the rate at which it takes place is given by

$$\frac{dN_0}{dt} = -B_{10}N_0L \quad (48)$$

where L is the radiance at the resonant frequency and B_{10} is a constant determined by the nature of the two states. The rate at which atoms are excited (or quanta absorbed) is proportional to L .

The atoms in the excited state are also affected by the light, causing some of them to emit a quantum and return to the ground state. This process is called stimulated emission. The rate at which it takes place is

$$\frac{dN_1}{dt} = -B_{01}N_1L \quad (49)$$

This is in addition to the spontaneous emission. It can be shown that $B_{10} = B_{01}$ and $A_{01} = (hv^3/\pi c^2)B_{10}$. The photon emitted by stimulated emission is indistinguishable from the photon that stimulated it. There are now two photons instead of one; they have the same direction of propagation, the same frequency, the same phase, and the same polarization.

In most cases, $N_0 \gg N_1$, so that absorption predominates and stimulated emission is of little consequence. However, if it can be arranged so that $N_1 > N_0$, then the stimulated emission will exceed the absorption and the light can increase in L as it propagates. This might be called negative absorption. This condition must exist in order to produce a laser. The condition in which $N_1 > N_0$ is called a *population inversion*. It may be created in a variety of ways.

In the helium–neon laser, for example, the population inversion is produced as follows: The medium is a mixture of helium and neon atoms in the ratio of about 4 : 1; the gas pressure of the mixture is about 1.0 torr to obtain a stable discharge. Electrical discharge in this gas mixture has little direct effect upon the neon but serves to excite some of the helium atoms into metastable states known as the 2^1S and the 2^3S states. These states are metastable in the sense that there are no allowed radiative transitions by which the atoms can return to the ground state; these helium atoms remain excited long enough to experience inelastic collisions with neon atoms. Fortunately, the excitation energy of the $3s_2$ state of a neon atom is the same as the 2^1S state of a helium atom; collision between an excited helium atom and an unexcited neon atom can result in energy transfer, producing a neon atom in the $3s_2$ state and a helium atom in the ground state. In the same way, a helium atom in the 2^3S state can excite a neon atom to

the $2s_2$ state. In this way, a small but useful fraction of the neon atoms are excited into these two states even though the neon was not directly involved in the electrical discharge. At a lower energy than the two states we have been discussing is a state of the neon atom known as $2p_4$. There are essentially no neon atoms in this state, so there is a population inversion between states $3s_2$ and $2p_4$ and between states $2s_2$ and $2p_4$. These two population inversions can produce lasing at $\lambda = 632.8$ nm and $\lambda = 1152.3$ nm, respectively. For the process to run continuously, the neon atoms in the $2p_4$ state must return to the ground state. This involves a radiative transition to the $1s_5$ state and finally an inelastic collision of the neon atom with the walls of the tube.

Since the rate of stimulated emission is proportional to the spectral irradiance (or to the spectral energy density) and the rate of spontaneous emission is independent of the spectral irradiance, it follows that stimulated emission will become the dominant process when the spectral irradiance is large. To bring this about, the lasing medium [in our case the helium–neon (He–Ne) gas mixture] is placed between two mirrors as indicated in Fig. 29. These mirrors should have high reflectivity; it is common for the reflectivities to exceed 99.5%. One of the mirrors should have a slight transmissivity (a few tenths of a percent) so that some of the light may escape from the space between the mirrors (called the cavity) into outside space.

If the mirror separation l and the wavelength λ_m are such that a round-trip path equals an integral number m of wavelengths, that is,

$$2l = m\lambda_m \quad (50)$$

there will be constructive interference for light reflected from the mirrors upon successive round trips. The cavity is said to be resonant at wavelength λ_m and at the corresponding frequency $\nu_m = c/\lambda_m$. The frequency spacing $\Delta\nu$ between ν_m and ν_{m+1} is $\Delta\nu = c/2l$. Cavity resonances are called *modes*. For the typical He–Ne laser, l may be about 30 cm so that m is a very large number and $\Delta\nu$ is about 500 MHz.

If a resonance of the cavity exists at the same wavelength as the resonance of the neon states $3s_2$ and $2p_4$ and there is also a population inversion for these two states sufficiently large that the gain per pass exceeds

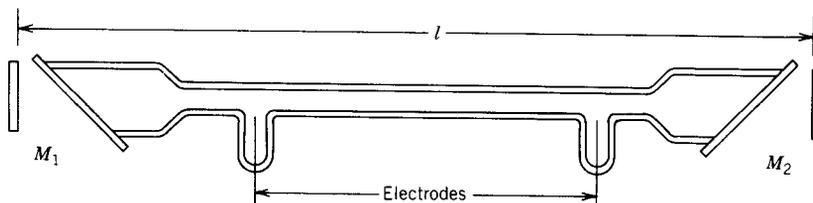

Fig. 29 Helium–neon laser with concave end mirrors and Brewster angle windows.

the losses, then there will be lasing (oscillation at optical frequencies) within the cavity. The losses from the cavity include (a) the light that escapes through the partially transparent mirrors, (b) absorption by the mirrors, (c) diffraction and scattering from the beam inside the cavity, and (d) any reflectio losses at the end windows of the discharge tube.

The spectral lines of neon have some width, primarily because of the Doppler broadening due to thermal motion. For an atom in motion, its Doppler-shifted resonant frequency must match the incident photon frequency in order to produce stimulated emission; that is, the Doppler-shifted frequency of the atom must match the cavity-resonant frequency for the system to lase. The spectral width of the neon resonance due to Doppler broadening is temperature dependent, but in a typical laser it is roughly 1.0 GHz. This width is sufficient to cover two, or sometimes three, cavity modes of a 30-cm laser cavity. These two or three modes will lase simultaneously.

In the first He-Ne lasers, the mirrors M_1 and M_2 were plane mirrors. It was necessary that they be accurately parallel to each other; if they were not, a ray reflecte back and forth between them would not remain in the discharge tube to be amplified by the active medium. It was later discovered that curved mirrors could be used, in which case the alignment is less critical. It can be shown by diffraction calculations or by ray tracing that a ray from M_1 to M_2 that is slightly off axis will remain trapped near the axis if the center of curvature of M_1 is to the right of M_2 and the center of curvature of M_2 is to the left of M_1 . The axis is a line through the two centers of curvature; the axis should pass through the discharge tube.

A limiting case is to use one plane mirror, M_1 , and let the center of curvature of the other (M_2) lie slightly to the left of M_1 ; this is called a hemispherical cavity. There are other mirror arrangements that form stable cavities (stable in the sense that rays are trapped near the axis), but the ones just mentioned are commonly used.

In contrast, there are unstable cavities in which a ray starting slightly off axis diverges from the axis and escapes from the cavity. As an example, we give a cavity for which the center of curvature of M_1 lies slightly to the left of M_2 and the center of curvature of M_2 lies slightly to the left of M_1 . (One center is inside the cavity and the other outside the cavity.) The rays are not trapped in this cavity but escape after a few round trips; the losses in this cavity are very large. It does not lase.

In the earliest He-Ne lasers, the reflectio losses at the windows on the ends of the discharge tube were so great that the system could be made to lase only by eliminating these windows and attaching the cavity mirrors directly onto the discharge tube. Later it was realized that by attaching the windows at the Brewster angle (see Fig. 3), one polarization (the polarization with E parallel to the plane of incidence) would experience no reflectio loss and the cavity mirrors could

be mounted independently of the discharge tube. The light from such a laser is linearly polarized since the gain exceeds the losses only for the polarization, which experiences no loss at the Brewster angle windows.

The mirrors M_1 and M_2 , which form the resonant cavity, are usually multilayer dielectric coatings since most metals do not have sufficiently high reflectivity. Also, with multilayer dielectric coatings the mirrors may be spectrally selective in their reflectivity. For example, the mirrors may be highly reflective at $\lambda = 632.8$ nm with much lower reflectivity at $\lambda = 1152.3$ nm. In this case, the He-Ne laser will lase at $\lambda = 632.8$ nm but not at 1152.3 nm. By exchanging the mirrors for a pair with high reflectivity at 1152.3 nm, we can cause the system to lase at that wavelength.

The modes considered a few paragraphs back are properly called longitudinal modes. A laser may also have several "transverse" modes, but the manufacturers of lasers usually suppress all the transverse modes except the TEM₀₀ mode. In this mode the amplitude of the electric field at the output mirror as a function of distance off axis r is given by

$$E = E_0 e^{-r^2/w^2} \quad (51)$$

where E_0 is the amplitude on axis, E is the amplitude at a distance r from the axis, and w is a constant depending upon the geometry of the cavity. The surface of the output mirror is a surface of constant phase (i.e., a wave front) for the emerging wave; the beam width w may be only a few millimeters.

We have given our attention to the He-Ne laser because it is readily available and illustrates the principles involved. There are many other media in which population inversion can be produced and which can provide lasing if used in a suitable cavity.

6 THE EYE AND VISION

The eye is important because most of the information obtained in a lifetime is brought to the brain through the eye. For the student of optics, the eye is important because many optical instruments, for example, microscopes and telescopes, are used in conjunction with the eye so that the eye becomes a part of the optical system. The pupil of the eye may become the aperture stop of the system or in some cases the eye may limit the spatial frequency response or resolution of the optical system. A geometrical or physical description is inadequate because the eye is a living, functioning organ that should be considered in terms of physiology and neurology, but these fields are beyond the scope of this chapter and can be considered only superficially.

6.1 Structure of the Eye

The human eye is an almost spherical organ about an inch in diameter. It is shown in cross section in Fig. 30. Six muscles, two of which are shown in the figure as Z_1 and Z_2 , hold the eye in place and rotate

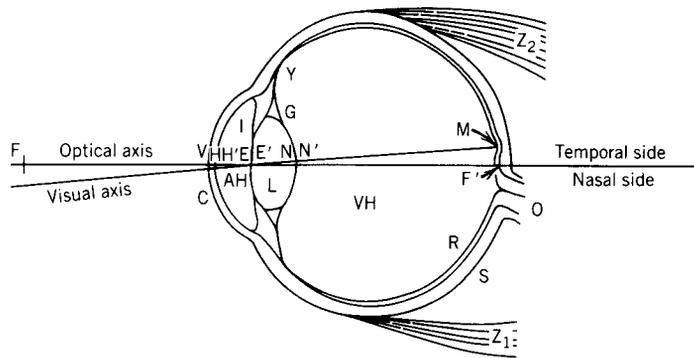

Fig. 30 Horizontal section of right human eye according to Helmholtz.

it relative to the head. These muscles are attached to the sclera S, which is a tough white skin covering most of the eye. At the front of the eye the sclera is replaced by the cornea C, which is a transparent membrane through which light enters the eye. After entering through the cornea, light passes through the aqueous humor AH, the crystalline lens L, the vitreous humor VH, and finally reaches the retina R. The aqueous humor is a weak salt solution; the vitreous humor is a soft jelly consisting primarily of water. The fluids of the eye are slightly (~25 torr) above atmospheric pressure. This pressure helps to maintain the shape of the eyeball. The crystalline lens is a fibrous jelly contained in a thin membrane or sac; it is hard at the center and progressively softer toward the outside. The lens is held in place and attached to the ciliary muscle Y by the suspensory ligament G. When the ciliary muscle is relaxed, the second focal point is at the retina and distant objects are in focus. To view nearby objects, the ciliary muscle contracts, allowing the lens to become more nearly spherical. This is known as accommodation; with age, the lens becomes less elastic, and the ability to accommodate gradually decreases. The lens of the eye is not transparent to ultraviolet light.

The retina is the interior lining for a large part of the eyeball. It consists of rods and cones that are light-sensitive nerve endings, along with a delicate network of nerve fibers connecting the rods and cones to the optic nerve O and a network of capillary blood vessels that supply the necessary oxygen and nutrients. The yellow spot, or macula lutea M, which contains many cones and relatively few rods, is a slight depression in the retina; the central region, called the fovea centralis, contains cones exclusively, no rods. The macula lutea is about 2 mm in diameter, and the fovea centralis is about 0.25 mm in diameter. Cones in the fovea centralis are about 1.5 μm in diameter, increasing in size to about 5.5 μm in the outer portion of the macula lutea and several times this size in other portions of the retina. See Fig. 31. In the outer portion of the retina, the rods outnumber the cones by 10:1.

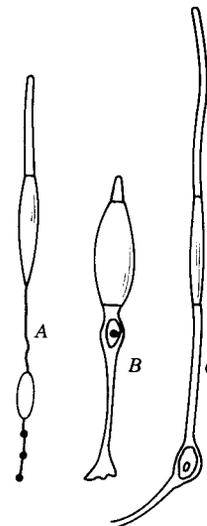

Fig. 31 Rods and cones of retina: A, rod; B, cone from extrafoveal region; C, cone from central fovea.

Each human eye contains roughly 7 million cones and 120 million rods.

Vision in the fovea centralis is so much more acute than in the extra foveal region that the muscles surrounding the eye involuntarily rotate the eyeball until the object of interest is imaged upon the fovea centralis. The angle in *object space* covered by the fovea centralis is less than 1°; it is only a little more than sufficient to cover one letter of this printed page when the book is held at the usual reading distance of 25 cm. In reading or examining an extended object, the eye must move frequently. Extra foveal vision is not useful in observing details but enables one to be aware of objects around him. For a healthy eye, the total field is about 128°; an early symptom of glaucoma is the shrinking of the field of view.

The mosaic structure of the cones in the fovea centralis limits the resolution of the eye. Considering the size of the cones, this varies from 0.3 to 1.0 min for the angular resolution in object space. These numbers should be slightly larger because the cones are separated by a small amount of inactive tissue. It is interesting to observe that this is comparable to the resolution limit set by diffraction at the pupil and also comparable to the limits produced by aberrations, primarily spherical aberration of the optical system. One minute is a good round number representing the overall resolution of the eye.

Part of the blood supply to the retina is provided by a network of blood vessels on the front of the retina. If one stares at a blue sky (or a white wall illuminated by blue or violet light), the red blood cells coursing through these blood vessels can be seen since they cast a shadow on the retina. Unlike the specks of dust that float upon the front of the eye or in the vitreous humor when one is tired, these shadows follow definite paths; that is, they are confined to the blood vessels. These shadows are called *muscae volitantes*, which means flying flies. Red blood cells are about $8\ \mu\text{m}$ in diameter, so each one can cast a shadow over several cones of the fovea.

6.2 Adaptation of Eye to Light

The iris diaphragm, I , is a ring-shaped involuntary muscle that controls the amount of light entering the eye. It is located just in front of the lens, and the diaphragm opening or pupil is the aperture stop of the eye. It varies in diameter from 2 to 8 mm. This is a factor of 4^2 , or 16, in the area of the entrance pupil. The eye functions under illumination conditions that vary by a factor of $\sim 10^9$. Variation in pupil size is certainly not sufficient to account for this wide range; most of the adaptation to light and dark is accomplished by changing the sensitivity of the retina. The photosensitive chemicals (or pigments) in the rods and cones are bleached or altered by light and must be constantly reconstituted. Due to the lower rate at which the pigment is consumed in low illumination, the steady-state concentration of the pigments is higher and the retina more sensitive in low illumination than in high illumination.

6.3 Scotopic Vision

When the eye has been dark adapted (i.e., kept for half an hour or more in darkness comparable to outdoor illumination by a moonless night sky), the eye becomes sufficiently sensitive to see a small source of 2×10^{-8} cd at a distance of 3 m. Neglecting atmospheric absorption, this is equivalent to seeing a standard candle at a distance of 13 miles. Astronomers observe that except under unusually good conditions, stars of sixth magnitude represent the limit of vision of the unaided eye. This corresponds to seeing a standard candle at a distance of about 6.6 miles through

the atmosphere. However one describes it, the dark-adapted eye is incredibly sensitive.

Vision by the dark-adapted eye is called *scotopic* vision and takes place in the rods of the eye, not in the cones. Since there are no rods in the fovea, the dark-adapted eye has no central vision, and in order to see an object in subdued light, one must look not at the object of interest but to the side so that the object of interest will be imaged on the outer part of the retina, which contains rods. There is no color in scotopic vision.

In the rods, the pigment that absorbs the light and somehow triggers the signal along the nerves to the brain is called rhodopsin. The chemical composition and structure is known to be a protein molecule combined with a molecule of retinal. Retinal is closely related to the compounds known as retinol (vitamin A) and carotene (the yellow pigment of carrots and many other yellow vegetables).

The spectral sensitivity of rod vision is shown in curve B of Fig. 32. The ordinate at each wavelength is inversely proportional to the minimum amount of energy that is just perceptible (i.e., to the threshold of vision). The curve is normalized to 1 at its peak. This closely matches the absorption curve of rhodopsin.

6.4 Photopic Vision

For conditions of ordinary illumination, the rhodopsin in the rods is almost completely bleached and vision is by the cones. This is called *photopic* vision, or cone vision. The spectral sensitivity for cone vision is shown by curve A of Fig. 32. Notice the shift of this curve toward the red relative to the scotopic curve B . Because of this shift, two nonluminous objects of different colors (e.g., yellow and blue-green) that appear "equally bright" in ordinary illumination will not appear equally bright in subdued illumination (e.g., twilight), the blue-green becoming much more conspicuous than the yellow. This shift in the spectral sensitivity and the resulting change in relative brightness of various colors is known as the Purkinje effect. It is a source of trouble in making visual comparisons of light sources of different colors.

The level of illumination at which the eye changes from photopic to scotopic vision (or vice versa) with the attendant change in spectral sensitivity, loss of color discrimination, and foveal vision is about the illumination level produced by the full moon on a clear night, or 0.16 lux.

6.5 Color Vision

Color vision takes place in the cones. There are three different types of cones in the eye; the three differ in that they contain different photosensitive pigments and have distinct spectral response curves. There is no observable physical structure that enables one to distinguish between the three types; the photosensitive pigments are present in such low concentrations that it is difficult to distinguish even on this basis.

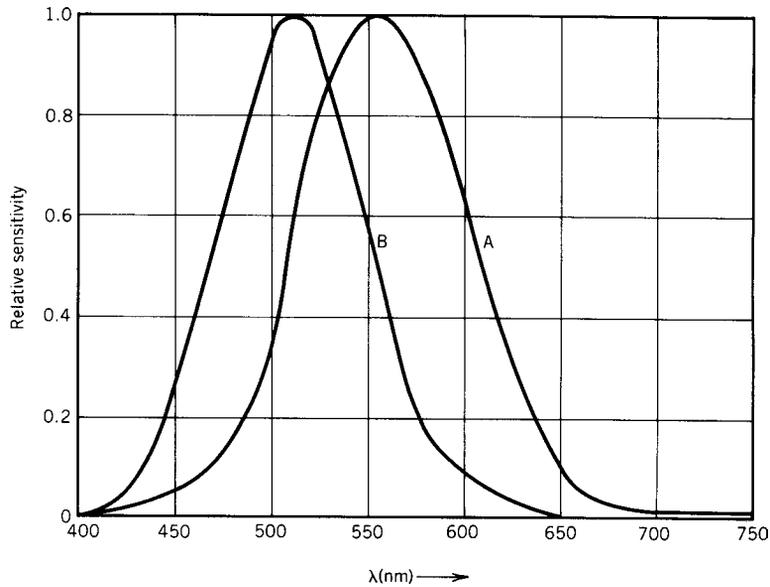

Fig. 32 Spectral sensitivity curves for normal human eye: A, light-adapted (photopic) eye; B, dark-adapted (scotopic) eye. Each curve is normalized to 1 at its maximum.

The three pigments are probably three different protein molecules, each in combination with a molecule of retinal. Because of the chemical similarity of the three dyes to each other and to rhodopsin (which is much more abundant), they are difficult to isolate and identify. The spectral sensitivity of the three cone types is given in Fig. 33. The output of each cone is determined by the intensity reaching it, the wavelength of the light, and the spectral sensitivity of the cone for that

wavelength; the same output signal could be obtained by use of a lower intensity at a wavelength closer to the peak of the sensitivity curve. Each cone is color blind (just as the rods are color blind); the sense of color is derived from the relative response of the three types of cones.

As shown in Fig. 33, the three cone types have peak sensitivities in the blue (~440 nm), green (~535 nm), and orange (~565 nm); they are labeled C, B, and A,

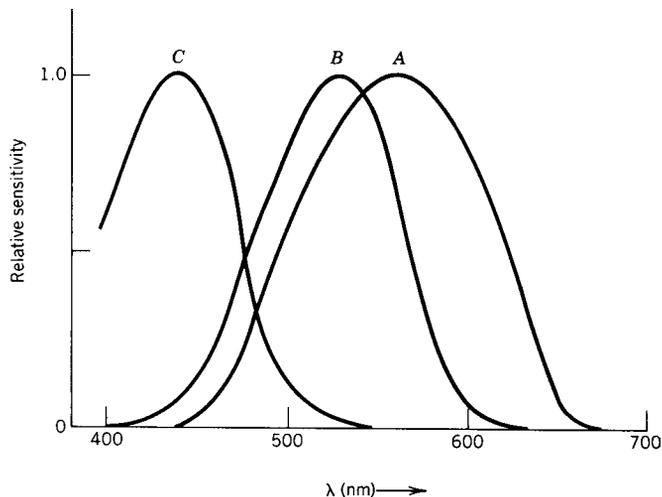

Fig. 33 Spectral sensitivity curves for three cone types of human eye. Each curve is normalized to 1 at its maximum.

respectively. For each spectral wavelength, the relative response of these three cone types is unique and determines the color sensation. If several wavelengths are present, each wavelength evokes a response in each cone type, and the relative size of the total response in each of the three cones determines the color sensation. Curve *A* peaks at 565 nm, which is in the orange; at this wavelength, the other curves, in particular *B*, still have nonzero values and the sensation of orange is produced by a signal from *A* and a weaker signal from *B*. At longer wavelengths, cones of type *A* respond less than they did at 565 nm, but the response from cones of type *B* decreases even more rapidly so that the signal from *A* makes up a larger fraction of the total output and the color sensation changes from orange to red.

Common forms of color blindness result from the absence of type *A* or type *B* cones. Protanopes are persons color blind due to lack of type *A* cones; deuteranopes lack type *B* cones.

In ordinary vision, the output of type *A* cones is added to the output of type *B* cones (with perhaps a weak contribution from type *C* cones), and this sum is transmitted to the brain along the optic nerves. This sum encoded as nerve pulses per second is interpreted by the brain as luminosity (white) without color information. Color information is transmitted in two channels as the difference ($A - B$) between the output of type *A* cones and type *B* cones and the difference ($A - C$) between the output of type *A* cones and type *C* cones. The data is processed into these sum and differences in or near the eye and then transmitted along nerve fibers to the brain in the form of an increase or a decrease of the pulse frequency from the spontaneous value of the pulse frequency that exists when the eye is in the dark. Type *C* cones have little effect upon the sensation of brightness but are effective in producing color discrimination.

Although the system just described is believed by many to be the usual one, others are possible and sometimes effective because one can cover the right eye with a red filter and the left eye with a green filter (or vice versa) and obtain color vision. In this case, some of the data processing that usually takes place at the eye appears to be deferred to some later stage of the visual process, perhaps in the brain or perhaps at the optic chiasma, the point at which the two optic nerves (one from each eye) come together on their way to the brain.

For a person with normal vision, the colors associated with various portions of the spectrum are as shown in Table 2.

Table 2 Colors and Associated Wavelengths

Color	Wavelength (nm)
Violet	<450
Blue	450–500
Green	500–570
Yellow	570–590
Orange	590–610
Red	>610

6.6 Colorimetry

The word *color* has several definitions. In one, it is associated with the properties of a dye; in another, it is a property of light; and in yet another, it is a physiological sensation produced in the brain by light entering the eye. In an earlier section, we have given a brief description of color vision. In this section, we use the word color as descriptive of the light entering the eye and present the methods used to give a quantitative description of the color. The branch of optics that deals with the quantitative specification of color is called colorimetry.

6.7 Color Mixing

In order to understand colorimetry, we must first establish the basic facts of color mixing, which are illustrated by the following experiment. We attempt to match all possible colors by mixing three "primaries." The selected primaries are monochromatic (or spectral) colors of wavelength 450 nm (blue), 550 nm (green), and 620 nm (red). We identify them as α , β , and γ , respectively. There is nothing unique about these particular wavelengths that entitle them to be primaries; we select them because the experimental data using these three primaries was carefully determined in early color-mixing experiments. We now allow the eye to look at a white diffusing card. Two adjacent areas of the card are illuminated (a) by light of arbitrary or unknown color and (b) by a mixture of the three primaries. Area 2 is illuminated by all three primaries, and the amount of each primary is adjusted to obtain a match with the unknown. Most colors can be matched by this mixing process; a few cannot. In cases for which the unknown cannot be matched by the preceding process, a match can be obtained by moving one (or very rarely two) of the primaries from area 2 to area 1 and then adjusting the amount of each primary; this is equivalent to subtracting or using a negative amount of the moved primary in area 2. The use of three primaries widely spaced in the spectrum, as are the ones suggested here, reduces the number of cases in which a negative amount of any of the primaries is required. Neither the unknown nor the primaries need be monochromatic (spectrally pure) colors; a match can always be made. If the unknown is represented by U and the amount of each primary by A , B , and C , respectively, the experimental results may be represented by the equation

$$U = A + B + C \quad (52)$$

which is interpreted to mean that the sensation of light and color produced by the unknown may be duplicated by the mixture of the three primaries. The values of A , B , and C are unique if U is given. The eye sees the overall effect of the mixture; it is not aware of the individual primaries that make up the mixture.

If we now restrict our unknown to spectrally pure (i.e., monochromatic) light and keep the power of the

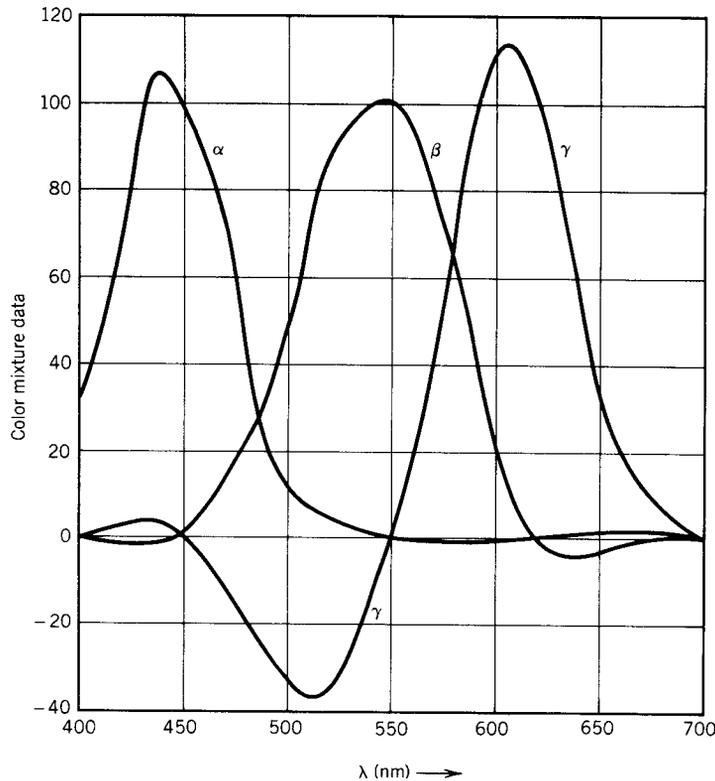

Fig. 34 Color mixture curves for matching spectrally pure colors by mixing primaries having wavelengths 450, 550, and 620 nm.

unknown constant but vary its wavelength, we can at each wavelength determine experimentally the power of each primary required to produce a match. The results of this experiment are given in Fig. 34, which gives the amount of each primary α , β , and γ required to match each spectral color. The curves have been normalized to $\beta = 100$ at 550 nm; α and γ are zero at this wavelength, which corresponds to the β primary. Each curve is normalized to 100 when the unknown wavelength is the same as that primary. For example, the curves indicate that a match is obtained for an unknown at 500 nm by combining 47.5 units of α (light at 450 nm) with 125 units of β (light at 550 nm) and subtracting (i.e., adding to the unknown) 30.0 units of γ (light at 620 nm). Notice that the primaries do not add to 100; this is because the spectral sensitivity of the eye for each of the primaries differs from its sensitivity at the unknown wavelength. In this case, the most significant difference is a factor of about 3 between the sensitivity of the eye to the β primary and its sensitivity to the 500 nm unknown.

Similar curves for the mixing of other sets of monochromatic primaries could be determined experimentally, but it is unnecessary to do so because it

is possible to deduce them from the curves already given. The process is straightforward but tedious, and we shall not describe it. It is also possible to specify a new set of primaries by giving the curves α' , β' , and γ' , which give the mixing data required to match spectral colors using the new primaries. As long as the new curves α' , β' , and γ' (as functions of wavelength) are a linear combination of the experimental curves α , β , and γ (which were given in Fig. 34), the new system will give a satisfactory system of color specification. The requirement of algebraic linearity means that

$$\begin{aligned} \alpha' &= K_{11}\alpha + K_{12}\beta + K_{13}\gamma \\ \beta' &= K_{21}\alpha + K_{22}\beta + K_{23}\gamma \\ \gamma' &= K_{31}\alpha + K_{32}\beta + K_{33}\gamma \end{aligned} \quad (53)$$

where the K_{ij} are real and independent of wavelength but are otherwise subject to no restriction except that the determinant

$$\begin{vmatrix} K_{11} & K_{12} & K_{13} \\ K_{21} & K_{22} & K_{23} \\ K_{31} & K_{32} & K_{33} \end{vmatrix} \neq 0 \quad (54)$$

With such a wide choice of primaries and with the possibility of algebraic transformation from one set to another, color-mixing data could not provide any insight into the spectral sensitivity curves of Fig. 33, but this did not prevent the development of colorimetry in advance of a detailed understanding of color vision.

With so much freedom in the choice of the K_{ij} (or the curves α' , β' , and γ'), it is probably not surprising that some of the possible sets of primaries so described contain primaries that are not spectral colors (e.g., purples) or not spectrally pure (e.g., pinks). It is also true that many acceptable sets of primaries contain primary colors that are not real; by this we mean that they exist mathematically in terms of the mixing curves α' , β' , and γ' , which produce real colors; in this sense, they are entirely satisfactory primaries, and yet they do not exist in the sense that the single primary alone cannot be seen as light and color.

6.8 Tristimulus Values and Trichromatic Coefficients

Since color specification is commercially important and since there is so much freedom in the choice of

primaries, it was inevitable that there should develop some agreement on what set of primaries would be used. In 1931, the International Commission on Illumination (ICI) [also known by its French name, Commission Internationale de l'Eclairage (CIE)] agreed to express all color specification in terms of three primaries defined by the color-mixing curves of Fig. 35. The letters \bar{x} , \bar{y} , and \bar{z} have become standard, replacing the α , β , and γ used by earlier workers. The ordinates, called *tristimulus values*, are in arbitrary units and have been adjusted so that the areas under the three curves are equal. The shape of curve \bar{y} was arbitrarily chosen to be the same as curve A of Fig. 32. Curves \bar{x} and \bar{z} have shapes selected so that the three primaries satisfy Eq. (53). For computational convenience it was also required that none of the curves is ever negative. None of the primaries defined by this set of mixing curves is real; they form a satisfactory base for the quantitative specification of color, but only real colors can be produced and mixed in the laboratory.

For monochromatic light with wavelength 500 nm (green), the tristimulus values are

$$\bar{x} = 0.0049 \quad \bar{y} = 0.3230 \quad \bar{z} = 0.2720$$

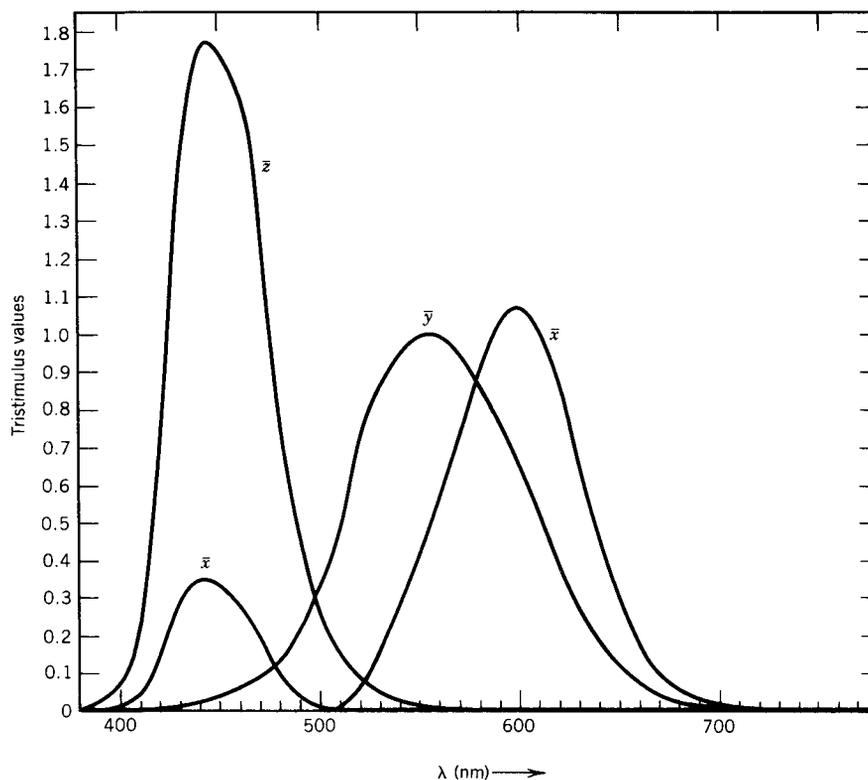

Fig. 35 Standard ICI (or CIE) tristimulus curves \bar{x} , \bar{y} , and \bar{z} for unit power at indicated wavelength. Numerical values for these curves may be found in Refs. 1 and 2.

Define three new quantities x , y , and z such that

$$x \equiv \frac{\bar{x}}{\bar{x} + \bar{y} + \bar{z}} \quad y \equiv \frac{\bar{y}}{\bar{x} + \bar{y} + \bar{z}} \quad z \equiv \frac{\bar{z}}{\bar{x} + \bar{y} + \bar{z}}$$

These new quantities are called *trichromatic coefficients* and by definition have the property that $x + y + z = 1$; any two of the three quantities are sufficient to specify the color. For 500-nm light, the values are

$$x = 0.0082 \quad y = 0.5384 \quad z = 0.4534$$

This system cannot contain any intensity information, only color information.

In this system, any spectral color may be specified by giving any two of the trichromatic coefficients; the values of x and y are usually given. If we plot on ordinary graph paper the values of x and y for the spectral colors, we obtain the curve of Fig. 36, where the wavelength (in nanometers) is shown at various places along the curve. A diagram such as this in which color information is plotted using the trichromatic coefficient is called a *chromaticity diagram*; the curve is known as the spectrum locus.

6.9 Trichromatic Coefficients for Nonmonochromatic Light

In the previous section we define the trichromatic coefficient of any monochromatic light using the ICI (or CIE) primaries. In very few cases is the light reaching the eye monochromatic; it is usually a mixture or distribution of spectral colors. If we represent the spectral distribution by the function $f(\lambda)$ define so that $f(\lambda) d\lambda$ is the power (e.g., in watts) in the spectral interval between λ and $\lambda + d\lambda$, then we calculate the *tristimulus values* of the light by the equations

$$X \equiv \int_0^\infty \bar{x} f(\lambda) d\lambda \quad (55a)$$

$$Y \equiv \int_0^\infty \bar{y} f(\lambda) d\lambda \quad (55b)$$

$$Z \equiv \int_0^\infty \bar{z} f(\lambda) d\lambda \quad (55c)$$

where \bar{x} , \bar{y} , and \bar{z} are the functions represented in Fig. 35, the ICI color mixture curves. This process

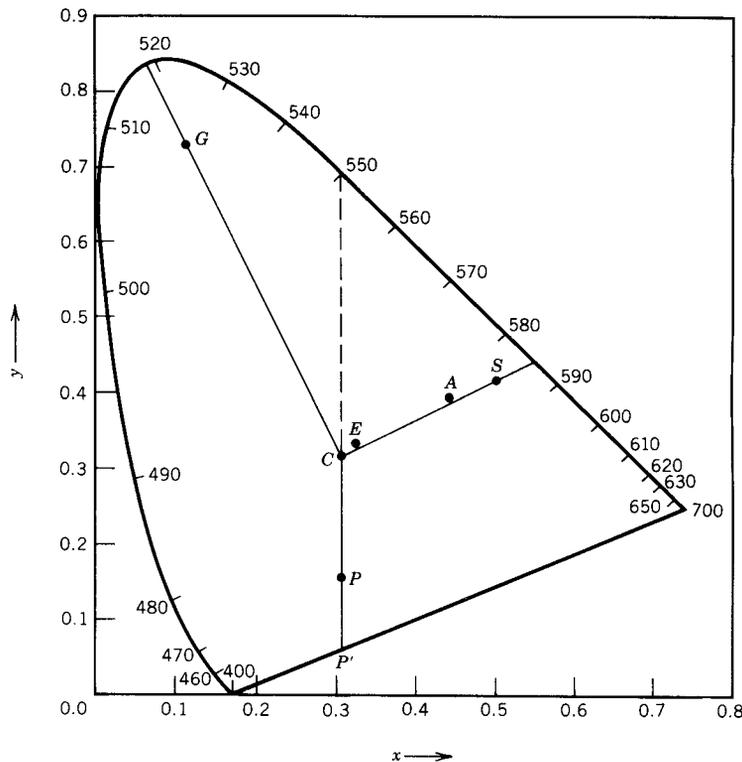

Fig. 36 Chromaticity diagram: Horseshoe curve, spectrum locus; E, source for which $f(\lambda)$ is constant; C, illuminant C, approximately daylight; A, illuminant A, illumination from tungsten filament lamp; S, light reflected from orange skin illuminated by illuminant C.

amounts to treating each spectral color in the light by the methods of the previous section and then adding (integrating) all of these effects together. By definition, the integrals are from zero to infinity but since the functions \bar{x} , \bar{y} , and \bar{z} are zero outside of the visible range, the integration is effectively limited to the visible-wavelength interval. The functions involved cannot be integrated by elementary methods; the integration is carried out numerically. The numerical data represented by the curves \bar{x} , \bar{y} , and \bar{z} may be found in the original ICI report¹ or in any textbook on colorimetry.²

The three tristimulus values calculated by Eqs. (55) are converted to *trichromatic coefficients* by the equations

$$\begin{aligned} x &= \frac{X}{X + Y + Z} & y &= \frac{Y}{X + Y + Z} \\ z &= \frac{Z}{X + Y + Z} \end{aligned} \quad (56)$$

We again have the property that

$$x + y + z = 1 \quad (57)$$

and any two of these may be used to specify the color of the light; x and y are usually used. Information about the total intensity of the light has been lost, but all color information is retained.

As an example, consider light for which the spectral distribution $f(\lambda)$ is a constant. This is light for

which, at any wavelength, a small wavelength interval $d\lambda$ contains the same power as an equal interval $d\lambda$ located at any other wavelength. Since the three curves x , y , and z of Fig. 35 have equal areas under them, the integrals of Eqs. (55) will, for this example, be equal, that is, $X = Y = Z$. When these are converted to the trichromatic coefficient x , y , and z , we obtain

$$x = y = z = 0.3333$$

On the chromaticity diagram (Fig. 36), this is represented by the point E at $(\frac{1}{3}, \frac{1}{3})$.

Another important example is light from a source known as illuminant C. Illuminant C is intended to have the same spectral distribution as average daylight, at least in the visible. It consists of a gas-filled tungsten lamp operated at the color temperature 2848 K combined with filter designed to alter the spectral distribution of the lamp to that of daylight. The spectral distribution of illuminant C is in Fig. 37. From this distribution, one can evaluate numerically the integrals of Eqs. (55) and then the trichromatic coefficient x , y , and z of Eqs. (56). The results of these calculations give point C at (0.3101, 0.3163) on the chromaticity diagram in Fig. 37. Light from illuminant C is generally considered to be "white," although the term *white light* has no universally accepted definition

6.10 Color of an Orange Skin

In Fig. 37, there is shown the reflectance of an orange skin as a function of wavelength, $R(\lambda)$. This curve may be obtained by illuminating the orange skin successively at several different wavelengths; at each

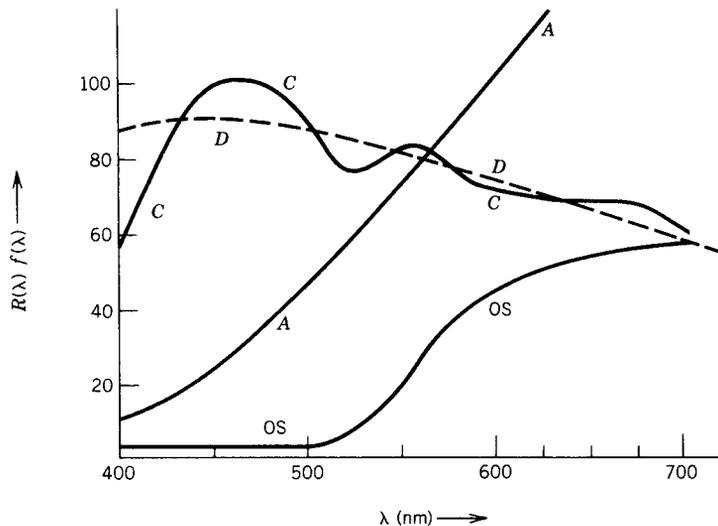

Fig. 37 Dashed curve D , curve A , and curve C are spectral distributions $f(\lambda)$ of average daylight, light from illuminant A , and light from illuminant C . (Vertical scale is arbitrary and not the same for the three curves.) Lower curve OS , spectral reflectance $R(\lambda)$ of orange skin; magnesium carbonate powder is taken as 100%.

wavelength, the reflectance is measured for the orange skin and for some white object. The reflectance $R(\lambda)$ at each wavelength is the ratio of these two measurements. Since the orange skin is a diffuse reflector the white comparison object should be a diffuse reflector also. Freshly fallen snow is a good white diffuse reflector but in the laboratory a powder of magnesium carbonate is more practical.

The observed color of the orange skin depends not only on its spectral reflectance but also on the spectral distribution of the illuminating light. Let us assume that illuminant C is used and we represent its spectral distribution by $C(\lambda)$. The spectral distribution of the light reflected from the orange skin is the product $C(\lambda)R(\lambda)$. We calculate the tristimulus values of this light from Eqs. (55):

$$X \equiv \int_0^\infty \bar{x}C(\lambda)R(\lambda) d\lambda = 341$$

$$Y \equiv \int_0^\infty \bar{y}C(\lambda)R(\lambda) d\lambda = 277$$

$$Z \equiv \int_0^\infty \bar{z}C(\lambda)R(\lambda) d\lambda = 50$$

and when these are normalized to the trichromatic coefficients we have

$$x = 0.511 \quad y = 0.414 \quad z = 0.075$$

These locate a point (marked S) on the chromaticity diagram (see Fig. 36). This point is fairly close to the spectral locus for 586 nm. The light reflected from this orange skin is therefore close to the orange-yellow color of the sodium D lines.

If we used another illuminant instead of illuminant C, the location of point S representing the chromaticity of the light reflected by the orange skin would have to be recalculated and would probably have changed.

Two pieces of cloth that have the same spectral reflectance will always look alike, that is, have the same coordinates on the chromaticity diagram, as long as the same illuminant is used on each piece no matter what illuminant is used. It is possible, and sometimes happens, that two pieces of cloth that have different spectral reflectance curves may look alike when illuminant C is used but will be noticeably different when another illuminant, such as illuminant A, is used. Illuminant A is the gas-filled tungsten lamp operated at the color temperature 2848 K and used without filters it is typical of the illumination produced by tungsten filament lamps. The chromaticity of illuminant A is represented by point A in Fig. 36. It more frequently happens that two pieces of cloth look alike under illuminant A but are noticeably different under illuminant C. Illuminant A is relatively weak in the short-wavelength region so that a match using this illuminant is relatively insensitive to the reflectance

of the cloth for blue light. Illuminant C is slightly stronger at the shorter wavelengths than it is at the longer wavelength (see Fig. 37).

6.11 Chromaticity Diagram as Aid to Color Mixing

From the definition of the trichromatic coefficient [Eqs. (55)], it follows that if we have two colors represented by points such as G and R (Fig. 38) of the chromaticity diagram, any additive mixture of these two colors will be represented by a point lying on the line GR . If each component (G and R) is assigned a weight proportional to the sum of its tristimulus values ($X + Y + Z$), the point representing the chromaticity of the mixture will lie at the center of gravity of these weights. For example, if the mixture contains more of light G than of light R such that the sum $X + Y + Z$ for light G is twice the corresponding sum for light R , the mixture will have color represented by the point D on the line GR located so that the distance DR is twice the distance GD . Any color on the line from G to R may be obtained by additive mixing properly selected amounts of lights G and R . After obtaining light D in this way, light D may be mixed with some other light, such as that represented by B , to obtain any color along the line BD . It follows that by additive mixing properly selected amounts of the three lights represented by points G , R , and B , one can obtain any color within the triangle GRB . Colors outside this triangle cannot be produced by additive mixing of colors GRB .

Since all the real colors are mixtures of the spectral colors, they must lie in the area enclosed by the horseshoe-shaped spectrum locus curve and the straight line connecting the violet and red ends of the horseshoe.

If the triangle GRB is to enclose most of the real colors, the point G should lie close to the spectrum locus point for 520-nm (green) light, and the points R and B should be near the red and violet ends of the spectrum locus curve. In this sense, red, green, and blue are desirable primaries.

Equations (55) and (56) give us a means of calculating the trichromatic coefficient (and therefore the location on the chromaticity diagram) for light with any given spectral distribution; the answer is unique. The reverse process is not unique. Given a light represented by a point such as G that has a specific set of trichromatic coefficients this light may be matched by a mixture of two monochromatic colors with wavelengths 500 and 530 nm, by a pair with wavelengths 510 and 550 nm, or by several other pairs of monochromatic colors or a variety of continuously variable spectral distributions. These various matches are easily distinguished with the aid of a spectrometer, but to the unaided eye all look the same. There is no unique spectral distribution associated with a given point on the chromaticity diagram.

Color television is an example of additive color mixing. The screen consists of a mosaic (dots) of three different phosphors that can be excited independently;

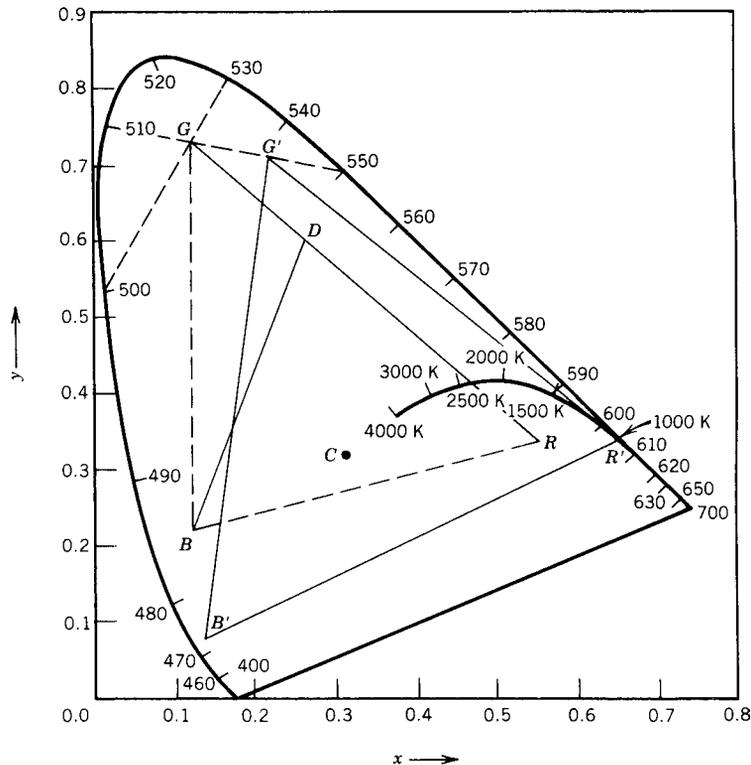

Fig. 38 Chromaticity diagram as aid to color mixing. Any color along line GR may be produced by adding colors G and R . Any color within triangle GBR may be produced by adding properly selected amounts of light of colors G , B , and R . Color television uses primaries G' , B' , and R' . Curve entering horseshoe near 610-nm locus gives color of blackbody radiation for several temperatures.

the three phosphors emit three different colors: red, green, and blue. At the customary viewing distance, the spacing of the dots is too small to be resolved by the eye and so the light from several dots is added together to give the sensation of color. The phosphors used give the colors represented by R' , G' , and B' in Fig. 38. The coordinates of these points are $R' = (0.670, 0.330)$, $G' = (0.210, 0.710)$, and $B' = (0.140, 0.080)$. By exciting these three phosphors in the proper ratio, any color within the triangle $R'G'B'$ can be produced.

In Fig. 38, we have added a curve representing the color of a blackbody at temperatures from 1000 to 4000 K. It is "cherry red" at 1000 K and progresses through orange toward white as the temperature rises. At very high temperatures (e.g., 15,000 K), the blackbody color is on the blue side of illuminant C.

6.12 Dominant Wavelength and Purity

Dominant wavelength and purity are physical properties of light that evoke the physiological sensations called hue and saturation.

As an illustration, consider again the orange skin. The chromaticity of the light scattered from it is represented by the point S in Fig. 36. Continuing to use C as the white point, we see that a line C to S may be extended to intersect the spectrum locus at $\lambda = 587$ nm, which is labeled D and has coordinates $(0.56, 0.44)$. It follows that the light from the orange skin may be color matched by a mixture of white light (illuminant C) and monochromatic light of wavelength 587 nm. The light from the orange skin is said to have a *dominant wavelength* of 587 nm. The distance from C to S divided by the distance from C through S to D is 0.83; light from the orange skin is said to have spectral purity p of 83%.

Similar procedures show that light represented by the point G has dominant wavelength of 519 nm and spectral purity of 80%. Specifying dominant wavelength and spectral purity is an alternate method of locating a point on the chromaticity diagram. For most people, these quantities are easier to interpret than the trichromatic coefficient x and y .

One runs into trouble for colors in the lower part of the diagram, for example, the color represented by

the point P . A line from C to P , if extended, does not intersect the spectrum locus but intersects at P' , the straight line closing the bottom of the horseshoe. If the line is extended backward, it intersects the spectrum locus at P'' , or 550 nm. The color represented by P is said to have dominant wavelength of -550 nm, or complementary, 550 nm. The spectral purity is the ratio of the distances $\overline{CP}/\overline{CP'}$, which is about 65% for this case.

Colors commonly called "pastel colors" are of low spectral purity. The color pink is a red of low spectral purity; but in every-day language, low purity is often indicated by some adjectives (e.g., "baby" blue and "apple" green).

Two colors are said to be complementary if they may be added to make white. In terms of the chromaticity diagram, two colors are complementary if the line joining the two points representing them passes through C . The negative, or complementary, greens are called magenta or purple; frequently they are incorrectly called red.

6.13 Average Reflectance

We have seen that the dominant wavelength and purity of light reflecte by an object depends upon the spectral distribution of the illuminant. The average reflectanc also depends upon the illuminant; the average reflectanc will be large if the spectral distribution of the illuminant is large at the wavelengths for which the reflectanc of the object is also large. The average reflectanc depends in this same way upon the spectral sensitivity of the detector. For the light-adapted (photopic) eye, the spectral sensitivity is represented by curve A of Fig. 32, which is the same as curve \bar{y} of Fig. 35. Since the eye has its maximum sensitivity in the wavelength interval near 550 nm, the averaging process must be weighted in favor of these wavelengths. The average reflectanc r_a is calculated as

$$r_a = \frac{\int_0^\infty r(\lambda)\bar{y}(\lambda)C(\lambda) d\lambda}{\int_0^\infty \bar{y}(\lambda)C(\lambda) d\lambda} \quad (58)$$

where $r(\lambda)$ is the spectral reflectanc of the object; $r(\lambda)$ for an orange skin was given in Fig. 37. The spectral distribution of the illuminant is $C(\lambda)$, and $\bar{y}(\lambda)$ is the spectral sensitivity of the photopic eye. If some other detector were used, its spectral sensitivity would replace $\bar{y}(\lambda)$ in the equation.

For the orange skin, illuminant C , and the photopic eye we obtain an average reflectanc

$$r_a = 0.26 \quad \text{or } 26\%$$

6.14 Subtractive Color Mixing

If a white paper is used as a background for water colors, light must pass through the water color to get to the paper and after diffuse reflectio from the paper again pass through the water color. Selective absorption by

the dye in the water color gives the scattered light its color. Consider a dye that is absorbent and transmits only a little (say, 10%) for wavelengths shorter than 500 nm but is only slightly absorbent, transmitting 80 or 90%, for wavelengths longer than 500 nm. If this dye is painted on white paper, it will produce a yellow color. Another dye may transmit well for wavelengths shorter than 550 nm and absorb most of the light of longer wavelength; this dye will produce a blue color. If these two dyes do not react chemically and are used one on top of the other (or mixed together) so that light must pass through both of them, then most of the light between 500 and 550 nm will emerge but only a little of the light outside this wavelength interval will emerge. The resultant is a green color. This is a subtractive process in which yellow and blue give green; it must not be confused with the additive processes discussed earlier.

The principles in the water color experiment just described may be illustrated using a slide projector and two pieces of cellophane, one yellow and the other blue. Light projected onto a white wall through one piece of cellophane appears either yellow or blue, but when it passes through both pieces in series, it appears green.

In Fig. 39 are the transmission curves of a yellow filter (A), a blue filter (B), and the two in series (G). At each wavelength, the transmission represented by curve G is the product of the transmission for A and the transmission for B .

Color pictures and color slides (i.e., transparencies) use the subtractive method of producing colors. Three dyes are sufficent, and those that are most effective (i.e., produce the widest range of colors) are dyes that control the red, green, and blue. The dye that subtracts the red is blue in color and often is described as cyan. The dye that subtracts the green, leaving the red and blue, is magenta. The third dye subtracts the blue, leaving the green and longer wavelengths unaffected; it is yellow. By varying the concentration of each of these dyes, one can produce all real colors except the highly saturated ones. The available colors are sufficent for all ordinary use since spectrally pure colors are rare outside of the laboratory.

In color printing, it is often necessary to include a black and white image in addition to the three subtractive colors described. The use of black controls the average reflectanc of a given area of the picture, not its color.

Good color reproduction in prints or in slides for projection necessitates prior knowledge of the illuminant used in viewing them. Slides are usually projected using a tungsten filament lamp so the dyes are adjusted on the assumption of illuminant A . In many cases, the color purity is increased deliberately and the blues emphasized because it is pleasing to have "bright colors" and "nice blue skys." Color pictures are more likely to be viewed in daylight and therefore are processed for use with illuminant C . If the pictures were produced photographically, the illuminant used for the initial exposure affects the fina color.

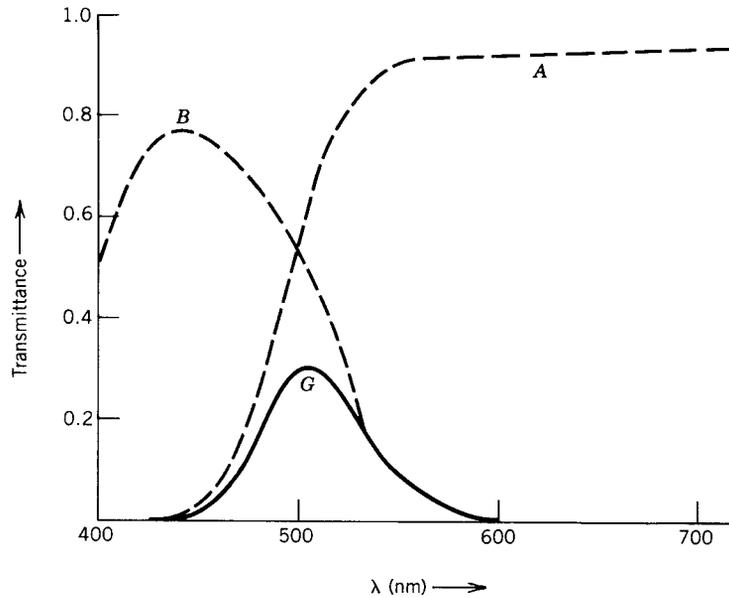

Fig. 39 Subtractive combination of yellow filter, *A*, and blue filter, *B*, to produce green, *G*. At each wavelength, *G* is product of *A* and *B* (*A* and *B* are Wratten filters 9 and 47A).

6.15 Munsell System

In matching or specifying paints, the average reflectance is as important as the dominant wavelength and spectral purity. In the Munsell system, paint samples are assigned a "value" from 0 to 10. Zero is black (i.e., nonreflecting) and 10 is white (100% diffuse reflecting) the intermediate shades of gray are equally spaced *subjectively*. At each value level is a plane polar arrangement in which the distance from the center indicates saturation or the sensation called *chroma* in subjectively equal steps, from zero or neutral at the center to 12 for a saturated color. Dominant wavelength, or its subjective equivalent *hue*, is represented by the horizontal direction on the polar plot; five principal hues—red, yellow, green, blue, and purple—are recognized with the intermediate hues—yellow-red, green-yellow, and so on—making a total of 10 equally spaced hue segments. Each of these is divided into 10 numbered subdivisions (see Fig. 40). The Munsell quantities value, hue, and chroma are subjective, corresponding roughly to the physical quantities average reflectance, dominant wavelength, and purity. About a thousand distinguishable paints have been prepared and classified in this way. These samples preserved as an atlas are used to specify paints.

The average reflectance and ICI color specification (under illuminant C) for these samples have been measured, but equating the subjective and the physical quantities is difficult. The Munsell system predates the ICI system.

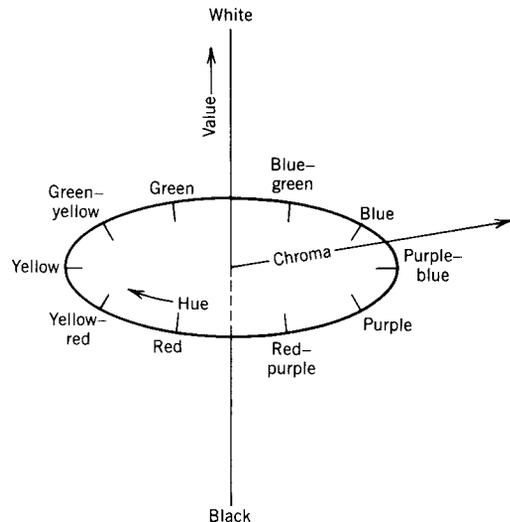

Fig. 40 Munsell representation of color data.

6.16 Photometric Units

In our earlier discussions of sources, such as the black-body, we measured the radiated energy in physical units (i.e., in watts). The units used are called radiometric units. Long before it became possible to make such measurements, light sources and levels of illumination

were compared and measured using the eye as the detector. The eye is quite good at judging the equality of illumination on two adjacent areas. A whole set of units evolved around this process and are still in use; these are known as photometric units, often distinguished from the corresponding radiometric units by including the word *luminous* in the name and the subscript *v* on the symbol.

The unit of luminous flux is the *lumen*. At the wavelength 555 nm, 1 W produces 683 lm; but since the sensitivity of the photopic eye follows curve *A* of Fig. 32 (or curve \bar{y} of Fig. 35), the number of lumens per watt at other wavelengths is smaller, as indicated by this curve. For a nonmonochromatic source, the luminance (or luminous radiance) is

$$L_v = 683 \int_0^\infty L(\lambda)\bar{y}(\lambda) d\lambda \quad (59)$$

and has units of nits. A nit is one lumen per square meter per steradian.

A small source that radiates 1 lm into each steradian is said to have a luminous intensity I_v of 1 candela. (It was formerly called a “standard candle.”) Common units of illuminance are the foot-candle (1 lm/ft²), the lux (1 lm/m²), and the phot (1 lm/cm²).

7 DETECTORS OR OPTICAL TRANSDUCERS

Aside from the eye, there are numerous devices that are used to detect and measure radiant flux. These are usually separated into two groups: (a) thermal detectors and (b) quantum detectors. In thermal detectors, the radiation is absorbed and converted into heat, which raises the temperature of the detector. The temperature change causes a measurable change in some other physical property of the detector (e.g., its resistance). Thermal detectors are sensitive throughout the spectrum. For quantum detectors, the incident light (photons) affect the detector directly (i.e., without heating it); the best known of these is the photoelectric detector in which light causes electrons to be emitted from a surface.

Two thermal detectors are in common use. (a) In the *thermocouple*, two different materials (usually metals) are connected to form a closed circuit. One junction is exposed to the radiation and thereby heated slightly while the other junction is shielded from the radiation and remains at ambient temperature. The temperature difference between the two junctions produces an electromotive force (emf) in the circuit that may be measured. (This is known as the Peltier effect.) (b) The **bolometer** depends upon the change of electrical resistance with temperature. Two identical small detectors are arranged in a Wheatstone bridge circuit; again one detector is exposed to the radiation and the other shielded from the radiation. Small changes in the resistance of the exposed detector are taken as a measure of the incident flux

If the bolometer element is small and thermally well insulated (except for the thin connecting wires) from its surroundings, then a very small optical or radiant power will produce a relatively large temperature rise; in this sense, the detector is very sensitive. However, it will cool slowly and be unable to respond to rapid fluctuation of the incident flux. For rapid response, the thermal isolation of the bolometer should be reduced. For any given application, one must find the optimum compromise between good sensitivity and rapid response.

Bolometer elements may be small flakes or ribbons of metal; nickel or platinum are commonly used. For metals, the resistance **increases** with increasing temperature, as represented by the equation

$$R = R_0[1 + \alpha(T - T_0)] \quad (60)$$

where R is the resistance at temperature T and R_0 is the resistance at ambient temperature T_0 . The constant α depends upon the metal used, but values of 0.003–0.004 per degree Kelvin are typical.

Semiconductor bolometer elements (known as thermistors) are also available. For semiconductors, the resistance *decreases* with increasing temperature according to the equation

$$\frac{R(T)}{R(T_0)} = \frac{e^{\beta/T}}{e^{\beta/T_0}} \quad (61)$$

A typical value of β is 3600 K, which gives dR/dT equivalent to $\alpha = -0.04$ per degree Kelvin in Eq. (60). In this sense, the thermistor is about 10 times as sensitive as a metal bolometer. Since the resistance decreases with increasing temperature, it must be used with a suitably large series resistance to prevent self-burnout.

In detecting or measuring weak signals, the signal-to-noise ratio becomes important. It is important to realize that a small object (such as a bolometer element) that is in thermal equilibrium with its surroundings is not at a constant temperature but is constantly exchanging energy with its surroundings and fluctuating in temperature. It will experience a root-mean-square random fluctuation of temperature ΔT given by

$$\overline{\Delta T^2} = \frac{kT^2}{C} \quad (62)$$

where k is Boltzmann’s constant, T is the absolute temperature of the surroundings, and C is the thermal capacity of the small object. Even if all the amplifying and/or measuring circuits could be noise free, the random temperature fluctuations given by this equation represent unavoidable noise. If the incoming radiation in this ideal case produces a temperature rise equal to ΔT , it is said to have *noise equivalent power* (NEP) and a signal-to-noise ratio of 1.0. In this respect, the

thermistor has no advantage over the metal bolometer; it gives larger response to both signal and noise but does not improve the signal-to-noise ratio.

The simplest quantum detector is an evacuated glass tube containing two electrodes. The anode (or positive electrode) collects electrons emitted from the cathode (or negative electrode). Light striking the cathode, called the photocathode, causes the emission of electrons from the cathode; these are collected by the anode and are measured as current in an external circuit. Not every photon causes the emission of an electron, and the term *quantum efficiency* is used to represent the ratio of the number of electrons emitted to the number of photons incident on the cathode. Quantum efficiencies of 10–15% are typical of good photocathode surfaces.

Even in a light beam from a well-stabilized source, the photons do not arrive on the cathode at equally spaced times but at random time intervals. Also, the photons that produce electrons are randomly selected from those that arrive. The subject is usually treated by Poisson statistics, giving the result that if many measurements are made of n (the number of observed electrons in some constant time interval) and the average value of n is \bar{n} , then the departures of the individual measurements from the average, \bar{n} , will be given by

$$\overline{(n - \bar{n})^2} = \bar{n} \quad (63)$$

This statistical fluctuation of n about its average value \bar{n} is known as photon noise; it arises from the same statistical considerations as “shot noise” in electric circuits. The signal-to-noise ratio is $\sqrt{\bar{n}}$, which may be increased by making \bar{n} larger by (a) increasing the rate at which photons arrive or (b) increasing the observation time for each measurement. The time allotted to each measurement is often built into the associated amplifier that is, the reciprocal of its bandwidth.

Quantum detectors are wavelength selective. The long-wavelength (low-frequency) limit is determined by the equation

$$\frac{hc}{\lambda} = hv \geq \phi e$$

where e is the electronic charge, ϕ is the “work function” of the photo cathode. Here, ϕe is the minimum energy required to remove an electron from the cathode into the vacuum, where ϕ is this energy expressed in electron volts and e is the electronic charge. The short-wavelength (high-frequency) limit is usually determined by the absorption of light by the glass walls of the vacuum tube. The sensitivity of photocathodes is wavelength dependent, and a variety of photocathodes are available having peak sensitivities at different regions of the spectrum.

At room temperature, there will be some emission from the cathode even in the dark. This is known as “dark current” and is due mainly to thermionic emission; it may be reduced by refrigerating the detector.

Some photodetectors realize an amplification of about 10 in the current by having a few torrs of gas in the tube. The electrons are accelerated toward the anode and gain enough energy to ionize some of the gas; the ions then contribute to the current. The recommended cathode-to-anode potential difference must be maintained. Too little will not provide the specific gain; too much will result in a glow discharge independent of light input (and damaging to the cathode). Recommended potential differences are usually 50–100 V.

The photomultiplier is a vacuum tube in which the photocathode is followed by several other electrodes called dynodes. Electrons emitted by the cathode are accelerated to the first dynode, which has a positive potential relative to the cathode on the order of 100 V. Each electron striking the dynode gives up its kinetic energy, thereby causing emission from the dynode of several (e.g., four) slow-moving electrons; this process is called secondary emission. These secondary electrons are accelerated to the next dynode where the process is repeated. It is repeated at each dynode until the electrons are finally collected on the anode and measured in some external circuit. If there is a gain of 4 electrons at each dynode and there are 10 dynodes, there will be $\sim 10^6$ electrons at the anode for each electron that left the cathode; under these conditions, one can observe individual photoemissive events and count their number. The photon noise is determined by the number of electrons leaving the cathode; the large gain makes the individual events easier to count; it does not improve the signal-to-noise ratio. The anode is usually at or near ground potential; to get 100 V for each of 10 dynodes requires the cathode to be -1000 V. The gain is sensitive to this voltage. The photomultiplier is useful primarily at low levels of illumination.

Advances in semiconductor science and technology have provided a number of solid quantum detectors that are more rugged and easier to use than the vacuum tube detectors of earlier years.

The electrical behavior of solids is usually described in terms of allowed energy bands for the electrons. For intrinsic semiconductors, the valence band contains all of the valence electrons of the solid and is filled by these electrons. There is no room for any net motion of these electrons. Above the valence band there is an energy region in which no electrons can exist. The width of this forbidden region is called the bandgap ϕ (usually expressed in electron volts). Above the bandgap is an energy band in which electrons are permitted and in which they are free to move; this is called the conduction band. Normally there are no electrons in the conduction band except for a negligible few that may be thermally excited there from the valence band. Light of wavelength shorter than that given by Eq. (63) can be absorbed by the semiconductor. A photon so absorbed can excite an electron from the valence band to the conduction band. An empty space, or hole, is left in the valence band; this hole acts as a small positive charge and can move through the solid in the valence band.

If the semiconductor just described is connected to a current meter and a source of small emf, the observed current is due to the motion of electrons and holes; it will depend upon the irradiance. This process is called photoconductivity, and a semiconductor used in this way is called a photoconductor. There are a number of photoconductors available, each having its characteristic bandgap. A semiconductor made by mixing mercury telluride and cadmium telluride will have a bandgap dependent upon the relative concentration of the components. In practice, one seeks a detector with bandgap a little less than the quantum energy $h\nu$ of the radiation to be detected; in this way the detector becomes blind to undesired radiation at lower frequencies.

The electron has a mean lifetime before it recombines with a hole, after which it no longer contributes to the current. The lifetime is a random variable. This randomness contributes to the noise and is known as generation recombination noise; it is larger than the photon noise of photoemissive detectors.

An extrinsic semiconductor is an intrinsic semiconductor (such as silicon) into which a small concentration of "impurity" has been introduced. Silicon, as carbon, has four valence electrons, and these are just sufficient to fill the valence band. The bandgap for silicon is 1.14 eV. If a small concentration of an element with five valence electrons (e.g., phosphorus or arsenic) is included, each impurity atom will contribute four electrons to the valence band and the fifth electron will be loosely bound to its parent atom. A little energy, <0.1 eV, will be sufficient to ionize this electron into the conduction band where it can move about and contribute to a measurable current. The ionization energy can be supplied by a photon. Impurities of this type are called donor impurities, and the semiconductor is known as n type since negative charges (electrons) produce the current.

If the impurity is trivalent, such as boron or aluminum, then there is an electron missing (a hole). This hole is loosely bound to its parent atom. A little energy can move an electron from the valence band into this hole, leaving in the valence band a hole that is free to move. Impurities of this type are known as acceptor impurities, and the semiconductor is p type since the hole behaves as a positive charge. Photoconductive detectors can be made of either p -type, n -type, or intrinsic semiconductors.

A short length of semiconductor that is p type at one end but n type at the other is called a p - n junction diode. This device is commonly used as a rectifier because it conducts electricity much better if a small potential difference (a few volts) is applied positive to the p type and negative to the n type than if the polarity is reversed. The first case is called forward biased (good conductivity); the second case is reverse biased (poor conductivity).

This device may be used as an optical detector. If the device is reverse biased, it will show a small dark current and, in addition, a current that is nearly

linear with the irradiance at the junction between the p region and the n region. It is characterized by shot or photon noise, not generation recombination noise. This is known as the photoconductive mode. These p - n junction photodiodes usually show faster response to changes of irradiance than photoconductors.

Junction photodiodes are also used in the photovoltaic mode. In this case, there is no external bias provided. A voltmeter (or sometimes an ammeter) is connected to the two ends of the diode. A potential difference (or current) is observed that is dependent on the irradiance at the junction. Usually the output is not a linear function of the irradiance.

The p - i - n photodiode is a p - n junction with an intrinsic region separating the p region from the n region. The radiation is absorbed in the intrinsic region. This device has a low internal capacitance, allowing it to respond quickly to changes of irradiance. It can respond in times shorter than 10^{-9} s. It also functions over a very large dynamic range of irradiance.

This is certainly not an exhaustive list of the available photodetectors, but perhaps it gives a favor of the subject. For details, one should consult the manufacturers' specification sheets.

The most commonly used figure of merit for detectors is the specific detectivity, or D^* . By definition

$$D^* = \frac{\sqrt{A \Delta f}}{P_N}$$

where P_N is the incident radiant power that produces a signal just equal to the noise signal, A is the area of the detector, and Δf is the bandwidth of the detector and its amplifying circuits. (These are low-frequency circuits used to monitor fluctuations in radiant power.) Theoretical considerations show that if A and Δf are changed, P_N will change in such a way as to keep D^* constant. Therefore, D^* is characteristic of the process and material being used for detection and is not dependent upon detector geometry or bandwidth.

1 INTRODUCTION

Acoustics is the term used to describe the science of sound. It is derived from the Greek word *akoustos*, which means "hearing." Acoustics is a very broad field of science that covers the generation, reduction, control, transmission, and reception aspects of sound. The earliest known studies of sound were made by Pythagoras during the sixth century BC. Pythagoras was the first to identify the musical consonances described as the octave, the fifth and the fourth. He also initiated the theory of the inverse proportionality between pitch and the length of a vibrating string. In the Renaissance era of the late fifteenth century, the famous artist Leonardo da Vinci (1452–1519) also made many significant contributions to the theory of mechanics and wave motion. The works of Galileo Galilei (1564–1642) have had a larger impact on theoretical mechanics than any other before Newton. Galileo is recognized as having built on Leonardo's speculative work and developed it into quantitative logic. Some likely consider Galileo as formalizing the science of sound. However, most generally recognized as the first significant contributor to the quantitative study of acoustics is Marin Mersenne (1588–1648). Mersenne performed and developed significant experimental techniques that laid foundations in many areas of acoustics. From the time of Mersenne to the twentieth century, many significant contributions to the area of acoustics were made by those such as Newton, Euler, Green, Stokes, Helmholtz, Kirchhoff, Rayleigh, and Sabine. However, recent contributions during the twentieth century have also had a tremendous impact in the area of acoustics today. One of these developments was active noise control by Paul Leug in Germany in 1932. Other developments include computational sound field modeling, measurement methods, and measurement hardware, including computers, digital signal processors, and various transducers.^{1–3}

2 SOUND POWER, SOUND INTENSITY, AND SOUND PRESSURE

In this section we discuss three fundamental measures of sound. These are sound power, sound intensity, and sound pressure. These three terms are discussed in most books on acoustics.^{1,3}

2.1 Sound Power

Sound power is the term that describes the rate at which sound energy is radiated per unit time. The units of sound power are joules per second or watts. As an example of sound power, assume that there is a small spherical sound source. The sound power is a

measure of the total amount of sound that the source can produce. Assuming that the source has constant sound power output and that unobstructed radiation occurs, the sound power output of the source is the same at any radius away from the source. A balloon analogy is often used to describe sound power. A balloon has the same amount of material surrounding the internal gas whether the balloon is partially or fully inflated. This is the same concept in that the sound power radiating from the source is a constant independent of distance from the source.

The range of sound powers encountered can be extremely large. For example, the sound power of a large rocket engine is on the order of 1,000,000 W while the sound power of a soft whisper is approximately 0.000,000,001 W. Because of this large range in power values, a logarithmic scale known as the decibel scale is widely used in acoustic applications.

When sound power is expressed in terms of decibels, it is called a sound power level and is computed as

$$L_w = 10 \log \left(\frac{W}{W_{\text{ref}}} \right) \quad (1)$$

In Eq. (1), L_w represents the sound power level, W is the power of the sound energy source, and W_{ref} is the standard reference power, usually taken to be 1×10^{-12} W, or 1 pW. Table 1 provides an example of the range of sound power and sound power levels.

Sound power may be measured in various ways depending on the environment in which the measurements are to be made (free field, diffuse field, hemianechoic, etc). The two basic techniques of measuring sound power consist of using an array of pressure microphones placed around the source or by using a sound intensity probe. Other comparative techniques also exist where measurements are compared to calibrated sources. The international standards that outline the processes for measuring sound power are International Organization for Standardization (ISO) 3741, 3742, 3744, 3745.⁴

2.2 Sound Intensity

Sound intensity is defined as the amount of sound power for a given area of the wave front. Relating this back to the balloon analogy, sound intensity would be a measure of the balloon wall thickness. For a given balloon there will be more balloon material due to the thickness of the balloon wall if the balloon is partially inflated as compared to fully inflated where a thinner balloon wall will occur. This is the same as sound

Table 1 Sound Power and Sound Power Level

Sound Source	Sound Power (W)	Sound Power Level, L_w (dB re 1×10^{-12} W)
Saturn rocket	25–40 million	195
Rocket engine	1,000,000	180
Turbojet engine	10,000	160
Siren	1,000	150
Heavy-truck engine/rock concert	100	140
75-Piece orchestra pipe organ	10	130
Piano/small aircraft, jackhammer	1	120
Excavator/trumpet	0.3	115
Chain saw/blaring radio	0.1	110
Helicopter	0.01	100
Auto on highway, loud speech/shouting	0.001	90
Normal speech	1×10^{-5}	70
Refrigerator	1×10^{-7}	50
Auditory threshold	1×10^{-12}	0

intensity, in that the closer to the source, the higher the intensity for a given area. As previously mentioned, sound power and sound intensity are related by an area. For a spherical wave front, the relationship is expressed as

$$I = \frac{W}{4\pi r^2} \quad (2)$$

where I represents the sound intensity, W represents the sound power, and $4\pi r^2$ is the surface area of the sphere where r is the radius of the sphere. From Eq. (2), it should be noted that the decay of the sound intensity is directly proportional to the square of the radius of the sphere. This relationship is often referred to as the inverse-square law.

Sound intensity values are directly related to sound power values by an area term and hence also have a very wide range of values. It is therefore again common to express the sound intensity using a decibel scale and then refer to it as a sound intensity level. Sound intensity level is expressed as shown by Eq. (3), where L_i is the sound intensity level, I is the measured intensity at some distance from the source, and I_{ref} is the reference sound intensity usually taken as 1×10^{-12} W/m²:

$$L_i = 10 \log \left(\frac{I}{I_{\text{ref}}} \right) \quad (3)$$

Sound intensity is the time-averaged product of the pressure and particle velocity. The pressure can simply be measured with a pressure microphone. However, the particle velocity is somewhat more difficult to

measure. One common method of measurement is to place two similar microphones a known distance apart. By doing this, the pressure gradient can be measured. Then using Euler's equation the pressure gradient can be used to compute the particle velocity.

2.3 Sound Pressure

Sound pressure refers to the small deviations of pressure from the ambient value that are propagated by sound waves. To better understand this wave phenomenon, take, for example, a U-shaped tuning fork as shown in Fig. 1a. The tuning fork is a device used

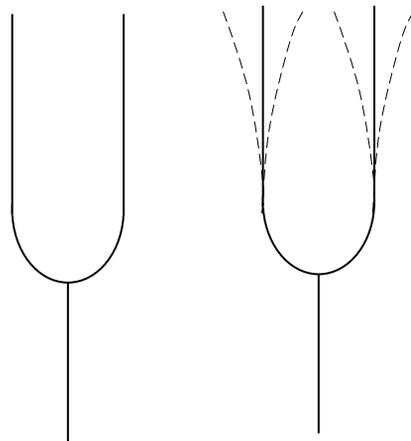

Fig. 1 Tuning fork: (a) static position; (b) vibrating motion showing tine motion.

to create a tone at a specific frequency that can then be used to tune various musical instruments. The tone is created by striking one of the tines with a hammer causing the forks to freely vibrate, as shown in Fig. 1*b*. As the tine moves outward from equilibrium, the air adjacent to the outward moving tine is compressed and forced outward. As the air adjacent to the tine is pushed outward, the pressure at that point increases as does the density of the air molecules. As the tine returns back to equilibrium and displacement in the opposite direction, the air molecules spread back out, leaving a lower pressure and air molecule density as they return to their original position. The expansion and subsequent return to equilibrium are commonly called rarefaction.

As with sound power and sound intensity, sound pressures encountered also have a very wide range of values. For example, a typical jet engine is on the order of 630 Pa while the threshold of hearing is approximately 2×10^{-5} Pa at 2 kHz. Therefore, as with sound power and sound intensity, sound pressure level L_p has been developed as

$$L_p = 20 \log \left(\frac{p}{p_{\text{ref}}} \right) \quad (4)$$

where p is the measured rms sound pressure and p_{ref} is the reference sound pressure usually taken as 20 μPa (2×10^{-5} Pa), which is the threshold of hearing for an undamaged ear and also corresponds closely with the reference power of 1×10^{-12} W. Table 2 shows the relationship between sound pressure and sound pressure level.

3 DECIBEL AND OTHER SCALES

The decibel scale is a unitless logarithmic scale that is widely used in many fields of science, including acoustics, electronics, signals, and communication. The decibel scale is used to describe a ratio of values which among others may be sound power, sound intensity, sound pressure, and voltage. One main advantage of

a logarithmic scale is that a very wide range of values can be reduced to a much smaller range which provides the user with a better feel for the particular values of interest.

In the field of acoustics, the decibel (dB), which is one-tenth of a bel, is almost exclusively used. Decibels are used over bels to simply increase the sensitivity of the values, similar to using inches instead of feet or centimeters instead of meters. The term bel (in honor of Alexander Graham Bell) refers to the basic logarithm of the ratio of two values. The definition of the base 10 logarithm is shown as

$$10^{\log p} = p \quad (5)$$

The log of p is the value to which 10 must be raised in order to obtain the value p . The decibel equation can then be expressed as

$$N(\text{dB}) = 10 \log \frac{A}{A_{\text{ref}}} \quad (6)$$

Two examples using the decibel scale are now provided to better illustrate the significance of the relationship.

Example 1. An increase in sound power of a ratio of 2 : 1 results in what gain in decibels?

Solution

$$N(\text{dB}) = 10 \log 2/1 = 10 \times (0.3010) = 3.01 \text{ dB}$$

Therefore a doubling of the sound power results in an increase of 3 dB.

Example 2. The noise level at a factory property line caused by 12 identical air compressors running simultaneously is 60 dB. If the maximum sound pressure level permitted at this location is 57 dB, how many compressors can run simultaneously?

Table 2 Sound Pressure and Sound Pressure Level

Sound Source	Sound Pressure (Pa)	Sound Pressure Level, L_p (dB re 20 μPa)
Krakatoa (at 160 km)	20,000	180
M1 Garand being fired	12,000	176
Jet engine (at 30 m)	630	150
Threshold of pain	100	130
Hearing damage (short-term exposure)	20	120
Jet (at 100 m)	6–200	110–140
Jack hammer (at 1 m)	2	100
Major road (at 10 m)	0.2–0.6	80–90
Passenger car (at 10 m)	0.02–0.2	60–80
Normal talking (at 1 m)	0.002–0.02	40–60
Very calm room	0.0002–0.0006	20–30

Solution For 1 compressor the L_p is $L_{p1} = 20 \log(P_{\text{rms}1}/P_{\text{ref}})$. For 12 compressors the L_p is $P_{\text{rms}12}^2 = 12P_{\text{rms}1}^2$; therefore $P_{\text{rms}12} = \sqrt{12}P_{\text{rms}1}$:

$$L_{p12} = 20 \log\left(\frac{\sqrt{12}P_{\text{rms}1}}{P_{\text{ref}}}\right) = 20 \log\left(\frac{P_{\text{rms}1}}{P_{\text{ref}}}\right) + 20 \log \sqrt{12}$$

Therefore, $L_{p12} - L_{p1} = 20 \log \sqrt{12} = 10.79$ and

$$L_{p1} = L_{p12} - 10.79 = 60 - 10.79 = 49.21 \text{ dB}$$

Now for x compressors

$$L_{p,\text{max}} = 20 \log \sqrt{x} + L_{p1}$$

Therefore,

$$\log \sqrt{x} = \frac{L_{p,\text{max}} - L_{p1}}{20} = \frac{57 - 49.21}{20} = 0.3895$$

$$x = (10^{0.3895})^2 = 6.01$$

Therefore 6 compressors, at most, can be operated in order to meet the 57-dB limit.

Besides the conventional decibel scale, there are other scales that have been developed which filter or weight the sound. This chapter continues by presenting and discussing several of these filter scales.

In 1933, Fletcher and Munson⁵ presented what is typically called the equal-loudness curves (see Fig. 2). This set of curves represents what is considered to be tones of equal loudness over the frequency range from 20 Hz to 15 kHz. The unit of measure for loudness is the phon. A phon is a unit of apparent loudness. The value for the unit of phon comes from the intensity level in decibels of a 1-kHz tone with the same perceived loudness. Therefore, a decibel value and a phon value are the same for a 1-kHz tone. These curves were determined experimentally. The experiment consisted of playing pure tones at a specific intensity level along with a 1-kHz reference signal. The intensity of the reference signal was increased until the two tones were perceived to be of the same loudness by the listener. Other work on the development of equal-loudness curves has been generated since Fletcher and Munson. The most recent standards can be found in ISO 226:2003.⁴

4 WEIGHTING FILTERS

The first weighting filter to be discussed is called A weighting and usually carries the associated symbol dBA or dB(A). This weighting was developed to apply the same filter to a tone that the human ear applies. As a result, this weighting is based on the 40-phon pure-tone equal-loudness curve. The 40-phon pure tone is a relatively quiet tone. It should be noted that the A-weighted curve roughly corresponds to the inverse of the 40-phon equal-loudness curve. The A-weighted curve tends to amplify signals in the region of 1–6 kHz. Sound outside this frequency range is reduced

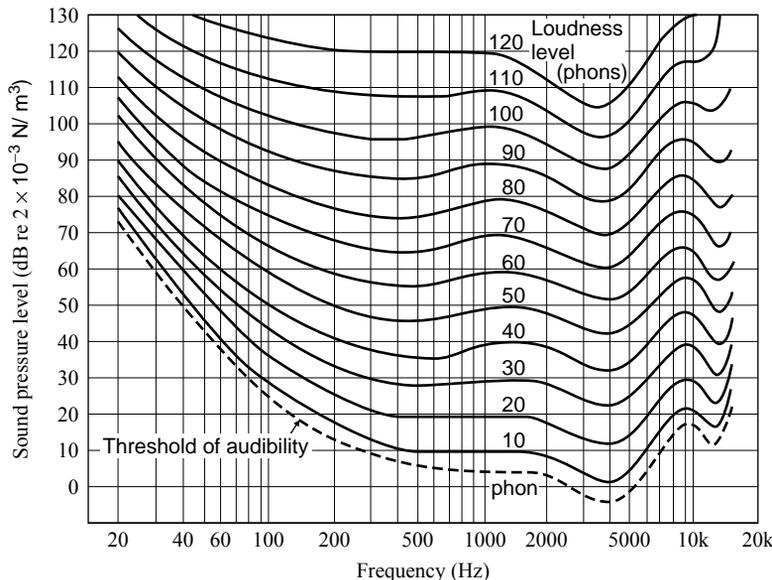

Fig. 2 Equal-loudness curves.

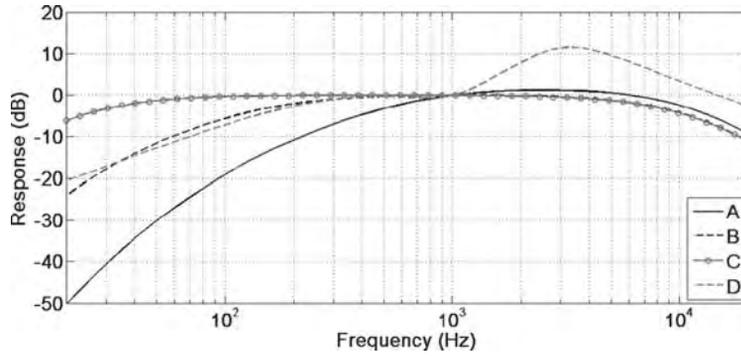

Fig. 3 A, B, C, and D weighting filters.

by the A weighting. The A-weighted filter is shown in Fig. 3.

The A-weighted scale is very popular and is used in many applications. These include environmental noise, noise control, construction noise, and community noise standards. The main violation of usage of the A-weighted scale is that it was developed for relatively quiet pure tones.

The dB(B) and dB(C) scales were developed along similar methods as the dB(A) scale except that they were developed for tones with higher sound pressure levels. The dB(B) scale is seldom used but was developed for tones between the low sound pressure level of the A-weighted scale and the high sound pressure level of the C-weighted scale. The dB(C) scale is used for the highest sound pressure levels and, as shown in Fig. 3, is nearly linear over a large frequency range. The dB(D) scale is often used for aircraft noise. The equations for the weighting scales are shown in Eqs. (7), where $s = j\omega$, $j = \sqrt{-1}$ and ω is the frequency:

$$G_A(s) = \frac{k_A s^1}{(s + 129.4)^2 (s + 676.7)(s + 4636)(s + 76,655)^2} \tag{7}$$

$$G_B(s) = \frac{k_B s^3}{(s + 129.4)^2 (s + 995.9)(s + 76,655)^2}$$

$$G_C(s) = \frac{k_C s^2}{(s + 129.4)^2 (s + 76,655)^2}$$

$$G_D(s) = \frac{k_D s (s^2 + 6532s + 4.0975 \times 10^7)}{(s + 1776.3)(s + 7288.5)(s^2 + 21,514s + 3.8836 \times 10^8)}$$

where $k_A \approx 7.39705 \times 10^9$, $k_B \approx 5.99185 \times 10^9$, $k_C \approx 5.91797 \times 10^9$, and $k_D \approx 91104.32$.

Another unit of measure for perceived loudness is the sone. The sone was developed experimentally to relate perceived loudness to phons. In the experiment, volunteers were asked to adjust the loudness of a tone until it was perceived to be twice as loud as the original tone. As a result, 1 sone is arbitrarily equal to 40 phons, and a doubling of the loudness (in sones) corresponds to a doubling of the perceived loudness. A graph relating sones and phons is shown in Fig. 4.

Octave Bands in Audio Range In reference to the audio range, the term octave corresponds to a doubling or a halving of a frequency. For example, 200 Hz is one octave above 100 Hz and 4000 Hz is one octave above 2000 Hz. The 400 Hz would be considered to be two octaves above 100 Hz and so on.

In audio acoustics, the term “octave band” is commonly used to represent a range of frequencies where the highest frequency is twice the lowest frequency. These octave bands are commonly used to represent what is going on in the acoustic signal over a band or range of frequencies as compared to discrete frequencies. Most sound level meters will output the data in some form of a standardized octave band.

Octave bands are typically defined by a center frequency f_C . The upper frequency f_U and the lower frequency f_L of the band are computed as

$$f_L = \frac{f_C}{\sqrt{2}} \quad f_U = \sqrt{2} f_C \quad \text{where } f_C = \sqrt{f_L f_U} \tag{8}$$

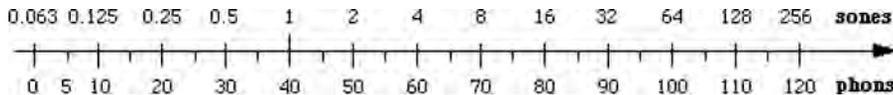

Fig. 4 Relationship of sones and phons.

Table 3 Octave-Band Lower, Center, and Upper Band Frequencies (Hz)

Lower Band Frequency, f_L	Center Band Frequency, f_C	Upper Band Frequency, f_U
22.4	31.5	45
45	63	90
90	125	180
180	250	355
355	500	710
710	1,000	1,400
1,400	2,000	2,800
2,800	4,000	5,600
5,600	8,000	11,200
11,200	16,000	22,400

Furthermore, the bandwidth for a given octave can be computed by as

$$\text{Bandwidth} = f_U - f_L = \frac{f_C}{\sqrt{2}} \quad (9)$$

In the field of acoustics standard octave bands have been defined. The lower frequency, center frequency, and upper frequency, for the standard acoustic octave bands are given in Table 3.

In many applications, a higher resolution on the frequency axis is desired. In these cases, the octave band is split into smaller groups. Another very common scale is the one-third octave band, in which each of the octave bands is split into three smaller bands. The one-third-octave-band scale is commonly used for environmental, noise control, and building acoustics, among others. The lower, center, and upper frequencies for the one-third octave bands are given in Table 4 and calculated using the equations

$$f_L = \frac{f_C}{\sqrt[3]{2}} \quad f_U = \sqrt[3]{2} f_C \quad \text{where } f_C = \sqrt[3]{f_L f_U}$$

$$\text{Bandwidth} = f_C \left(\sqrt[3]{2} - \sqrt[3]{\frac{1}{2}} \right) \quad (10)$$

5 IMPEDANCE

Mathematical models for mechanical, electrical, fluid, and thermal systems can be developed essentially independent of the discipline based on concepts of system similarity. In each discipline, the variables that are used to express the differential equations can be classified as either effort, flow, or combinations of effort and flow variables.⁶

Effort variables describe the effort which is put on a component. Typical effort variables are force, voltage, pressure, and temperature. Flow variables are those that describe the rate of change, such as velocity, current, volume flow rate, and heat flow. Impedance of a component is defined as the ratio of the effort

Table 4 One-Third-Octave-Band Lower, Center, and Upper Band Frequencies (Hz)

variable to the flow variable. For a mechanical system this is force divided by velocity.

In acoustic systems, the effort variable is pressure p and the flow variable is velocity. However, there are two velocities often considered in acoustics: volume velocity U and particle velocity u . With these two velocities there are two acoustic impedance terms. Acoustic impedance is defined as the acoustic pressure divided by the volume velocity as

$$Z = \frac{p}{U} \quad (11)$$

Specific acoustic impedance is defined as the acoustic pressure divided by the particle velocity as

$$z = \frac{p}{u} \quad (12)$$

Radiation impedance is a term often used to represent the coupling between acoustic waves and a driving

source or driven load. The radiation impedance for a vibrating surface with area A is given by the equation

$$Z_r = zA \quad (13)$$

This can also be computed as the ratio of the force f acting on the fluid and the particle velocity:

$$Z_r = \frac{f}{u} \quad (14)$$

The radiation impedance is part of the overall mechanical impedance of the system. The magnitude of the contribution of the radiation impedance to the overall mechanical impedance is generally small but is, of course, related to the magnitudes of the values in the impedance equations.

6 THEORY OF SOUND

In this section, some of the fundamental theoretical developments of acoustics in a fluid are summarized. For theoretical developments of acoustic propagation in solids, see Ref. 7. Of foremost importance in this section is a discussion of the acoustic wave equation and forms of solutions.

6.1 Constitutive Equations

Acoustic disturbances are ultimately an unsteady portion of the overall dynamics of the fluid. Consequently, the equations that describe the motion of a fluid—the equations of continuity, force, state, and so on—can be applied to describe acoustic pressure fluctuations. However, with the exception of Section 14 on nonlinear acoustics, we will consider the fluctuating pressure term in the overall description of the fluid to be “small.” In terms of the acoustic Mach number, which is a dimensionless quantity that describes the velocity of acoustic fluctuations \mathbf{u} , relative to the speed of sound in the fluid, c_0 , this assumption of “smallness” may be expressed as $|\mathbf{u}|/c_0 \gg 1$. This assumption applies to the vast majority of applications of acoustics and allows for considerable simplification of the constitutive equations of fluid mechanics to first-order accuracy.

The constitutive equations of the wave equation in fluid acoustics are used to relate the acoustic pressure p , the acoustic density ρ , and the acoustic “particle” velocity \mathbf{u} , which despite its name, describes the motion of a small volume or continuum of fluid. These acoustic variables describe the unsteady fluctuations in the fluid that are acoustic waves. On the other hand, variables that describe the ambient pressure or density will be denoted with the subscript 0. Note that both the mean velocity of the fluid and losses (e.g., thermoviscous) are considered to be zero in the equations that follow.

The first equation is the equation of continuity, which relates ρ to \mathbf{u} and connects the compression

of the fluid with its motion. In its linearized form, the equation of continuity may be written as

$$\frac{\partial \rho}{\partial t} + \rho_0 \nabla \cdot \mathbf{u} = 0 \quad (15)$$

where the first term, $\partial \rho / \partial t$, describes the time rate of change of the acoustic density for a small volume fixed in space. For continuity of the fluid to hold, $\partial \rho / \partial t$ must be equal to the net flux of fluid into the volume, approximated by $-\rho_0 \nabla \cdot \mathbf{u}$. (The minus sign is needed because the divergence operator describes flow of fluid away from the volume.)

The second equation relates \mathbf{u} to p and is an expression of Newton's second law, $\sum F = ma$. For a fluid element that moves with the surrounding fluid, the linearized Euler equation (a lossless form of the Navier–Stokes equation) is written as

$$\rho_0 \frac{\partial \mathbf{u}}{\partial t} = -\nabla p \quad (16)$$

Note that because \mathbf{u} is a vector that describes the velocity of the fluid in three-dimensional space, Eq. (16) is a composite vector equation.

The third constitutive equation necessary in the development of a small-amplitude wave equation relates the two scalars p and ρ . If we neglect losses and treat the acoustic processes in air as perfectly adiabatic, the equation of state between p and ρ may be approximated to first order as

$$p = c_0^2 \rho \quad (17)$$

where

$$c_0^2 = \frac{B}{\rho_0} \quad (18)$$

where B is the adiabatic bulk modulus of the fluid. In air, $B = \gamma p_0$, where γ is the ratio of specific heats ($\gamma = 1.402$). By use of the ideal gas law, the sound speed in air may be expressed as a function of temperature as

$$c_0^2 = \gamma r T \quad (19)$$

where r is the specific gas constant (287 J/kg·K) and T is the temperature in kelvin. An alternative expression is to write the sound speed relative to some reference value, which is 331 m/sec at 0°C (273.15 K). Relative to 331 m/sec, c_0 is expressed as

$$c_0 = 331 \sqrt{\frac{T}{273.15}} \quad \text{m/s} \quad (20)$$

Equation (19) may be used to calculate sound speed in other gases given the appropriate values of γ and r ,

whereas in fluid that cannot be considered ideal gases, Eq. (18) can be used. For the sake of completeness, the speed of compressional waves in solids may be calculated as

$$c_0 = \sqrt{\frac{Y}{\rho}} \tag{21}$$

where Y is Young's modulus and, in this case, ρ is the density of the solid in kilograms per meters cubed. A list of sound speed values in different media is given in Table 5. A more complete listing may be found in the literature.⁷

6.2 Wave Equation

Although not repeated here, the constitutive equations may be manipulated to form a wave equation for any of the acoustic variables, p , ρ , and \mathbf{u} . The acoustic wave equation for the pressure p may be expressed as

$$\nabla^2 p - \frac{1}{c_0^2} \frac{\partial^2 p}{\partial t^2} = 0 \tag{22}$$

If we assume a one-dimensional wave equation in the x direction, Eq. (22) may be divided up as

$$\left(\frac{\partial}{\partial x} - \frac{1}{c_0} \frac{\partial}{\partial t}\right) \left(\frac{\partial}{\partial x} + \frac{1}{c_0} \frac{\partial}{\partial t}\right) p = 0 \tag{23}$$

Equation (23) demonstrates that the wave equation may be viewed as right-going and left-going wave

Table 5 Speed of Sound in Various Media

operators that act on p . In fact, the general solution to the one-dimensional wave equation for p is

$$p(x, t) = p_1\left(t - \frac{x}{c_0}\right) + p_2\left(t + \frac{x}{c_0}\right) \tag{24}$$

where the function p_1 is a wave that travels in the $+x$ direction and p_2 is a wave that travels in the $-x$ direction. The forms of functions p_1 and p_2 depend on source, boundary, and initial conditions. Specific types of solutions to the acoustic wave equation are now discussed.

Plane Waves One possible solution to the wave equation is a monofrequency plane wave with angular frequency ω . A plane wave's amplitude and phase are constant on any plane perpendicular to the direction of travel. The most common application of plane wave propagation is in ducts at low frequencies, where the acoustic wavelength is much greater than the cross-sectional dimensions of the duct. In addition, at large distances from an acoustic source, spherical waves look locally planar. Expressed in complex exponential form, the plane wave solution for the acoustic pressure in one dimension (x) is

$$\mathbf{p}(x, t) = \mathbf{A}e^{j(\omega t - kx)} + \mathbf{B}e^{j(\omega t + kx)} \tag{25}$$

where the boldface italic text denotes a complex quantity and k is the wavenumber, where $k = \omega/c_0$. Complex notation is frequently used for mathematical convenience in this section and throughout the remainder of this section. The actual scalar pressure is

$$p(x, t) = \mathbf{Re}\{\mathbf{p}(x, t)\} \tag{26}$$

The above result may be extended for a plane wave of frequency ω that is propagating in an arbitrary direction. If we consider just a single forward-propagating plane wave, the solution to the wave equation may be expressed as

$$\mathbf{p}(\mathbf{r}, t) = \mathbf{A}e^{j(\omega t - \mathbf{k} \cdot \mathbf{r})} \tag{27}$$

where \mathbf{r} is the position vector from the origin and \mathbf{k} , the wavenumber propagation vector with magnitude $k = \omega/c_0$, is written as

$$\mathbf{k} = k_x \hat{x} + k_y \hat{y} + k_z \hat{z} \tag{28}$$

An example of a two-dimensional plane wave is shown in Fig. 5.

One final point regarding plane waves is the relationship between p and \mathbf{u} . Use of the linearized Euler

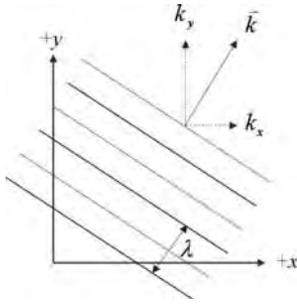

Fig. 5 Representation of plane wave propagation perpendicular to z axis. The lines represent surfaces of constant phase.

equation for a wave traveling in the positive direction results in the expression

$$\frac{p}{|\mathbf{u}|} = \rho_0 c_0 \quad (29)$$

which has units of specific acoustic impedance. This quantity is referred to as the characteristic impedance of the medium and is approximately equal to 415 Pa·sec/m in air.

Spherical Waves For sources of sound whose dimensions are much less than a wavelength or for distances much greater than the source dimensions, the acoustic radiation in free space is spherically diverging. For radial symmetry, the wave equation in spherical coordinates may be written as

$$\frac{\partial^2 p}{\partial r^2} + \frac{2}{r} \frac{\partial p}{\partial r} = \frac{1}{c_0^2} \frac{\partial^2 p}{\partial t^2} \quad (30)$$

A different form of Eq. (30) lends insight into the physical behavior of spherical waves. Rather than p as the dependent variable, rewriting Eq. (30) in terms of rp results in

$$\frac{\partial^2(rp)}{\partial r^2} = \frac{1}{c_0^2} \frac{\partial^2(rp)}{\partial t^2} \quad (31)$$

Comparison of Eq. (31) with the general wave equation (24) shows that the general solution to this wave equation for spherical waves can be written as

$$p(r, t) = \frac{1}{r} p_1 \left(t - \frac{r}{c_0} \right) + \frac{1}{r} p_2 \left(t + \frac{r}{c_0} \right) \quad (32)$$

The first term in Eq. (32) represents outgoing waves and the second term, incoming waves. For diverging

monofrequency waves of frequency ω , the solution to Eq. (30) in complex form is

$$p(r, t) = \frac{A}{r} e^{j(\omega t - kr)} \quad (33)$$

From this expression for p , particle velocity, intensity, and sound power can all be calculated. However, of particular interest are the ratios of acoustic pressure between r_1 and r_2 . For spherical spreading between r_1 and r_2 ,

$$\frac{p(r_1)}{p(r_2)} = \frac{r_2}{r_1} e^{-jk(r_2 - r_1)} \quad (34)$$

For $r_2 = 2r_1$,

$$\left| \frac{p(r_2)}{p(r_1)} \right| = \frac{1}{2} \quad (35)$$

6.3 Absorptive Processes

Although losses were neglected in the theoretical development of the wave equation, they are essential to everyday acoustic analyses. Losses may be readily incorporated into the solution of a propagating wave by making the wavenumber k complex:

$$k = k - j\alpha \quad (36)$$

The variable α is known as the absorption coefficient, with units of nepers per meter, and its value depends on both frequency and the propagation environment (the Neper is a dimensionless unit). The solution for a traveling plane wave takes the form

$$p(\mathbf{r}, t) = A e^{-\alpha r} e^{j(\omega t - \mathbf{k} \cdot \mathbf{r})} \quad (37)$$

The term $e^{-\alpha r}$ represents an exponential decay in amplitude as a function of distance. The absorption coefficient can also be directly considered with regards to its impact on sound pressure level. For plane wave propagation from the source ($x = 0$) to some distance x ,

$$L_p(x) = L_p(0) - 8.686\alpha x \quad (38)$$

Two types of absorption are briefly considered, atmospheric absorption and boundary layer absorption in pipes. Note that the absorptive processes in the atmosphere and near pipe walls give rise to not only absorption but dispersion as well. However, because dispersion does not affect amplitude at a given frequency, the phenomenon is not discussed further in this section. Instead the reader is referred to Refs. 8 and 9, which contain more in-depth discussions on the absorptive processes.

The absorption of sound by the atmosphere is dominated by thermoviscous (tv) losses and vibrational relaxation losses due to the diatomic molecules of oxygen (O₂) and nitrogen (N₂). The combined effects of these processes represent the total atmospheric absorption coefficient

$$\alpha = \alpha_{tv} + \alpha_{O_2} + \alpha_{N_2} \quad (39)$$

To calculate atmospheric absorption as given below, values of p_0 in atmospheres, ambient temperature (T_0) in kelvin, and relative humidity (RH) in percent are needed as inputs. Although other units are possible, they result in different expressions for α . With ambient pressure, temperature, and relative humidity expressed in the appropriate units, α is calculated as

$$\begin{aligned} \alpha = p_0 F^2 & \left\{ 1.84 \times 10^{-11} \left(\frac{T_0}{293.15} \right)^{1/2} \right. \\ & + \left(\frac{T_0}{293.15} \right)^{-5/2} \left[0.01275 \frac{e^{-2239.1/T_0}}{F_{r,O} + F^2/F_{r,O}} \right. \\ & \left. \left. + 0.1068 \frac{e^{-3352/T_0}}{F_{r,N} + F^2/F_{r,N}} \right] \right\} \quad (40) \end{aligned}$$

where

$$F = \frac{f}{p_0} \quad F_{r,O} = \frac{f_{r,O}}{p_0} \quad F_{r,N} = \frac{f_{r,N}}{p_0} \quad (41)$$

The normalized relaxation frequencies F_r for oxygen and nitrogen are respectively

$$F_{r,O} = 24 + 4.04 \times 10^4 h \frac{0.02 + h}{0.391 + h} \quad (42)$$

and

$$\begin{aligned} F_{r,N} = & \left(\frac{293.15}{T_0} \right)^{1/2} \\ & \times \left(9 + 280h \exp \left[-4.17 \left\{ \left(\frac{293.15}{T_0} \right)^{1/3} - 1 \right\} \right] \right) \quad (43) \end{aligned}$$

where h is the absolute humidity, or molar concentration of water vapor, in percent. Absolute humidity can be calculated from relative humidity as

$$h = RH \frac{p_{sat}}{p_0} \quad (44)$$

Finally, the saturation vapor pressure p_{sat} can be calculated from

$$\log_{10}(p_{sat}) = -6.8346 \left(\frac{273.16}{T_0} \right)^{1.261} + 4.6151 \quad (45)$$

In Fig. 6, curves of the absorption coefficient for 1 atm and 20°C (293.15 K) are displayed as a function of frequency for three values of relative humidity. The figure shows that variation in water vapor content in the atmosphere can significantly affect the absorption over the audio range (20 Hz–20 kHz). At low frequencies, the dominant absorption mechanism is due to nitrogen relaxation. Above a few hundred hertz, oxygen relaxation becomes the dominant process. It is not until high frequencies (50–100 kHz) that the diatomic molecules are considered frozen and thermoviscous processes dominate.

The second type of absorption is boundary layer absorption, which is relevant to propagation in pipes or ducts. The additional absorption near the walls of the duct is due to the viscous and thermal boundary layers. For a duct with a given hydraulic diameter (HD = 4S/C, where S is the area and C is the perimeter

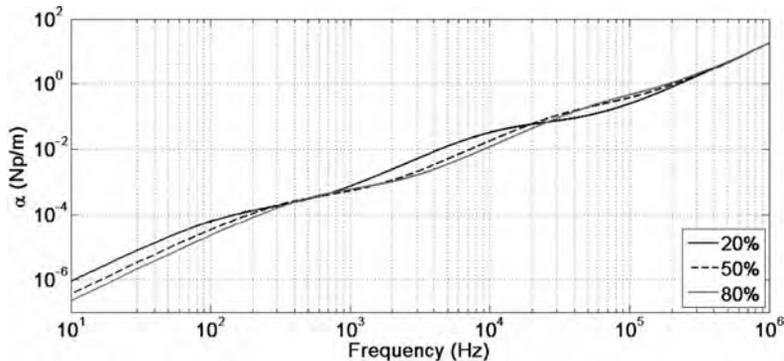

Fig. 6 Atmospheric absorption coefficient as function of frequency for 1 atm, 20°C, and various values of relative humidity.

of the cross section), α for an air-filled pipe may be calculated as

$$\alpha = \frac{2}{HD} \sqrt{\frac{\pi f \mu}{\rho_0 c_0^2}} \left(1 + \frac{\gamma - 1}{\sqrt{\text{Pr}}} \right) \quad (46)$$

where μ is the shear viscosity coefficient, γ is the ratio of specific heats, and Pr is the Prandtl number. Unlike atmospheric absorption, which approaches an f^2 dependence well above the relaxation frequencies, boundary layer absorption only increases as \sqrt{f} .

7 REFLECTION, TRANSMISSION, AND ABSORPTION

When a wave propagating in a medium encounters a change in the impedance presented to the wave, reflection and transmission of the wave occur. There are two general ways in which this could occur: (i) the medium could change, such as when a wave propagates from air into water, or (ii) the geometry could change even though the medium does not, such as when a wave propagates from a pipe into an expansion chamber.

The physical concepts that govern the reflection and transmission are not difficult to understand, although the algebra that results in analyzing the situation can quickly become very cumbersome. Thus, for all but the simplest cases, one would typically solve the resulting expressions with the aid of a computer.

There are several reflection and transmission coefficients of interest. The *pressure* reflection and transmission coefficient (\mathbf{R} , \mathbf{T}) provide the ratio of the reflected and transmitted pressure to the incident pressure. The *intensity* reflection and transmission coefficients (R_I , T_I) provide the ratio of the reflected and transmitted acoustic intensity to the incident acoustic intensity. Note that these two sets of coefficients are not generally the same, as they involve two different physical quantities. Finally, the *power* reflection and transmission coefficient (R_{Π} , T_{Π}) provide the ratio of the reflected and transmitted acoustic power to the incident acoustic power. These coefficients will, in general, be different than the intensity reflection and transmission coefficients except in the case of normal incidence.

7.1 Reflection/Transmission from a Single Interface

Consider first the case of a plane wave impinging on an interface between two fluid media. One of the most common examples considered for this case is that of sound propagating from air into water (or vice versa), although it can be used for any two fluids in contact with each other. The general configuration can be seen in Fig. 7. There are two physical conditions that must be met. First, the pressure in fluid 1 at the interface will be the same as the pressure in fluid 2 at the interface.

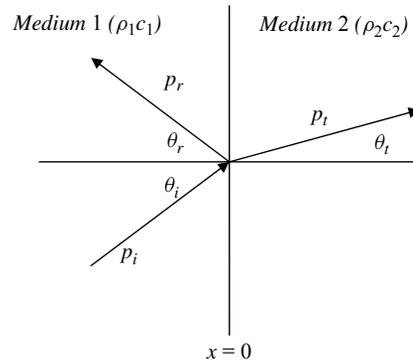

Fig. 7 Reflection and transmission at interface of two fluid media. The vectors represent the propagation directions of the incident, reflected, and transmitted waves.

Second, the displacement normal to the interface (or equivalently, the particle velocity) in fluid 1 will be the same as the normal displacement (particle velocity) in fluid 2 at the boundary. If the interface lies in the y - z plane, the waves in the two media can be expressed as

$$\begin{aligned} p_i &= \mathbf{p}_i e^{j(\omega t - k_1 x \cos \theta_i - k_1 y \sin \theta_i)} \\ p_r &= \mathbf{p}_r e^{j(\omega t + k_1 x \cos \theta_r - k_1 y \sin \theta_r)} \\ p_t &= \mathbf{p}_t e^{j(\omega t - k_2 x \cos \theta_t - k_2 y \sin \theta_t)} \end{aligned} \quad (47)$$

where, θ_i is the angle of incidence of the wave, θ_r is the angle of reflection and θ_t is the angle of transmission. The wavenumber k is specific to the medium of interest and will differ for the two media, since the phase speed c differs in the two media. Analysis of the conditions at the boundary leads to the following important result:

$$\theta_i = \theta_r \quad (48)$$

This result is known as the law of reflection and simply indicates that the angle of reflection must equal the angle of incidence. This is the same result as for light reflecting from a plane mirror.

Equation (49) is known as Snell's law and governs the refraction of sound waves as they propagate from one medium into another. Note that the refraction depends on the speed of sound in the two media. This is also manifest in the atmosphere when there is a temperature gradient in the air. In this case, there is a continuous rather than a discrete change in the sound speed, and as a result the sound waves bend either upward or downward as the wave propagates. This phenomenon is responsible for being able to clearly

hear a cricket that is a long distance away on a cool evening, for example:

$$\frac{\sin \theta_i}{c_1} = \frac{\sin \theta_t}{c_2} \quad (49)$$

Equations (50) are the pressure reflection and transmission coefficients. In these expressions, Z_n refers to the normal specific acoustic impedance of either medium 1 or medium 2. For a fluid, this is given by $Z_n = \rho c / \cos \theta$, where the angle θ is the angle of incidence in medium 1 and the transmitted angle in medium 2 and the ρc of the appropriate medium is used. For normal incidence, $\cos \theta = 1$. It is also of note that $T = 1 + R$ for the pressure coefficients but for the power coefficient (and intensity for normal incidence), $R_\Pi + T_\Pi = 1$ (conservation of energy). Equations (51) are the intensity and power reflection and transmission coefficients

$$R = \frac{Z_{n2} - Z_{n1}}{Z_{n2} + Z_{n1}} \quad T = 1 + R = \frac{2Z_{n2}}{Z_{n1} + Z_{n2}} \quad (50)$$

$$R_I = R_\Pi = \left(\frac{Z_{n2} - Z_{n1}}{Z_{n2} + Z_{n1}} \right)^2$$

$$T_I = \frac{\rho_1 c_1}{\rho_2 c_2} \left(\frac{2Z_{n2}}{Z_{n2} + Z_{n1}} \right)^2 \quad (51)$$

$$T_\Pi = \frac{4Z_{n1}Z_{n2}}{(Z_{n2} + Z_{n1})^2}$$

An analysis of these results yields several important special cases:

1. Angle of Intromission. This occurs when R in Eq. (50) equals zero and corresponds to complete transmission through the interface. Although the material properties of density and speed of sound change, the normal specific impedance does not so that the wave does not “see” any discontinuity.
2. Grazing Incidence. In this case, θ_i goes to 90° and Z_{n1} goes toward infinity resulting in a pressure reflection coefficient of $R = -1$. Thus, the boundary between the two fluids acts as a pressure release boundary.
3. Critical Angle for $c_1 < c_2$. If $c_1 < c_2$, there is an angle of incidence θ_i where $\sin \theta_t = 1$ [using Eq. (49)]. This gives $\theta_t = 90^\circ$. For angles of incidence greater than this, θ_t must become complex to satisfy the mathematical condition. Physically, this means that the transmitted waves become “evanescent,” meaning that the waves decay exponentially in the x direction, propagate in the y direction, and cannot effectively penetrate into the second medium.

7.2 Reflection/Transmission from a Solid Surface

In the case of a wave in a fluid impinging upon a solid surface, the nature of the reflection/transmission phenomena depends upon the properties of the solid. If the solid has properties consistent with a bulk isotropic solid (no significant elastic response), the transmission of the wave into the solid will obey the equations given above, and the analysis can proceed as if the solid behaved as a fluid. If the solid behaves as a *locally reacting* material, the analysis must be modified slightly. One example of such a material would be an anisotropic solid, where waves propagate much faster in a direction perpendicular to the solid surface than they do in a direction parallel to the surface. Examples of such materials include many sound absorption materials such as acoustic tile, perforated panels, and other materials with a honeycomb structure. In these cases, the expressions given above can be used if one lets the transmission angle θ_t go to zero, that is, $Z_{n2} = \rho_2 c_2$.

Reflection/Transmission through a Fluid Layer

One can often encounter situations where sound waves propagate through one or more fluid layers. These fluid layers may be small or large relative to an acoustic wavelength. The expressions will be developed here for a single layer with normal incidence. The methods can be extended in a straightforward manner to multiple layers and/or oblique incidence, but the algebra is such that use of a computer would be desirable. Use of these techniques can allow one to design a single or multilayer to have desired reflection/transmission characteristics. It also can be used for the analysis needed for noise control problems such as transmission through walls and other barriers.

The general configuration for understanding transmission through a layer can be seen in Fig. 8. With normal incidence, the acoustic waves involved can be

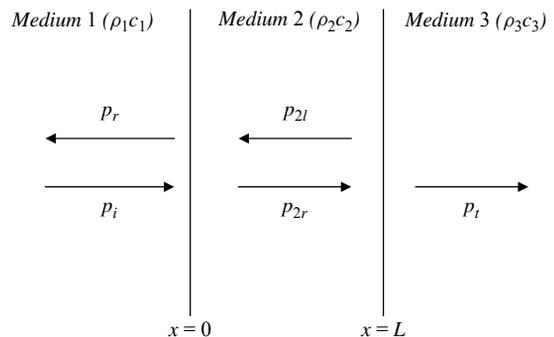

Fig. 8 Reflection and transmission through a fluid layer. The vectors represent the propagation directions of the incident, reflected, and transmitted waves in the three fluids.

represented as

$$\begin{aligned} p_i &= P_i e^{j(\omega t - k_1 x)} \\ p_r &= P_r e^{j(\omega t + k_1 x)} \\ p_{2r} &= P_{2r} e^{j(\omega t - k_2 x)} \\ p_{2l} &= P_{2l} e^{j(\omega t + k_2 x)} \\ p_t &= P_t e^{j(\omega t - k_3 x)} \end{aligned} \quad (52)$$

The new terms in these equations represent the right- and left-going waves in the fluid layer. Again using continuity of acoustic pressure and acoustic particle velocity at the two interfaces ($x = 0$ and $x = L$) leads to the following result for the pressure reflection coefficient:

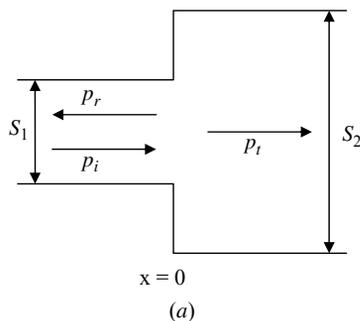

$$R = \frac{[1 - \rho_1 c_1 / (\rho_3 c_3)] \cos(k_2 L) + j[\rho_2 c_2 / (\rho_3 c_3) - \rho_1 c_1 / (\rho_2 c_2)] \sin(k_2 L)}{[1 + \rho_1 c_1 / (\rho_3 c_3)] \cos(k_2 L) + j[\rho_2 c_2 / (\rho_3 c_3) + \rho_1 c_1 / (\rho_2 c_2)] \sin(k_2 L)} \quad (53)$$

For transmission through the layer, the intensity transmission coefficient is given by

$$T_I = \frac{4}{2 + [\rho_3 c_3 / (\rho_1 c_1) + \rho_1 c_1 / (\rho_3 c_3)] \cos^2(k_2 L) + [(\rho_2 c_2)^2 / (\rho_1 c_1 \rho_3 c_3) + \rho_1 c_1 \rho_3 c_3 / (\rho_2 c_2)^2] \sin^2(k_2 L)} \quad (54)$$

It is of note that this expression is symmetric, implying that the same energy propagates through the layer regardless of the direction of incidence. Many specific cases could be analyzed. However, one case that is often of practical interest is when fluid 1 is the same as fluid 3, such as transmission through a wall with air on both sides. In this case,

$$T_I = \frac{1}{1 + (1/4)[\rho_2 c_2 / (\rho_1 c_1) - \rho_1 c_1 / (\rho_2 c_2)]^2 \sin^2(k_2 L)} \quad (55)$$

From this expression, it can be seen that for low frequencies and/or thin walls ($k_2 L \gg 1$) there will be nearly perfect transmission through the layer. There will also be perfect transmission at discrete frequencies where $\sin(k_2 L) = 0$. Also, if the specific acoustic impedance of the layer ($\rho_2 c_2$) is large (as is the case with most walls, for example) and $k_2 L \gg 1$, the expression in Eq. (55) reduces to the well-known mass law, expressed as

$$T_I = \left(\frac{2\rho_1 c_1}{\omega \rho_2 L} \right)^2 \quad (56)$$

Thus, at low frequencies, one must increase the mass per unit area of the intermediate layer in order to reduce transmission for this case.

7.3 Reflection/Transmission at Discontinuities in Pipes

Another important class of problems involves the reflection and transmission that occurs when waves propagating in pipes or vents encounter a geometric discontinuity, such as a branch in the pipe or an expansion chamber or constriction, as shown in Fig. 9. For this analysis, continuity of pressure still holds at the discontinuity. However, instead of continuity of particle velocity, there is now continuity of volume velocity, given as the product of the particle velocity and the cross-sectional area ($U = uS$). For this case, the pressure reflection coefficient is given by

$$R = \frac{Z_0 - \rho c / S_1}{Z_0 + \rho c / S_1} \quad (57)$$

where Z_0 is the acoustic impedance at $x = 0$ and S_1 is the cross-sectional area of the pipe for $x > 0$. The power reflection and transmission coefficient are given by $R_{\Pi} = |R|^2$ and $T_{\Pi} = 1 - R_{\Pi}$. For the case of a single pipe with a different cross-sectional area, for $x > 0$, $Z_0 = \rho c / S_2$. For branches in the pipe or for

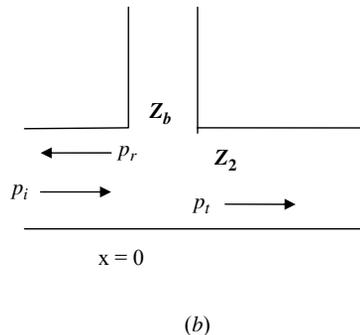

Fig. 9 Reflection and transmission from geometric discontinuities: (a) pipe expansion; (b) side branch with impedance Z_b .

more complex impedances such as expansion chambers and constrictions, the measured or calculated acoustic impedance at $x = 0$ should be used.

Side Branch A special case of practical interest is where a side branch exists at $x = 0$. This could be a branching of the pipe or it could be a noise reduction device such as a Helmholtz resonator (see Section 9). Let the acoustic impedance of the side branch be given by $Z_b = R_b + jX_b$ and the impedance of the continuing pipe be $\rho c/S_1$. Using these values leads to the power reflection coefficient, the power transmission coefficient for waves propagating further down the pipe, and the power transmission coefficient for waves propagating into the side branch:

$$\begin{aligned} R_{\Pi} &= \frac{(\rho c/2S_1)^2}{(\rho c/2S_1 + R_b)^2 + X_b^2} \\ T_{\Pi} &= \frac{R_b^2 + X_b^2}{(\rho c/2S_1 + R_b)^2 + X_b^2} \\ T_{\Pi b} &= \frac{(\rho c/2S_1) R_b}{(\rho c/2S_1 + R_b)^2 + X_b^2} \end{aligned} \quad (58)$$

8 HEARING LOSS

8.1 Hearing Protection

Because excess noise can be damaging to the human ear, precautions must be taken to protect one's hearing. Sensorineural hearing loss, or permanent damage to the inner ear, can occur through sudden trauma, for example, caused by an explosion at close range. It can also occur if chemicals that are damaging to the cilia (called ototoxic chemicals) are not handled properly. However, the most common cause of sensorineural hearing loss is prolonged exposure to significant noise levels. To help workers safeguard their hearing, the Occupational Safety and Health Administration (OSHA) act (see <http://www.osha.gov/dts/osta/otm/noise/standards.html>) set forth permissible exposure limits in the workplace. Table 6 summarizes daily exposure limits for various A-weighted sound levels. Note that if noise exposure occurs at various levels throughout the day, in order to be under the cumulative noise exposure limit, the condition of $\sum t_i/T_i \leq 1$, where t_i is the exposure time at the i th level and T_i is the daily limit for that level that must be met. However, because a typical workday may consist of many different sound levels for as many different exposure periods, a noise dosimeter, which consists of a microphone and a sound level logger, can be worn by workers to track total daily noise exposure. Other noise and vibration exposure criteria are summarized by von Gierke and Ward.¹⁰

There are underlying assumptions regarding the OSHA act that should be made clear. First, the act is only intended to protect hearing for the purposes of understanding speech. Hearing loss above 4 kHz

Table 6 Daily Noise Exposure Limits (L_{pA}) in dBA

is likely to occur and is deemed acceptable. Second, an 8-hr workday and a 5-day workweek are assumed. It is further assumed that leisure time is not spent in high-noise-level activities that could be damaging to the ear. Finally, and perhaps most importantly, the OSHA criteria are designed to protect only 85% of the population exposed at the limits. The remaining, more damage-prone 15% are to be financially compensated for the hearing loss suffered as part of their jobs.

The risk of hearing impairment can be summarized another way, as a function of both frequency and level. Shown in Fig. 10 are different zones which represent different amounts of potential for damage to the ear. In zone I, sounds are inaudible. The levels in zone II are everyday audible sounds that present no risk. In zone III, there is a qualified risk, especially for prolonged exposure periods, and in zone IV, there is a high risk of hearing damage. The division between zones II and III roughly follows the equal-loudness contours, meaning the ear is most susceptible to damage at those frequencies where it is most sensitive.

8.2 Hearing Protection Devices

To preserve hearing, in addition to limiting exposure time, hearing protectors can be worn to reduce the noise levels to which the ear is exposed. Figures 11 and 12 summarize many classes of hearing protectors and ranges for attenuation provided by each type as a function of frequency. In general, the effectiveness of hearing protectors increases as a function of frequency, but to achieve sufficient attenuation, the user should take care to wear them properly. For simple formable earplugs, the attenuation can be quite high, but care must be taken to insert them sufficiently deep into the ear canal. For ear muffs to provide the proper attenuation, the wearer needs to ensure that the cushioned cups that enclose the pinnae (outer ears) fit snugly enough that an airtight seal is formed.

9 PASSIVE NOISE CONTROL

There are numerous situations where it is desirable to reduce unwanted sound, or noise. There are many approaches for accomplishing this, with some

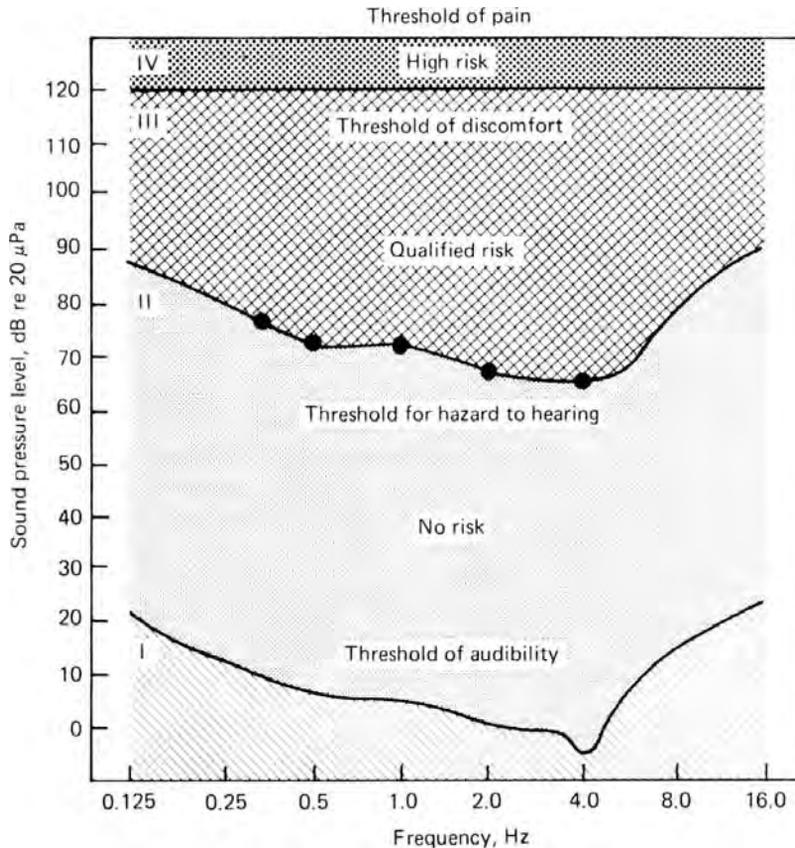

Fig. 10 Graphical representation of hearing damage risk as function of frequency and level.¹¹

approaches being more appropriate for a given situation than others. This section will outline some general concepts associated with the use of passive noise control for reducing unwanted noise and the next section will outline concepts associated with active noise control. Much more information regarding these control methods can be found using the references at the end of the chapter (see particularly Refs. 13 and 14). The distinguishing feature between these two approaches is that passive noise control relies on the inherent acoustic properties of the noise control material or device being used to reduce the unwanted noise, while active noise control involves the active generation of additional sound or vibration to interact with the existing noise or vibration in a manner that attenuates the field.

9.1 Source/Path/Receiver Considerations

For any given noise control application, one should consider that three components exist: (a) there is an acoustic source that is responsible for generating the noise, (b) there is an acoustic path that the sound

energy propagates through, and (c) there is a receiver (often the human ear) that receives the acoustic energy. Where possible, this also gives the hierarchy of how to most effectively attenuate unwanted noise. The most effective solution is to modify the source characteristics so that less acoustic energy is generated. If that is not possible, the next most effective approach would be to modify the acoustic path. This can be done, for example, by using walls, barriers, absorptive materials, acoustic mufflers, and so forth. The final possibility is to modify the receiver. There is little possibility for doing much in this regard when the receiver is the human ear (except that the ear has a protective mechanism that reduces the sensitivity of the ear when exposed to loud sounds; however, this mechanism has a finite response time, and one should never rely on this ear protection as a means of making noise exposure acceptable). (Depending on one's point of view, hearing protectors such as ear muffs could be viewed as part of the receiver or part of the acoustic path.) If the receiver is not the human ear, there may be the possibility of modifying its response characteristics.

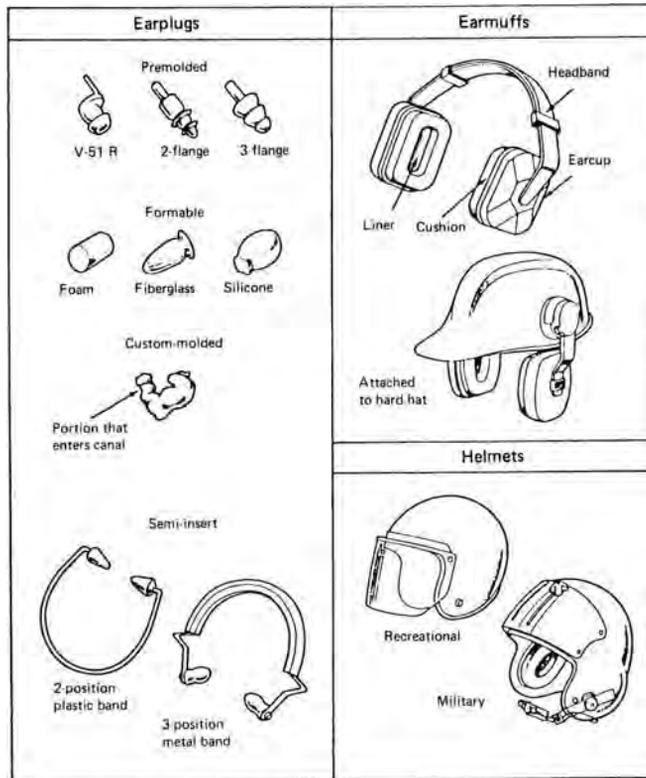

Fig. 11 Various types of hearing protectors.¹²

Most typical noise control approaches are based on the assumption that the source has been optimized and the receiver characteristics are fixed. Thus, the focus then needs to be on modifying the acoustic path.

9.2 Definitions

A number of terms are commonly used in the context of noise control, and an understanding of their meaning is beneficial.

Transmission Coefficient (τ): The fraction of incident energy that is transmitted through a noise control element.

Transmission Loss (TL): Expresses the transmission coefficient on a logarithmic scale and is obtained as $TL = -10 \log_{10} \tau$ (dB).

Insertion Loss (IL): The decrease in sound power level measured at a receiver location after a noise control element is inserted into the acoustic transmission path.

Absorption Coefficient (α): The fraction of energy that is randomly incident on a given material that is absorbed.

Noise Reduction Coefficient (NRC): Given by the arithmetic mean of the sound absorption coefficients for a material at 250, 500, 1000, and 2000 Hz and used as a single-number rating of the absorption characteristics of the material.

9.3 Impedance Considerations: Vibration Isolation Mounts

Many noise control situations involve a source that converts mechanical vibration energy into acoustic energy. Such examples could be a vibrating motor or generator that transmits energy to a support structure which then radiates acoustic energy or a vibrating wall or casing which in turn radiates acoustic energy. In general, there are three properties of the source that can be modified to attenuate the noise: mass, stiffness, and damping. Modifying each of these properties will be effective under certain conditions but completely ineffective under other conditions. This can best be seen by considering a vibration isolation mount, such as might be used for mounting a motor or generator. The general configuration is shown in Fig. 13. The

Type of protection	One-third-octave-band center frequencies, Hz						
	125	250	500	1000	2000	4000	8000
 Earplugs (premolded, user formable)	10-30	10-30	15-35	20-35	20-40	30-45	25-45
 Foam earplugs (attenuation varies with depth of insertion)	20-35	20-35	25-40	25-40	30-40	40-45	35-45
 Earplugs (custom-molded)	5-20	5-20	10-25	10-25	20-30	25-40	25-40
 Semi-insert earplugs (also called semiaural devices or canal caps)	10-25	10-25	10-30	10-30	20-35	25-40	25-40
 Earmuffs (with or without communications components)	5-20	10-25	15-30	25-40	30-40	30-40	25-40

Fig. 12 Expected attenuation (dB) for various types of hearing protectors.¹²

mechanical impedance of this mount is given by

$$Z_m = R_m + j \left(\omega m - \frac{s}{\omega} \right) \quad (59)$$

Looking at this expression in various frequency regions indicates how to most effectively modify the

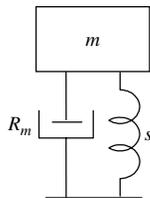

Fig. 13 Single-stage vibration isolation mount showing mass m to be isolated, spring element with stiffness s , and mechanical damping R_m .

vibration response. At low frequencies, the stiffness term dominates, and the impedance is given as $Z_m \approx -js/\omega$. This is referred to as the stiffness-controlled region, and one should alter the stiffness of the mount to most effectively modify the response of the structure. Around the resonance frequency of the mount, the impedance is given as $Z_m \approx R_m$. This is referred to as the damping-controlled region, and increased damping will be most effective in this frequency region. At higher frequencies above the resonance frequency, the impedance is given by $Z_m \approx j\omega m$. This is referred to as the mass-controlled region, and one should alter the mass to most effectively modify the response of the structure.

Although this was developed for a vibration isolation mount, the same concepts hold for all vibrating sources—at any given frequency the system response will be dominated by the stiffness, damping, or mass properties of the structure. An investigation of the phase of the impedance can reveal which property is dominant. The stiffness-controlled region exhibits an

impedance phase near -90° , the damping-controlled region has a phase near 0° , and the mass-controlled region has a phase near 90° .

9.4 Transmission Loss for Isolation Mounts

Isolation mounts are normally designed for operation above the resonance frequency of the mount. For the single-stage isolation mount shown in Fig. 13, the resonance frequency is given by

$$f_r = \frac{1}{2\pi} \sqrt{\frac{s}{m}} \tag{60}$$

The transmission loss for the mount is given by

$$TL = -10 \log_{10} \left[\frac{1 + \left[2 \left(\frac{R}{4\pi m f_r} \right) \left(\frac{f}{f_r} \right) \right]^2}{\left[1 - \left(\frac{f}{f_r} \right)^2 \right]^2 + \left[2 \left(\frac{R}{4\pi m f_r} \right) \left(\frac{f}{f_r} \right) \right]^2} \right] \tag{61}$$

In this expression, the quantity $4\pi m f_r$ is commonly called “critical damping” and represents the damping that results in the fastest decay time for a disturbance with no oscillation. It can be seen that at frequencies above the resonance frequency the transmission loss increases by 12 dB/octave (doubling of frequency). If additional isolation is required, a two-stage isolation mount can be implemented, as shown in Fig. 14. For this type of mount, the transmission loss increases by 24 dB/octave above the resonance frequencies of the mount. The trade-off is that an additional resonance frequency is introduced at lower frequencies, so the isolation performance is degraded at lower frequencies. However, if operation will always be at frequencies above the resonance frequencies, this type of mount design can be desirable when greater isolation is required.

9.5 Acoustic Filters

Acoustic filter can be designed effectively when the wavelength at the frequencies of interest is significantly larger than the dimensions of the acoustic elements used to construct the acoustic filters. It can be shown that a tube whose length is small relative to a wavelength behaves as a mass, and a cavity (enclosed volume of fluid) behaves as a spring. These, along with damping materials, allow one to develop low-pass, high-pass, and bandstop filters in much the same way as one designs *LRC* electrical circuits. These three types of filters are reviewed briefly

Bandstop Filter The design of a bandstop filter is typically dependent on the use of a Helmholtz resonator. A Helmholtz resonator consists of a tube connected to a cavity, typically with some damping included. A common example we are familiar with is

a soda bottle, where the neck of the bottle behaves as a tube and the portion below the neck behaves as the cavity. A Helmholtz resonator has a resonance frequency associated with it, and when used as a filter it is capable of attenuating that frequency. The use of such a filter is shown in Fig. 15. The reactance of the side branch (Helmholtz resonator) is given by

$$X_b = \rho_0 \left(\frac{\omega L_{\text{eff}}}{S_b} - \frac{c^2}{\omega V} \right) \tag{62}$$

where L_{eff} is the effective length of the tube (including end corrections), S_b is the cross-sectional area of the tube, and V is the volume of the cavity. The effective length is given by

$$L_{\text{eff}} = \begin{cases} L + 1.7a & \text{(outer end flanged)} \\ L + 1.4a & \text{(outer end unflange)} \end{cases} \tag{63}$$

where a is the radius of the tube. This configuration will give a stopband centered at the frequency

$$\omega_{\text{sb}} = c \sqrt{\frac{S_b}{L_{\text{eff}} V}} \tag{64}$$

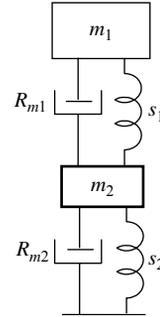

Fig. 14 Two-stage vibration isolation mount showing mass m_1 to be isolated, spring elements with stiffness s_1 and s_2 , mechanical damping R_{m1} and R_{m2} , and intermediate mass (raft) m_2 .

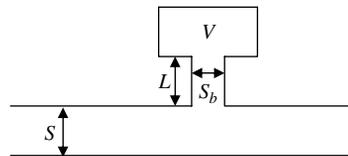

Fig. 15 Bandstop filter using Helmholtz resonator as side branch. The stopband is centered at the resonance frequency of the Helmholtz resonator.

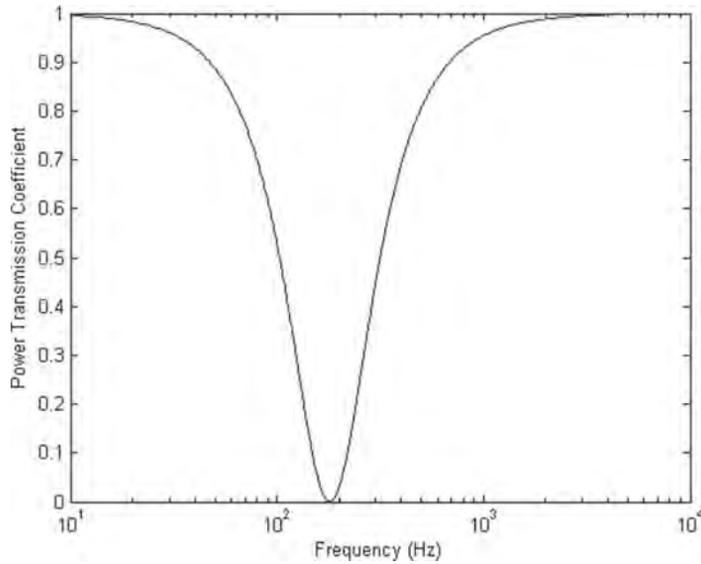

Fig. 16 Power transmission coefficient for bandstop filter using Helmholtz resonator. The resonator has a volume of 2000 cm³, a neck length of 0.8 cm, and a cross-sectional area of 7.5 cm². The main pipe has a cross-sectional area of 28 cm².

and the power transmission coefficient for this filter is given by

$$T_{\Pi} = \frac{1}{1 + [(c/2S)/(\omega L_{\text{eff}}/S_b - c^2/\omega V)]^2} \quad (65)$$

where S is the cross-sectional area of the main duct. Figure 16 shows the characteristics of the power transmission coefficient for a typical bandstop filter.

Low-Pass Filter An acoustic low-pass filter can be constructed using an enlarged section of pipe or a constriction in the pipe. An enlarged section of pipe is used, for example, in the basic design of mufflers and will be considered here, as shown in Fig. 17. The enlarged section behaves acoustically as a cavity, and

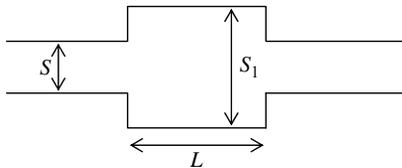

Fig. 17 Low-pass filter using expansion chamber.

the acoustic impedance of the cavity is given by

$$Z_c \approx \frac{-j\rho_0 c^2}{\omega(S_1 - S)L} \quad (66)$$

The resulting power transmission coefficient is given by

$$T_{\Pi} \approx \frac{1}{1 + \{[(S_1 - S)/2S]/kL\}^2} \quad (67)$$

A typical response for this low-pass filter is shown in Fig. 18. It should be remembered that this acoustic response is only valid for low frequencies (wavelength significantly larger than the acoustic elements), and the response shown in Fig. 18 will not be valid for $kL > 1$.

High-Pass Filter An acoustic high-pass filter can be constructed using a side branch consisting of a short length of unflange pipe (with radius a), such as is used for toneholes in musical instruments like a flute or clarinet, as shown in Fig. 19. The acoustic impedance of the side branch is given by

$$Z_{\text{sb}} = \frac{\rho_0 c k^2}{4\pi} + j\omega \left(\frac{\rho_0 L_{\text{eff}}}{\pi a^2} \right) \quad (68)$$

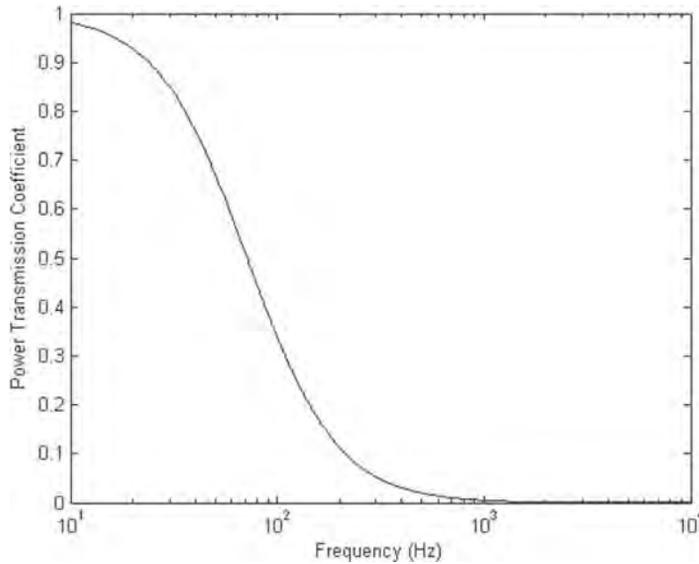

Fig. 18 Power transmission coefficient for low-pass filter using enlarged section of pipe. The main pipe has a radius of 2.54 cm, and the enlarged section has a length of 30.5 cm and an area six times that of the main pipe.

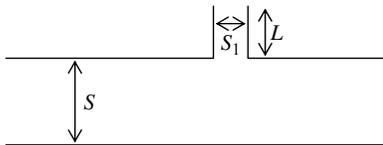

Fig. 19 High-pass filter using open side branch.

The resulting power transmission coefficient is given by

$$T_{\Pi} = \frac{1}{1 + [S_1 / (2SL_{eff}k)]^2} \quad (69)$$

A typical response for this high-pass filter is shown in Fig. 20. It should again be remembered that this acoustic response is only valid for frequencies where the wavelength is significantly larger than the side branch.

9.6 Lined Ducts

Ducts lined with absorbing material are often used as dissipative muffler devices to muffle fans in heating and air conditioning systems. The liner material generally consists of a porous material such as fiber glass or rockwool, usually covered with a protective facing. The protective facing may be a thin layer of acoustically

transparent material, such as a lightweight plastic sheet, or it may be a perforated heavy-gage metal facing. If a perforated facing is used, it should have a minimum open area of 25% to ensure proper performance.

The performance of a lined duct with liner thickness *l* and airway width *2h* is shown in Fig. 21 for the case of zero mean flow. This figure shows some of the dependencies on the ratio of liner thickness to airway width as well as the flow resistivity.

9.7 Single- and Double-Leaf Partitions

Partitions (such as walls) are often used to separate a noise source from a receiving space. When partitions are used, flanking paths and leakage are important to check for. Small openings or flanking paths with low impedance can easily reduce the effectiveness of partitions significantly. Single-leaf partitions exist when there is a single surface or when both surfaces of the wall vibrate as a unit. Double-leaf partitions consist of two unconnected walls separated by a cavity.

At low frequencies for single-leaf partitions, the transmission through the partition is governed by the mass of the partition, and the mass law governs this behavior. The intensity transmission coefficient is given in Eq. (56), and the resulting transmission loss can be expressed as

$$TL = 20 \log(f\rho_s) - 47(\text{dB}) \quad (70)$$

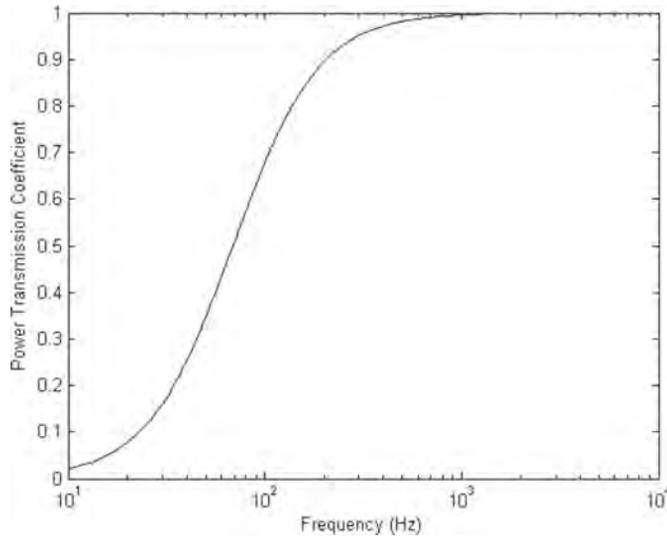

Fig. 20 Power transmission coefficient for high-pass filter using open side branch. The main pipe has a cross-sectional area of 28 cm², and the side branch has a length of 8 cm and a cross-sectional area of 7.5 cm².

where ρ_s is the surface density of the partition, given as the product of the density and thickness of the partition. Thus, at low frequencies, one must increase the density of the partition in order to increase the transmission loss; doubling the density of the partition increases the transmission loss by 6 dB.

For a single-leaf partition, wave effects in the partition lead to a coincidence frequency, which corresponds to the condition where the flexural wavelength in the partition matches the acoustic wavelength along the direction of the partition. When this condition is met, the transmission loss drops significantly with the decrease being governed by the damping in the partition. Above the coincidence frequency, the partition becomes stiffness controlled, and the transmission loss increases at a rate higher than the mass law (theoretically 18 dB/octave for a single angle of incidence or about 9 dB/octave for diffuse-field incidence). The coincidence frequency separates these two behaviors and is given by

$$f_{co} = \frac{1}{2\pi} \sqrt{\frac{\rho_p h}{D}} \left(\frac{c}{\sin \phi} \right)^2 \quad (71)$$

In this equation, c is the speed of sound in the fluid, ρ_p is the density of the partition, h is the thickness of the partition, and D is the bending rigidity of the partition, given by $D = Eh^3/[12(1 - \nu^2)]$, where E is Young's modulus of the partition and ν is Poisson's ratio for the partition.

The transmission loss through a double-leaf partition is noticeably higher than through a single-leaf partition with the same mass density. While the behavior is too

complex to be covered extensively here, the following characteristics are generally associated with double-leaf partitions. (a) At low frequencies, the transmission loss follows the mass law, with the combined mass of the two leaves being used to determine the surface density. (b) A mass-air-mass resonance exists where the air cavity between the two leaves behaves as a spring between two masses. (c) Above the mass-air-mass resonance, the transmission loss increases sharply (18 dB/octave) until resonance effects in the cavity become important. (d) The transmission loss oscillates as the cavity resonance effects become important. At resonances of the cavity (cavity depth $\approx n\lambda/2$), the transmission loss drops to values consistent with the mass law, while the peaks in the transmission loss occur at antiresonances of the cavity and continue to rise at about 12 dB/octave. Experimental transmission loss measurements typically show some variation from these predicted trends, but the results are generally consistent with predicted behavior.

9.8 Enclosures

For noisy equipment, one can install an enclosure around the piece of equipment. The insertion loss of the enclosure can be estimated using

$$IL = TL - C \quad (\text{dB}) \quad (72)$$

where TL is the transmission loss associated with the walls of the enclosure and

$$C = 10 \log \left(0.3 + \frac{S_E (1 - \bar{\alpha}_i)}{S_i \bar{\alpha}_i} \right) \quad \text{dB} \quad (73)$$

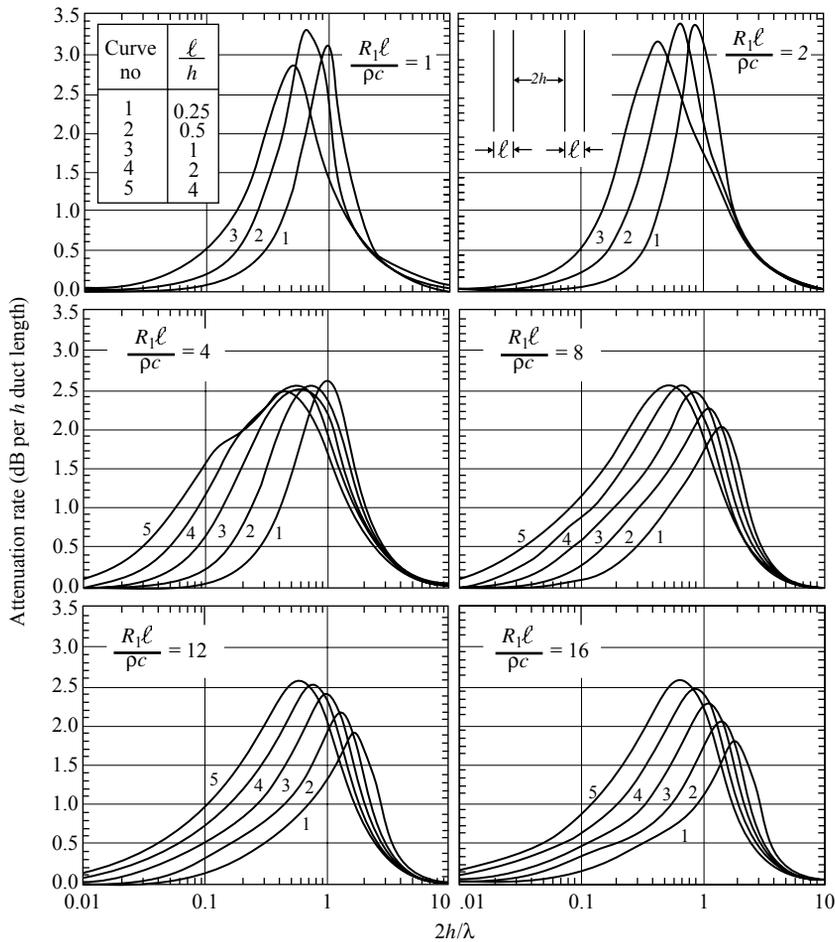

Fig. 21 Predicted octave-band attenuations for rectangular duct lined on two opposite sides. Lined circular ducts or square ducts lined on all four sides give twice the attenuation shown here. The quantity ρ is the density of fluid flowing in the duct, c is the speed of sound in the duct, ℓ is the liner thickness, h is the half width of the airway, and R_1 is the liner flow resistivity. For these results, a bulk reacting liner with no limp membrane covering and zero mean flow is assumed.¹⁴

$\bar{\alpha}_i$ is the mean Sabine absorption coefficient of the interior of the enclosure, S_i is the interior surface area of the enclosure, and S_E is the external surface area of the enclosure.

10 ACTIVE NOISE CONTROL

Over the last couple of decades, there has been considerable interest in the use of active noise control to address noise control applications. In many cases, it has been a technology that has not been well understood. There are many applications for which active noise control is not a good solution. In such cases, active noise control will be quite ineffective, and as a result, people can be easily disappointed. Thus, active noise control as a noise control solution should be

chosen with care. However, for applications where active noise control is appropriate, it works *very* well and can produce impressive results. While active noise control can be very effective for proper applications, it is generally not a straightforward “off-the-shelf” solution. Thus, the focus of this section is to give an overview of how active noise control works and the direction in identifying proper applications. If active noise control is a viable solution, expertise should be sought in implementing the solution.

In deciding whether active noise control is a viable solution, there are several characteristics of active noise control that should be understood. First, active noise control is inherently a low-frequency solution. Implementation at high frequencies has several

difficulties associated with it. First, effective control requires precise phase and amplitude matching. For example, if one wishes to achieve 20 dB of attenuation, the control signal must have a phase error of less than 4.7° (assuming perfect amplitude matching) or a magnitude error of less than 0.9 dB (assuming perfect phase matching). This tight tolerance in phase and magnitude matching is significantly easier to achieve at lower frequencies than at higher frequencies.

It is also easier to achieve significant spatial control of the acoustic field at lower frequencies than it is at higher frequencies. In active noise control, one can achieve localized control or global control of the field, depending on the physical configuration of the problem. In those cases where local control is achieved, the spatial volume where significant attenuation occurs scales according to the wavelength. The diameter of the sphere where at least 10 dB of attenuation is achieved is about one-tenth of a wavelength. Thus, lower frequencies result in larger volumes of control. If global control is to be achieved, good spatial matching must be achieved, which is also easier to achieve at lower frequencies than at higher frequencies.

In a number of applications, it is desirable to achieve global control of the acoustic field. In order to accomplish this, there must be a good acoustic coupling between the primary noise source and the secondary control source used to control the field. This can be achieved using one of two mechanisms. The first is to have the spacing between the primary noise source and the secondary control source be significantly less than an acoustic wavelength. For an extended noise source, this would require multiple control sources that will acoustically couple to the primary noise source. For an enclosed noise field (such as in rooms or cabs), it is also possible to achieve acoustic coupling without the control source being less than a wavelength away from the noise source. Instead, the coupling occurs through the acoustic modes of the enclosed field. The acoustic modes have a distinct spatial response, and by exciting the secondary control source properly, it is possible to achieve the same spatial (modal) response but with opposite phase, thus resulting in global attenuation of the field. However, it should be noted that this approach is effective only for low modal density fields. If too many modes are excited, global control can rarely be achieved and local control is the result.

It is also important to understand that discrete tonal noise is significantly easier to control than broadband noise. When multiple frequencies must be controlled, it is necessary to control the precise phase and amplitude matching at all frequencies. This is easier to accomplish with a small number of discrete tones than it is with many frequencies or broadband noise. In addition, when controlling broadband noise, *causality* also becomes an important issue. When controlling tonal noise, if it is not possible to generate the control signal to arrive with the noise signal at the error sensor at exactly the same time, it is still possible to

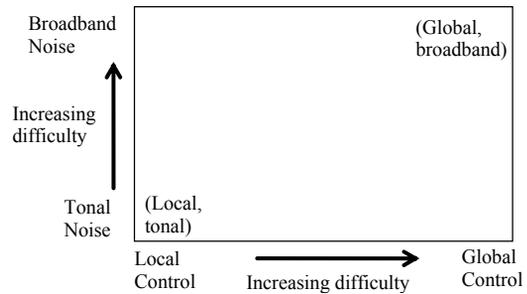

Fig. 22 Level of difficulty for various classes of noise control problems.

achieve effective control by delaying the control signal to match the noise signal one period later. However, with broadband noise, this approach is not possible. If broadband control is to be achieved, the control signal and the noise signal must be temporally aligned, which cannot occur if it takes longer for the control signal to get to the error sensor than the primary noise signal.

To summarize, when considering a particular application, the lower the frequencies involved, the more effective the control can be, in general. In addition, the difficulty of the solution depends on the frequency content of the noise and the spatial extent of the control needed, as shown in Fig. 22.

10.1 Control Architectures

Active control can be implemented in either an adaptive mode or a nonadaptive mode. In a nonadaptive mode, the control filter is fixed such that if the filter is designed properly, good attenuation results. However, if the acoustic system changes, reduced effectiveness can result. In adaptive mode, the control filter has the ability to adjust itself to a changing acoustic environment, based on the response of one or more error sensors. Most active noise control solutions are based on an adaptive mode solution that is based on a digital signal processing (DSP) platform.

There are two general architectures that can be implemented with an active noise control system. These are referred to as feedforward and feedback. While both adaptive control and nonadaptive control have been used with both architectures, adaptive control has generally been used for feedforward control systems. To understand the basic working of an adaptive feedforward control system, consider the control of a plane wave propagating in a duct, as shown in Fig. 23. This is a prototypical application and allows one to understand the basic configuration in a straightforward manner. The noise to be controlled is detected by a "reference sensor," which could be a microphone in the duct or some other sensor whose output is correlated to the noise to be attenuated. It should be understood that the control system will only be capable of attenuating noise that is correlated with the signal

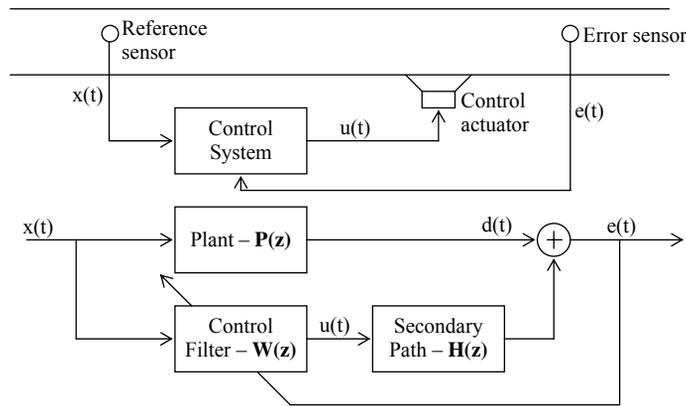

Fig. 23 Adaptive feedforward control for a duct. The upper figure shows the physical layout of the system, while the lower figure shows a block diagram of the control system implementation.

from this reference sensor. This signal is then used as the input to an adaptive control filter that determines the control signal output. The output signal is passed to a control actuator (such as one or more loudspeakers), where it generates an acoustic response that combines with the uncontrolled field and is measured by one or more error sensors. The error sensor response is then used to update the adaptive control filter. For implementation of a feedforward control system, care must also be taken to account for any possible response from the control output at the reference sensor. In our example, not only does the control signal propagate “downstream” in the duct to provide the desired attenuation, but it also propagates “upstream” in the duct where it can alter the reference signal if a microphone is being used. This can be accounted for either by using a nonacoustic reference signal (such as a tachometer signal if the noise is being created by some piece of rotating equipment such as a fan) or by modeling the feedback contribution from the control output to the reference sensor and compensating for that feedback component in the control system.

Causality is a potentially important issue in implementing feedforward control. There is an acoustic delay that exists as the noise to be controlled propagates from the reference sensor to the error sensor. If the reference signal can be processed and the response from the control actuator can arrive at the error sensor at the same time as the uncontrolled noise, the system will be causal. In this case, both random and periodic noise could be effectively controlled, since it will be possible to achieve the precise time alignment needed. If the noise to be controlled is periodic, the causality constraint can be relaxed. If the control signal does not arrive in time to be perfectly aligned in time, the DSP will adjust itself to effectively line up the signal properly one cycle later, thus still achieving the desired attenuation.

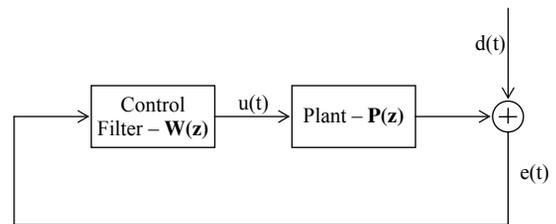

Fig. 24 Block diagram of feedback control implementation. The uncontrolled signal is given by $d(t)$.

Feedback control systems have used both adaptive and nonadaptive control configurations. Perhaps the most common example involving feedback control is with active headsets that are commercially available to reduce noise (although some headsets are now also implementing feedforward control). For a feedback control system (Fig. 24), the noise to be controlled is detected by a reference sensor that is used as the input to the control filter. The output of the control filter is again sent to a control actuator, and the sound generated combines with the uncontrolled field. The result is measured at the reference sensor and thus creates the “feedback loop.” Feedback control systems are generally more tolerant of model errors in the control system implementation. Thus, implementation of feedforward control in a nonadaptive mode is rarely effective in a practical application. However, feedback control systems can also easily become unstable if designed improperly. Staying within stability constraints often leads to a solution that does not achieve as much attenuation as with feedforward control. The stability constraint also often determines the frequency bandwidth that can be effectively controlled.

It should also be understood that there is inherently an acoustic delay present in the feedback loop when

implementing feedback control. This delay results from the finite response time of the control actuator, the acoustic propagation time from the control actuator to the reference sensor, and any delays associated with the electronics of the system. As a result, it is impossible to achieve perfect time alignment of the uncontrolled noise and the noise generated by the active control system. In general, the shorter the delay time in the feedback loop, the greater the attenuation that can be achieved and the wider the frequency bandwidth that can be controlled.

10.2 Attenuation Limits

Good estimates of the maximum attenuation achievable can be determined for both feedforward and feedback control implementations. Because of the structure of feedforward systems, the control system will only attenuate noise that is correlated with the reference sensor signal. Thus, it is imperative that the error signal sensor and the reference signal sensor be correlated. This is embodied in the expression that gives the maximum obtainable attenuation,

$$\Delta L_{\max} = 10 \log[1 - \gamma_{xd}^2(\omega)] \quad (74)$$

where ΔL_{\max} is the maximum obtainable attenuation and $\gamma_{xd}^2(\omega)$ is the coherence (frequency dependent) between the reference signal, $x(t)$, and the uncontrolled error signal, $d(t)$. A quick method of determining if active noise control would be effective would be to measure the coherence between a proposed reference sensor and a proposed error sensor. It should be remembered that this gives a prediction of the attenuation at the error sensor. If local control is being achieved, this will give no indication as to how effective the control will be at locations removed from the error sensor location.

For feedback control, the autocorrelation of the reference signal can be used to predict the attenuation that can be achieved if the time delay associated with the feedback loop is known. Conversely, if the desired attenuation is known, this autocorrelation can also be used to determine how short the time delay must be. The predicted attenuation is given by

$$\Delta L_{\max} = -10 \log \left(1 - \frac{E_p}{E_0} \right) \quad (75)$$

where E_0 is the autocorrelation level at zero delay and E_p is the largest magnitude of the autocorrelation that exists in the autocorrelation at any time greater than the group delay of the feedback loop.

10.3 Filtered-x Algorithm

The most common adaptive algorithm in current use for active noise control is the filtered-x algorithm or some variation of that algorithm. A brief review of the algorithm is helpful in understanding the general

architecture of most active noise control systems. In the DSP architecture, the control filter is implemented as a finite impulse response filter whose response can be represented by a vector of the filter coefficients. Thus,

$$\mathbf{W} = [w_0, w_1, w_2, \dots, w_{I-1}]^T \quad (76)$$

Similarly, the secondary path transfer function (represented by \mathbf{H} in Fig. 23) can be represented by a vector of filter coefficients:

$$\mathbf{H} = [h_0, h_1, h_2, \dots, h_{J-1}]^T \quad (77)$$

The output of a digital filter is the convolution sum of the input signal with the filter response vector. Thus, if the reference input and control output signals are represented as vectors,

$$\begin{aligned} \mathbf{X}(t) &= [x(t)x(t-1)x(t-2) \dots x(t-I+1)]^T \\ \mathbf{U}(t) &= [u(t)u(t-1)u(t-2) \dots u(t-J+1)]^T \end{aligned} \quad (78)$$

the control output signal is given by $u(t) = \mathbf{W}^T \mathbf{X}(t)$ and the error signal is given by $e(t) = d(t) + \mathbf{H}^T \mathbf{U}(t)$. Most active noise control systems are based on quadratic minimization techniques. For the filtered-x algorithm, the algorithm updates its coefficient according to the negative gradient (with respect to the control filter coefficients) of the squared instantaneous error signal. Calculating the gradient of the squared error signal leads to

$$\mathbf{W}(t+1) = \mathbf{W}(t) - \mu \mathbf{R}(t)e(t) \quad (79)$$

which gives the control filter coefficients for the next iteration of the algorithm. In this expression, μ is a convergence parameter chosen to maintain stability and $\mathbf{R}(t)$ is the "filtered-x" signal vector, whose components are given by

$$r(t) = \hat{\mathbf{H}}^T \mathbf{X}(t) \quad (80)$$

where $\hat{\mathbf{H}}$ is a vector of filter coefficients that models the physical secondary path transfer function \mathbf{H} .

10.4 System Identification

In order to achieve stable, effective control, it is necessary to have a reasonable model of the secondary path transfer function \mathbf{H} . It has been shown that the phase of the model is the primary concern in achieving good control. While phase errors of up to $\pm 90^\circ$ can be tolerated in order to maintain stability, the performance of the control system degrades seriously as the phase errors approach this limit. Thus, an accurate model with minimal phase errors will result in substantially improved control results.

There are several methods that have been used to obtain a good model of \mathbf{H} . The most straightforward method is to obtain a model of \mathbf{H} a priori. This is done by injecting broadband noise into the secondary path (typically from the DSP used for the control) and measuring the response at the error signal with the primary noise source turned off. In this manner, a straightforward adaptive system identification routine can be used to obtain the coefficient of \mathbf{H} .

A second method implements an adaptive online secondary-path estimation technique by injecting low-level broadband noise, $n(t)$, along with the control signal, $u(t)$. This broadband signal is uncorrelated with the primary noise, $d(t)$, and with the control signal, $u(t)$. Thus, the error signal can be used as an output, with the noise signal $n(t)$ as an input in a typical adaptive system identification routine. Since the primary noise and control signal are not correlated with $n(t)$, they do not affect the system identification and the process proceeds similar to the offline approach. The difficulty with this approach is that the injected noise must be high enough in level to achieve good system identification and yet kept low enough in level to not affect the overall noise level at the error sensor. In many cases, this can involve adaptive gain control to maintain the correct balance between the control signal and the injected noise.

A final method that has been used is also adaptive in nature. This method performs system identification not only for the secondary path but also for the plant, P . In other words, it implements a model of the entire system which is unlike the previous two methods. One of the results of this approach is that the model of the secondary path is not unique, unless the excitation of the system can be characterized as "persistent excitation," which essentially means broadband excitation. For excitation signals that are narrowband in nature, although there is not a unique solution for the secondary path, it has been shown that the solution obtained leads to stable, effective control. For more information on both adaptive system identification methods, the reader is referred to Refs. 15 and 16.

10.5 Control Applications

This section briefly outlines application areas where active noise control may be applicable:

- (i) Active Control in Ducts. Active control of ducts has been implemented in a number of commercial applications, such as in exhaust stacks at industrial plants and in heating, ventilation, and air-conditioning (HVAC) ducts. The most successful applications have been at low frequencies, where only plane waves propagate in the duct. At higher frequencies, higher order modes propagate in the duct. While control of such field can be effective, it requires sensing and actuating configuration that are able to sense and control those higher order modes. Another consideration is that even in the frequency range where only plane waves propagate the control actuator will generate evanescent higher order modes. Thus, the control system must be configured so that all evanescent modes have effectively decayed by the time they reach the error sensor and/or the reference sensors.
- (ii) Active Control of Free-Field Radiation. Active control has been investigated for applications such as radiation from transformers and even as part of noise barriers for highways. For these applications, the control configuration significantly impacts the amount of control that can be achieved and whether the control is local or global. The control source configuration must be carefully selected for these applications if control in a desired direction or even global control is to be achieved.
- (iii) Active Control in Enclosures. The most successful application currently is for active headsets. These implement control in a small confined volume surrounding the ears and a number of active headsets are commercially available. Other applications include active control in automobile cabins, aircraft fuselages, other vehicles, and rooms. The active control will be more effective at lower frequencies and is dependent to a large extent on the modal density in the enclosure. In a number of applications, local control is achieved, although if the modal density is low, it can be possible to achieve global control, or at least control extended over a much broader portion of the volume. In general, if global control is desired, the number of control actuators used must be at least as great as the number of modes to be controlled.
- (iv) Active Vibration Isolation Mounts. This approach uses active vibration control to minimize the transmission of vibration energy through isolation mounts associated with engines, generators, and so forth. Active mounts have been investigated for automobile engine mounts and aircraft engine mounts, among others. Depending on the mount configuration it may be necessary to control multiple degrees of freedom in the mount in order to achieve the desired isolation, and it may be necessary to use active mounts on most, if not all, of the engine mounts.
- (v) Active Control of Transmission Loss. This approach is focused on increasing the transmission loss through a partition, such as an aircraft fuselage or a partition in a building. There are multiple possible approaches, including controlling the structural response of the partition using structural actuators or directly controlling the acoustic field (on either the source or receiver side) through the use

of acoustic actuators. For these applications, a thorough understanding of the physics associated with the structural response of the partition and its coupling with the incident and transmitted acoustic field is essential in developing an effective solution.

With all of these applications, it is important to do a careful analysis of the noise reduction requirements in order to assess whether active noise control is an appropriate solution. Several applications using active noise control are currently commercially available and others are nearing commercialization. Nonetheless, if one does not carefully consider the application, it is easy to be disappointed in active noise control when it is not as effective as hoped. In review, active noise control is better suited for low frequencies. It is easier to achieve success for tonal noise than it is for broadband noise. It will generally be more effective for compact noise sources than for complex extended sources. If these criteria are met, active noise control could be a very effective and viable solution, although currently it would still generally require the involvement of someone knowledgeable in the field.

11 ARCHITECTURAL ACOUSTICS

This section defines the four principal, physical measures used to determine performance hall listening quality. Several perceptual attributes correlated with a physical measure are also listed.

The four main measures used to qualify concert halls are the binaural quality index (BQI), the early decay time (EDT), the strength (G), and the initial time delay gap (ITDG). The BQI is defined as $BQI = 1 - IACC$, where IACC is the average of the interaural cross correlation in octave bands of 500, 1000, and 2000 Hz. The BQI and IACC are measures of the relative sound reached at each ear. If a listener's two

ears receive identical reflection such as from a ceiling, floor or back wall, the BQI would equal zero and the IACC would equal unity. If reflection at both ears are received from side walls or such that the reflection at both ears are not identical the BQI would be greater than zero and the IACC would be less than unity. BQI values of 0.65–0.71 are representative of the best concert halls.

The second measure is EDT. This is a measure of the time required for a 10-dB decay to occur in the signal. This time is then multiplied by a factor of 6 that provides an extrapolated comparison to a 60-dB decay time that is a similar measure of the reverberation time ($\frac{T}{60}$). Because of the 10-dB decay, the abbreviation of EDT10 is often used. EDT typically has a linear relationship in frequency between occupied and unoccupied halls. This can simplify the process of gathering data. The better concert halls have EDT values in the range from 1.7 to 2.1 sec.

The third measure is G , defined as $G = L_p - L_w + 31$ dB, where L_p is the sound pressure level measured at the point of interest and L_w is the power level of the source. Typically, L_p will decrease as the room volume and room absorption increase. However, if the reverberation time (RT) also increases with room volume, the L_p can be held constant. The better concert halls have G values that range from 3–6 dB while relatively large concert halls with less sound quality have G values in the range of 0–3 dB.

The fourth measure is the ITDG, which is defined as the time interval in milliseconds from the direct sound to the first reflected sound. ITDG values are functions of walls, balconies, and other obstacles which provide a reflective surface for the sound. ITDG values should not exceed 35 msec for best results.

There are also several perceptual attributes which are used to describe concert halls. These attributes are listed and defined by providing a measure in Table 7.

Table 7 Perceptual Attributes, Physical Measures, and Optimal Values for Concert Halls

Perceptual Attribute	Physical Measure	Optimal Values
Spaciousness	Binaural quality index, lateral fraction	BQI > 0.64
Reverberance	Early decay time	EDT and RT depend on type of music
Dynamic loudness	Strength	$G > 3$ dB, low background level
Intimacy	Initial time delay gap	ITDG (15–35 msec)
Clarity	Early/late ratio	Large early/late ratio for speech, depends on music
Envelopment	Highly diffuse, reverberant sound	Similarity of EDT and RT
Warmth	Frequency dependence of EDT	$EDT_{low} > EDT_{high}$
Ensemble	Early (15–35-msec) stage reflections, at frequencies above 500 Hz	Stage with ample reflecting surfaces

This table was produced from class notes provided by William Strong at Brigham Young University.¹⁷ It is important to note that halls that provide good speech intelligibility are not necessarily the best halls for music.

12 COMMUNITY AND ENVIRONMENTAL NOISE

Measurement and analysis of the impact of noise on both individuals and communities represent a major subfield within acoustics. They are also topics inherently fraught with debate, because human perception of noise is ultimately a subjective phenomenon. To introduce this section, some of the basic principles of outdoor sound propagation are summarized. This is done to demonstrate the impact the propagation environment can have on the noise at a receiver.

12.1 Outdoor Sound Propagation

Many phenomena can affect the propagation of noise from source to receiver and therefore have a direct impact on community noise issues. Some of these phenomena are:

- Geometric spreading
- Atmospheric absorption
- Ground effect
- Refraction
- Atmospheric turbulence
- Barriers

The effects that each of these can have on sound pressure level are now reviewed.

Geometric spreading for distances much larger than the characteristic dimensions of the source will be spherical. For every doubling of distance, ΔL_p will be -6 dB. There are situations, such as supersonic aircraft or steady traffic near a roadway, where the spreading will be cylindrical, which reduces ΔL_p to -3 dB for every doubling of distance.

Because of its frequency-dependent nature, absorption causes high-frequency energy to decay much more rapidly than low-frequency energy. In addition to overall level, absorption can play an important role in changing spectral shape and therefore community response to the noise.

Another effect is that of reflection of nonplanar waves off a finite-impedance ground. If we consider the basic setup in Fig. 25, where the distance from the source to the receiver is r_1 and the distance from the image source to the receiver is r_2 , the complex pressure amplitude at the receiver may be expressed as

$$p = \frac{Ae^{-jkr_1}}{r_1} + Q \frac{Ae^{-jkr_2}}{r_2} \quad (81)$$

where the quantity Q is the spherical wave reflection coefficient and may be calculated from Appendix D.4

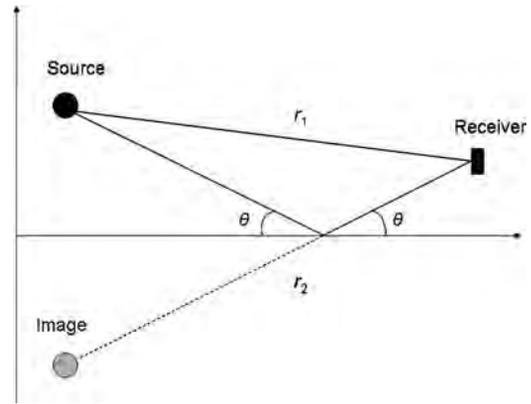

Fig. 25 Direct and ground-reflected paths from source to receiver.

in (Ref. 18). This coefficient is generally complex and accounts for the amplitude and phase changes encountered when the nonplanar sound wave reflect off the finite-impedance ground.

An example of the significant effect that the impedance of the ground can have is shown in Fig. 26, where the impedance values chosen are representative of grass, gravel, and asphalt. In this example, for which one-third octave bands are displayed, the source and receiver are both at a height of 6 ft (1.8 m) and are separated by a distance of 500 ft (152 m). At low frequencies, the wavelengths of sound are such that the direct and reflected sound waves arrive in phase, resulting in constructive interference and a doubling of pressure ($+6$ dB ΔL_p). The first interference null varies significantly in frequency for the three surfaces. Note that asphalt begins to approximate a rigid ground surface.

Atmospheric refraction can also have a significant impact on the propagation of sound from source to receiver. Refraction is caused by variations in sound speed. The first cause of a variable sound speed is wind. For sound propagation upwind, upward refraction occurs. For sound propagation downwind, downward refraction occurs, as illustrated in Fig. 27. The second cause of sound speed variation is a temperature gradient. During the day, solar radiation causes the ground to warm up and a temperature lapse to occur, meaning that the temperature decreases as a function of height. This condition causes upward refraction to occur as the sound waves bend toward where the sound speed is slower and can create a “shadow region” near the ground where the sound (theoretically) does not reach. At night, however, temperature inversions can occur as the ground cools more quickly than the surrounding air. In this case, downward refraction occurs. This also occurs at the surface of a body of water, where the air temperature just above the water is cooler than the surrounding air. This condition makes

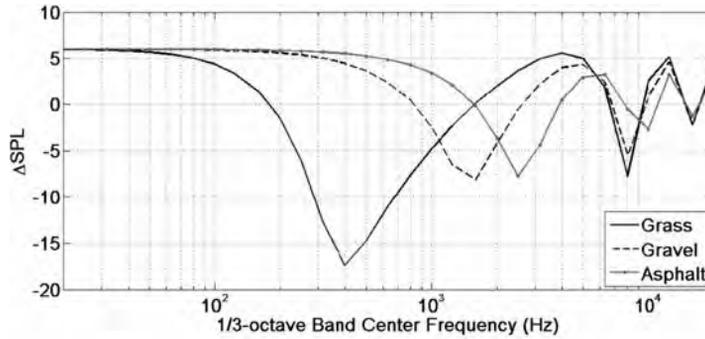

Fig. 26 Change in sound pressure level relative to free-field propagation due to ground reflections. The source and receiver are both at a height of 6 ft and the distance between them is 500 ft.

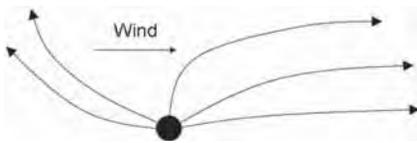

Fig. 27 Effect of wind on direction of sound rays radiating from a source.

sound propagated over large distances near the ground more readily audible and can greatly impact community noise issues.

Atmospheric turbulence may be viewed as small-scale refraction. Small-scale inhomogeneities in temperature or air velocity can cause sound to be scattered (diffracted). The main effect of turbulence is to generally lessen the impact of other propagation effects. For example, in Fig. 28, ΔL_p has been calculated for propagation over grass with and without atmospheric turbulence. Turbulence minimizes the interference nulls at high frequencies because the scattered sound takes slightly different paths to the receiver. The effect for a refracting atmosphere is similar. Although the shadow zone can readily occur near the ground for upward refraction, turbulence causes some sound to be scattered into the region.

The final phenomenon in outdoor sound propagation that is discussed is the behavior of acoustic waves when a barrier is encountered. For the case of natural barriers, such as hills, acoustic propagation over a hill can often be treated as propagation through an upward-refracting atmosphere over a flat plane. For the case of man-made barriers, such as sound walls, analytical methods may be used to account for the sound that reaches a receiver. If the length of the barrier is much greater than the height, there are four basic paths that need to be accounted for, which are depicted in Fig. 29. The first path is a direct path from the source to barrier and then, due to diffraction, from the top of the barrier to the receiver. The other paths involve one or two ground reflection before reaching the receiver.

Although more sophisticated analytical methods exist (e.g., Ref. 18), the basic effects of the multipath problem can be included in the following equation,¹⁹ which describes the insertion loss, in decibels, of a thin barrier for a point source and for ranges less than 100 m, where atmospheric effects are ignored:

$$IL = -\Delta SPL = 10 \log_{10} [3 + 10N] - A_{ground} \quad (82)$$

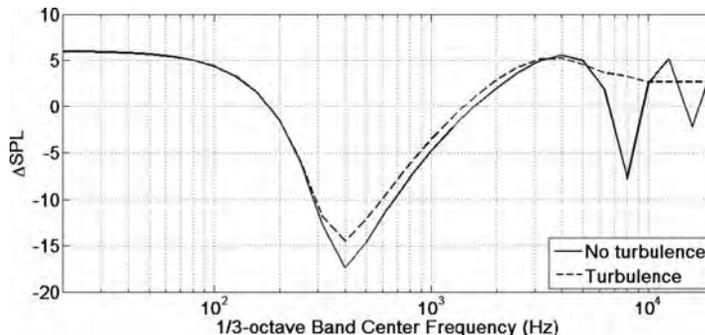

Fig. 28 Change in sound pressure level for propagation over grass with and without atmospheric turbulence.

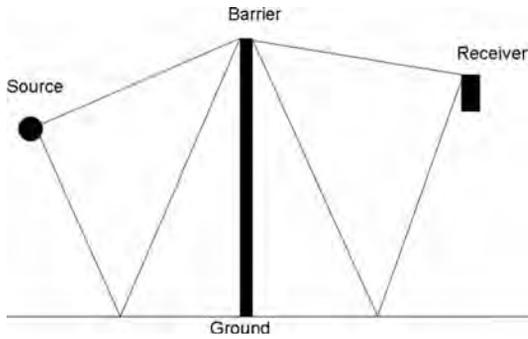

Fig. 29 Four different paths that the barrier-diffracted sound can take between the source and receiver.

where A_{ground} is the absorption due to the ground (in decibels) before the barrier is installed, JPL stands for sound pressure level, and N is the Fresnel number, which for sound of wavelength λ can be calculated as

$$N = \frac{2}{\lambda} (d_{\text{SB}} + d_{\text{BR}} - d_{\text{SR}}) \quad (83)$$

The distances are the distances from the source to the top of the barrier (SB), from the barrier to the receiver (BR), and the direct line-of-sight distance from the source to the receiver (SR). One point to make is that although the barrier effectiveness does generally increase as a function of frequency, the diffraction from the top of the barrier can play a significant role and result in diminished performance. This is especially true for pathlengths for which the interference is constructive. More general analytical techniques, applicable to thick barriers or diffraction due to gradual structures like hills, do exist and can be found in Refs. 14 and 18. However, explicit inclusion of atmospheric effects (e.g., refraction) is usually accomplished with numerical models.

12.2 Representations of Community Noise Data

There are numerous ways of representing the noise to which communities are subjected. One way is to simply display the A-weighted sound pressure level (L_A) as a function of time. One example, displayed in Fig. 30, is the emptying of several trash dumpsters during the early morning at an apartment complex in Provo, Utah. Before the garbage truck arrived, major noise sources were due to intermittent traffic from the nearby street. The most significant noise events were due to the dumpsters being shaken by the hydraulic arms on the truck before being noisily set back down.

Other representations of community noise are statistical in nature. Using the same garbage truck example, the estimated probability density function of the A-weighted level is displayed in Fig. 31. The broad tail of large values is caused primarily by the garbage truck noise events. Another statistical representation is a cumulative distribution, which displays the percentage of time that the noise levels exceed a given value. This is shown for the same garbage truck data in Fig. 32. Finally, statistical moments can also be calculated from the time series. For example, the mean level during the 15-min sampling period was 62.4 dBA and the skewness of the data was 1.1. This latter moment emphasizes the non-Gaussian characteristics of the noise distribution because skewness is zero for Gaussian distributions.

In addition to A-weighted sound pressure level, there are many other single-number metrics that are used to describe community noise. These metrics have been the result of attempts to correlate subjective response with objective, albeit empirical measures. Some of the commonly used metrics are as follows:

- Equivalent Continuous Sound Level (L_{eq}). The A-weighted level of the steady sound that has the same time-averaged energy as the noise event. Common averaging times include hourly levels, day levels (7 AM–10 PM), evening levels (7–10 PM), and night levels (10 PM–7 AM).

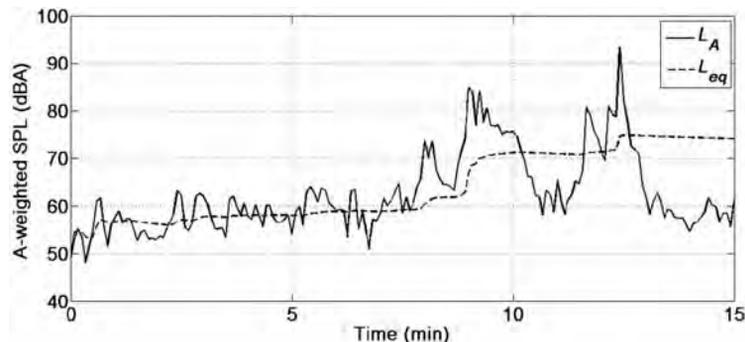

Fig. 30 A-weighted L_p and L_{eq} as function of time before, during, and after garbage truck arrival.

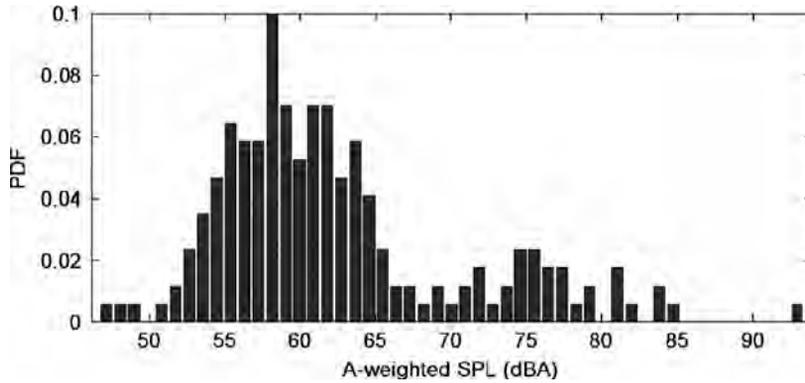

Fig. 31 Probability density function (PDF) of L_p for time series shown in Fig. 30.

For the time interval T which runs between T_1 and T_2 , L_{eq} is calculated as

$$L_{eq} = 10 \log_{10} \left\{ \frac{1}{4 \times 10^{-10}} \frac{1}{T} \int_{T_1}^{T_2} p_A^2(t) dt \right\} \tag{84}$$

where p_A is the instantaneous A-weighted sound pressure. The L_{eq} as a function of time was shown for the previous garbage truck example in Fig. 30.

- Day-Night Level (DNL or L_{dn}). The L_{eq} obtained for a 24-hr period after a 10-dBA penalty is added to the night levels (10 PM–7 AM). For individual L_{eq} calculations carried out over 1-hr intervals (L_{1h}), L_{dn} may be expressed as

$$L_{dn} = 10 \log_{10} \left\{ \frac{1}{24} \left[\sum_{i=0100}^{0700} 10^{0.1[L_{1h}(i)+10]} \right. \right.$$

$$\left. \left. + \sum_{i=0800}^{2200} 10^{0.1L_{1h}(i)} + \sum_{i=2300}^{2400} 10^{0.1[L_{1h}(i)+10]} \right] \right\} \tag{85}$$

- Community Noise Equivalent Level (CNEL). The L_{eq} obtained for a 24-hr period after 5 dBA is added to the evening levels (7–10 PM) and 10 dBA is added to the night levels. It can be calculated similar to L_{dn} , with the appropriate penalty given during the evening (between 2000 and 2200 hours).
- X-Percentile-Exceeded Sound Level (L_X). Readily calculated from the cumulative distribution (e.g., see Fig. 32), L_X is the level exceed X percent of the time. Common values are L_{10} , L_{50} , and L_{90} . In Fig. 33, L_X values are shown as bars for L_{99} , L_{10} , L_{50} , L_{90} , and L_1 for representative noise environments.
- C-Weighted Sound Pressure Level (L_C). Similar to A weighting, but designed to mimic the

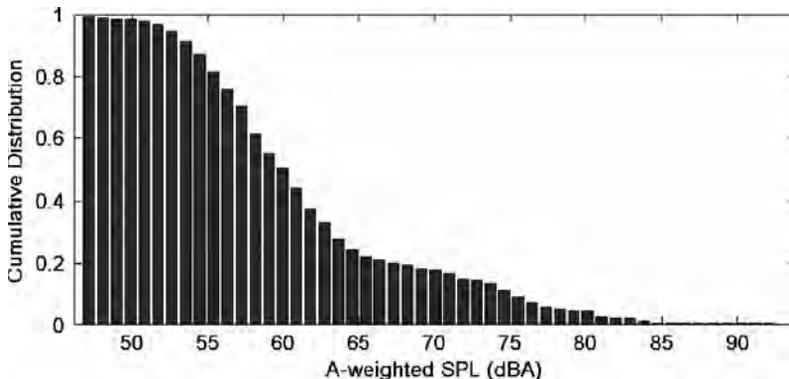

Fig. 32 Cumulative distribution of time series in Fig. 30 showing fraction of time sound level exceeds given L_p .

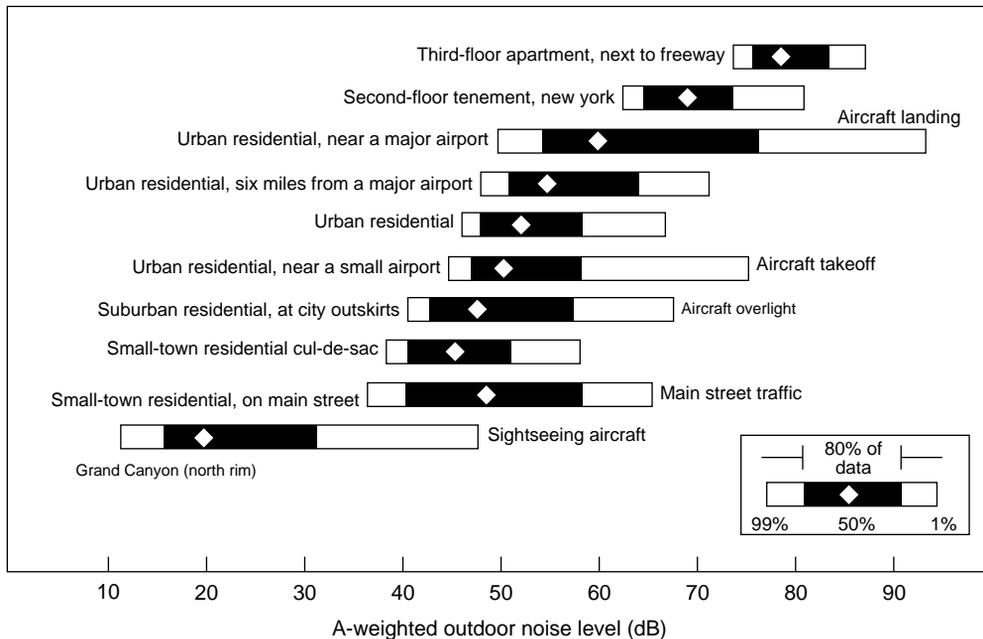

Fig. 33 Community noise data showing L_{99} , L_{90} , L_{50} , L_{10} , and L_1 data points for various noise events.

90-phon equal-loudness contour. Consequently, C weighting is more appropriate than A weighting for louder sounds. The equation for the C-weighting filter was given previously in Eq. (7).

- D-Weighted Sound Pressure Level (L_D). Developed for assessing the auditory impact of aircraft noise. The weighting curve heavily penalizes high frequencies to which the ear is most sensitive (see Fig. 3). The equation for the D-weighting filter was given previously in Eq. (7).
- Effective Perceived Noise Level (EPNL). This metric was designed for characterizing aircraft noise impact and is used by the Federal Aviation Administration (FAA; see FAR Part 36, Sec. A.36) in the certification of commercial aircraft. The metric accounts for (a) the nonuniform response of the human ear as a function of frequency (i.e., the perceived noise level), (b) the additional annoyance due to significant tonal components of the spectrum (the tone-corrected perceived noise level), and (c) the change in perceived noisiness due to the duration of the flyover event. Too involved to be repeated here, calculation procedures for EPNL may be found in FAR Part 36, Sec. A.36.4, or Ref. 20.

12.3 Community Noise Criteria

Because of increased awareness regarding community noise issues, city noise ordinances are becoming more

commonplace. Many of these ordinances are based on maximum allowable A-weighted sound pressure level, broken down into land usage and day or night. In addition, consideration can be given to the nature of the noise source (e.g., is it essential to commerce/industry) and its duration (e.g., is it intermittent or continuous). As an example, portions of the Provo, Utah, noise ordinance, which is representative of many cities, are summarized in Table 8. Continuous sounds are those that have a duration greater than 6 min, intermittent sounds last between 2 sec and 6 min, and impulse sounds last less than 2 sec. The level listed is not to be exceeded at the property line of interest.

Noise levels are an important consideration when considering land use. Guidelines for outdoor DNL (for structures in 24-hr/day use) or L_{eq} (for structures being used only part of the day) have been put forth in a land use compatibility report published by the FAA. If the appropriately measured outdoor levels for a yearly average are <65 dB, then the land is compatible for all the uses listed below. In Table 9, if a number is listed, then the guidelines indicate that the transmission loss between outdoors and indoors needs to meet the value listed.

In the case of airports, DNL contour maps showing community noise impact are used to make land usage decisions. Shown in Fig. 34 is an example of a DNL map for the Colorado Springs Airport superimposed on a photograph of the area. The figure shows appropriate land usage in that urban development has occurred

Table 8 Summary of A-Weighted Level Limits (dBA) in Provo, Utah

^aApplies to areas sensitive to noise.

outside the 65-dB DNL contour. The land usage that occurs closest to the airport is not a residential district, but rather an Air Force base.

12.4 Community Response to Noise

The response of an individual to a given noise event is a highly subjective, variable measure. Noise surveys

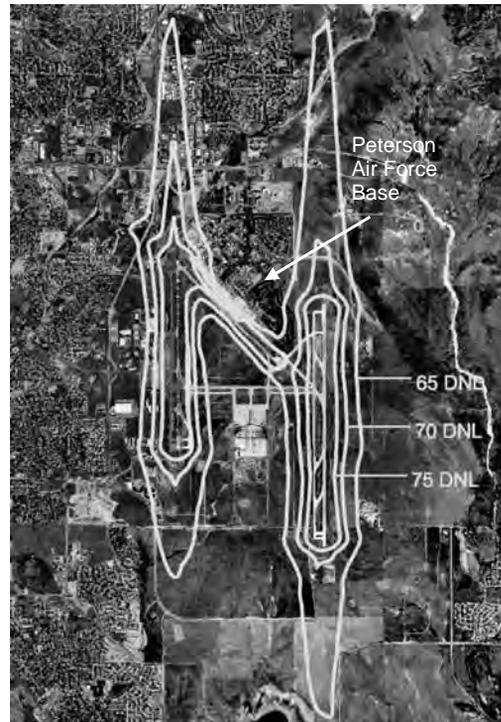

Fig. 34 DNL contour map for Colorado Springs Airport. Urban development has occurred outside the 65-dB DNL contour.

are conducted to obtain the average response of citizens to different noise sources. For transportation noise (e.g., traffic aircraft), these surveys have resulted in an empirical relationship between transportation noise events and the percentage of people that were highly annoyed.²¹ If this percentage is defined as %HA, it may be expressed in terms of the DNL (L_{dn}) as

$$\%HA = 0.0360L_{dn}^2 - 3.265L_{dn} + 78.9 \quad (86)$$

The uncertainty for this measure is approximately ± 5 dBA between 45 and 85 dBA. The percent highly annoyed is plotted as a function of DNL in Fig. 35. Note that for 65-dB DNL 20% of the population will still be highly annoyed. This curve suggests the difficulty that noise control engineers and land use planners encounter when trying to balance the needs and desires of the community and industry.

13 SOUND QUALITY ANALYSIS

Good sound quality has traditionally been synonymous with quiet sounds. However, over the last three decades, the definition of sound quality has changed.

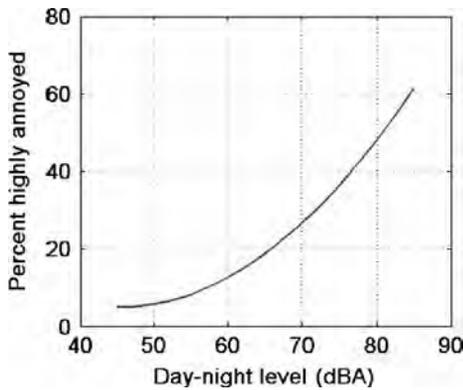

Fig. 35 Percentage of people highly annoyed for given DNL. Calculated from Eq. (86).

Blauert and JeKosch²² define sound quality as “the adequacy of a sound in the context of a specific technical goal and/or task.” The term “compatibility” has also been used in this context, especially with regard to sounds accompanying actions of product users.²³ With this definition in mind, sound quality now represents the “sensory pleasantness” of the sound, which is a combination of the perceived loudness, roughness, and pitch.²⁴ The difference in definition contrasts the one-dimensional approach initially used to the current multifaceted technique that includes aspects of psychology and anatomy as well as the physical parameters engineers are accustomed to using.

While much of what is now considered sound quality analysis originated in the automotive industry, there are a myriad of applications in nearly all consumer products and industrial processes. Sound quality analysis has generally focused on many automotive aspects, including exterior vehicle passing noise,²⁵ holistic vehicle sounds and research,^{26,27} engine noise, and exhaust noise.^{28,29} Sound quality analysis techniques have also been used to improve the acoustic signatures of everything from helicopter main rotor blades and aircraft interior noise^{30,31} to hairdryers and vacuum cleaners.^{32,33} Computer hard drives, HVAC systems in buildings,³⁴ construction machinery, and boxes at Italian opera houses³⁵ have also been improved through psychoacoustic studies.

As sound quality is dependent on the opinions of consumers, a common and effective approach is to form listening juries and survey their responses to different sounds. The primary reason for this method is the disparity between what a sound level meter measures and what an individual reports regarding the loudness of a given sound as well as the instrument’s inability to describe other parameters of sound that a consumer hears and recognizes. This inconsistency results from the nonlinear nature of the human auditory

system and the inability of traditional sound measurement techniques to approximate this behavior. A significant drawback to this technique is the requirement of large groups of research subjects to perform the listening tests. However, approximations using empirical equations have allowed the calculation of metrics that closely approximate the human subject responses.

These metrics are grouped into four categories: loudness, sharpness, grating, and tonality. Loudness characterizes the response of the cochlea given the sound’s frequency, bandwidth, and amplitude in decibels. Sharpness is a metric that describes the amount of high-frequency energy present in a sound. It is a weighted average, or area moment, of the loudness with more weight given to frequencies above ~3000 Hz. Grating describes two metrics: fluctuation strength and roughness. Fluctuation strength is a metric which characterizes amplitude modulation of the sound that is partially to entirely audibly perceptible. The modulation frequencies that cause the sensation of fluctuation strength are frequencies up to ~20 Hz. Roughness represents amplitude modulation of the sound that is too rapid to be even partially audibly perceptible; that is, it is perceived that the sound is modulated but the degree of modulation is unclear to the human ear. Frequencies of modulation that cause a sensation of roughness fall between ~20 and 300 Hz. Tonality characterizes the tonal presence in a sound. The question it answers is, “Are there distinct tones present in a seemingly broadband sound? If so, how strong are they?” These five metrics can then be combined into a relative-pleasantness measure when comparing two or more sounds. This pleasantness metric, called sensory pleasantness, is convenient as it consolidates these five independent metrics into a single response in the same way a juror does subconsciously.

13.1 Mathematical Metrics Procedures

This section continues by presenting an overview of the procedures developed for using mathematical metrics to assess sound quality. The complexity of using humans as instruments for sound quality evaluation has inspired several attempts to quantify human responses, hence creating parameters representing the acts of auditory perception, cognition, and judgment. These parameters can be measured using traditional sound analysis instruments and are quantified based on empirical equations to represent a juror’s response regarding the quality of a sound. The process consists of using standard microphone recordings in either a free field (with frontal incidence from the noise source) or a binaural field (microphones set up in a dummy head to approximate how the ears receive sound). The measured sound is then processed mathematically to calculate the sound quality metrics. These results can then be compared to jury listener tests and correlated for the given sound source. The result is a process that can accurately predict the sensory pleasantness of a sound with a minimum of human subjects, allowing sound quality analysis to be performed earlier in the product

development and often with fewer jurors during the product life cycle. To better understand the mathematical metric method, a few common terms and each of the sound quality metrics will be briefly reviewed (see Refs. 36–38 for more details).

13.2 Critical Band Rate

The human auditory systems response is dependent on both the frequency and amplitude of a given sound. Therefore, it is useful to alter the frequency scaling used in sound quality metric calculations. Characteristic frequency bands are defined as bandwidths that produce the same perceived loudness in a tone and in narrowband noise spectrum within that band when the tone is just masked. This scale of critical band rates is used to approximate the frequency dependence of each of the metrics, as it represents the bandpass nature of the auditory system. These critical band rates are given the name barks, named after Heinrich Barkhausen, an acoustician whose pioneering work in loudness approximations has produced two subjective-loudness amplitude scales. Figure 36 and Table 10 illustrate the relationship between barks (critical band rate) and center frequencies in hertz. All of the metrics will use critical band rate as the abscissa in all of their plots and calculations.

The following sections give derivations as to the method for calculating each metric as well as examples to help clarify the necessity for each of the individual metrics. The overall combination metric is called sensory pleasantness. Sensory pleasantness describes the holistic result similar to the response a juror would give when evaluating a sound.

Table 10 Frequency to Critical Band Rate for Selected Frequency Values

Frequency (Hz)	Critical Band Rate
100	1
510	5
1,000	8.5
2,000	13
4,800	18.5
10,500	22.5
15,500	24

13.3 Loudness

The loudness of a sound is a perceptual measure of the effect of the energy content of sound on the ear. It is related to but not the same as the sound pressure level (L_p), a logarithmic scale used to quantify the pressure amplitude of a sound. Loudness, however, is also dependent on the frequency content of a sound. For example, a low-frequency sound such as a 100-Hz tone at 40 dB would be perceived to be significantly quieter to a normal-hearing person than a 1-kHz tone at 40 dB; in fact, the 1-kHz tone would sound nearly four times as loud.

The fundamental assumption of this model of loudness is that it is not a product of spectral lines or obtained from the spectral distribution of the sound directly but that the total loudness is the sum of the specific loudness from each critical band. Empirical studies have shown that this process yields the best equivalent psychoacoustic values.

Hence, using the threshold of quiet as a base or minimum level of excitation, the specific loudness (N')

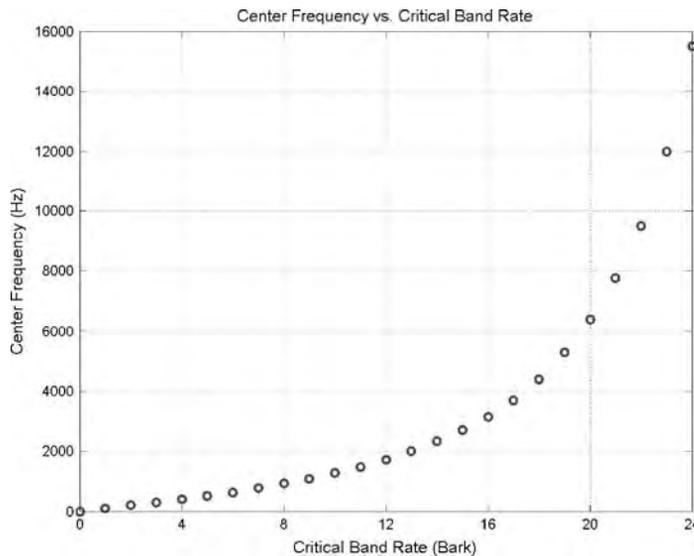

Fig. 36 Frequency versus critical band rate.

of a sound can be determined as

$$N' = N'_0 \left(\frac{E_{TQ}}{s \cdot E_0} \right)^k \left[\left(1 + \frac{s \cdot E}{E_{TQ}} \right)^k - 1 \right] \quad (87)$$

where E_{TQ} is the excitation level at the threshold of quiet, E_0 is the excitation level that corresponds to the reference intensity $I_0 = 10^{-12}$ W/m², and N'_0 is a reference-specific loudness. The variable s , which is the ratio between the intensity of a just audible test tone and the intensity of broadband noise appearing within the same critical band as the test tone, is determined experimentally. The exponent k is also determined experimentally.

The result of numerous jury tests using specific tones and broadband noise yields an approximation for the specific loudness in each critical band formulated by Zwicker and Fastl³⁶ and presented here as

$$N' = 0.08 \left(\frac{E_{TQ}}{E_0} \right)^{0.23} \left[\left(0.5 + \frac{E}{2E_{TQ}} \right)^{0.23} - 1 \right] \times \text{sone/bark} \quad (88)$$

The calculation of the total loudness is then a summation of all of the specific loudnesses across all of the critical bands, as shown in the equation

$$N = \sum_{z=1}^{24 \text{ bark}} N'_z \quad (89)$$

This results in a mathematical representation of the sensation of loudness in the human auditory system. This model accounts for the effects of masking as well

as the nonlinear relationship between loudness and frequency. Extensive empirical studies have verified the accuracy of this model and provided a foundation for its use in many applications.

The process for calculating the loudness of a given sound is as follows. Assuming this is being done digitally in a computer, the first step is to convert the amplitude from volts to a calibrated decibel value. The array of sound pressure levels is subsequently multiplied by a series of 24 one-third-octave filters to decompose the spectral response into the critical bands. The only unknown in the above equations is the excitation level (E) of the sound in a particular critical band, where E is approximated using the sound pressure level. The result is an array that can be interpreted to represent the excitation level of the cochlear duct over the audible spectrum. This array is then summed to give a value representing the total loudness that a listener would perceive when exposed to this sound.

13.4 Sharpness

Sharpness is a measure of the high-frequency energy content of a sound. Sharpness is therefore very similar to a weighted loudness ratio, with emphasis on the high-frequency sounds. A plot of the weighting function versus critical band rate is shown in Fig. 37. The unit of measure for sharpness is the *acum*, which is the Latin word for sharp.

This metric is normalized to the sound pressure level and frequency scales by the following relationship; 1 acum corresponds to a narrowband noise with a bandwidth of one critical band bandwidth wide at a center frequency of 1 kHz with a level of 60 dB. The model for sharpness is simply a weighted first moment of the critical band rate distribution of specific loudness, as seen in Eq. (90), where $g(z)$ is the weighting

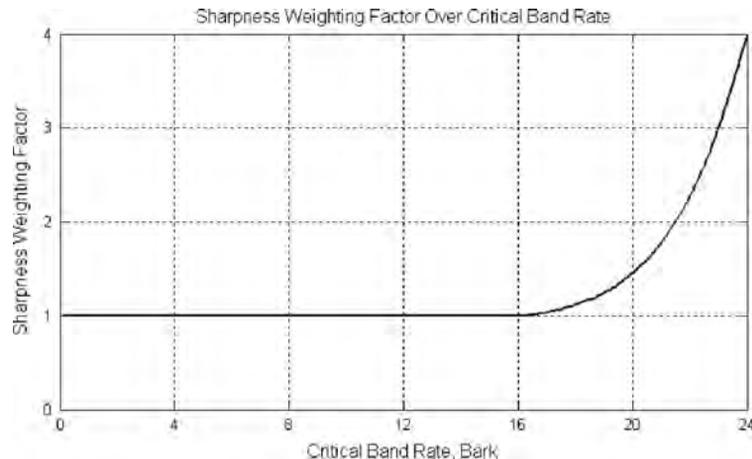

Fig. 37 Sharpness weighting factor versus critical band rate.

function given in Fig. 37:

$$S = 0.11 \frac{\int_0^{24 \text{ bark}} N'_0 g(z) z \, dz}{\int_0^{24 \text{ bark}} N' dz} \quad (90)$$

This model of sharpness takes into account that the sharpness of a narrowband noise increases significantly at high center frequencies. Although the model is relatively simple, empirical data show that the agreement between the model and test subject responses is very good.

13.5 Fluctuation Strength

Modulated sounds cause two different kinds of hearing sensations. At low modulation frequencies, fluctuation strength is produced. At higher modulation frequencies, a sensation of roughness is produced. The sensation of fluctuation strength occurs for modulation frequencies between 0 and about 20 Hz. This metric represents the modulation of the sound that is strongly audible.

This leads to a relationship for fluctuation strength. Empirical studies have shown that the total fluctuation for a fluctuating sound is approximated by Zwicker's model, given here as

$$F = \frac{0.008 \cdot \int_0^{24 \text{ bark}} [4 \log(N'_{\max}/N'_{\min}) \text{ dB (dB/bark)}] dz}{f_{\text{mod}}/4\text{Hz} + 4Hz/f_{\text{mod}}} \quad (91)$$

where f_{mod} is the modulation frequency, which is determined for a given sound by examining its spectral content and evaluating what frequency is modulating the sound. The unit for fluctuation strength is 'vacil', which is Latin for oscillate. The relationship describing vacils is that 1 vacil corresponds to a 60-dB, 1-kHz tone that is 100% amplitude modulated at a frequency of 4 Hz.

13.6 Roughness

Roughness is similar to fluctuation strength. However, it quantifies the subjective perception of rapid (15–300-Hz) amplitude modulation of a sound. This metric is often considered to be the property of a sound that would be described as grating, as the temporal masking effects of the human auditory system do not allow the total recognition of changes in amplitude at these frequencies. Roughness, like fluctuation strength, is therefore influenced by two main factors: frequency resolution and temporal resolution of the human auditory system.

For very low frequencies of modulation, roughness is also small. For midfrequencies, around 70 Hz, roughness is at its maximum. At very high frequencies, due to the restrictions of the temporal resolution of the human auditory system, roughness falls off. As the value of ΔL is also dependent on the critical

band rate, a more accurate approximation of roughness would include this dependence, which leads to a fairly accurate proportionality, given as

$$R \sim f_{\text{mod}} \int_0^{24 \text{ bark}} \Delta L(z) \, dz \quad (92)$$

Using the boundary conditions of one *asper* (a Latin word meaning rough, which will be the unit for this metric), corresponding to a 60-dB, 1-kHz tone that is 100% amplitude modulated at a frequency of 70 Hz, Zwicker and Fastl³⁶ propose the following model of roughness, again based on significant empirical data:

$$R = 0.3 \frac{f_{\text{mod}}}{1\text{kHz}} \int_0^{24 \text{ bark}} \frac{20 \log(N'_{\max}/N'_{\min}) \text{ dB}}{\text{dB/bark}} dz \quad (93)$$

where z is the critical band rate variable and the parameter dB/bark is simply a unit conversion factor. Similar to the rest of the metrics, roughness is a summation of effects across all of the critical bands.

13.7 Tonality

Tonality is concerned with the tonal prominence of a sound (i.e., are there tones present/absent in the sound). Several models of tonality have been developed, each with unique strengths and weaknesses. However, there is one common weakness with each of the currently accepted models of tonality. As the noise floor around the tone is increased in bandwidth to values greater than 100 Hz, the model for describing the tonality falls off at such a rate that it becomes inaccurate. Tonality can also be estimated using fast Fourier transform (FFT) analysis, where a time-aliased (frequency-averaged) FFT versus a non-time-aliased FFT are compared. Plotting the two FFTs in the same window, the position and amplitude of peaks can be compared versus averaging. If the peaks move, they are not tonal; however, if they remain the same, there is a tone at that frequency. The magnitude of tonality can be estimated from a comparison in amplitude of the "noise floor" versus the peak amplitude of the tone. This estimate is expressed in Eq. (94) as the ratio of amplitudes of the tone and the broadband noise. This is, however, a subjective approach to determining tonality:

$$T \approx \frac{\text{amplitude of tone}}{\text{amplitude of noise floor}} \quad (94)$$

13.8 Sensory Pleasantness

The relationship between sensory pleasantness and the sensations of loudness, sharpness, roughness, fluctuation, and tonality can be modeled based on relative values of each of the metrics. The resulting relationship proposed by Zwicker and Fastl³⁶ is presented in Eq. (95). It should be noted that because the influence

of tonality T is small, the tonality term [the term in the parenthesis in Eq. (95)] reduces to an approximate value of 0.24:

$$\frac{P}{P_0} = e^{-[0.023(N/N_0)]^2} e^{-1.08(S/S_0)} e^{-0.7(R/R_0)} \times (1.24 - e^{-2.43(T/T_0)}) \quad (95)$$

where P_0 , N_0 , S_0 , R_0 , and T_0 represent the sensory pleasantness, loudness, sharpness, roughness, and tonality of the reference sound to which the current sound is being compared. In other words, the model is a model of relative sensory pleasantness measured against a benchmark sound.

One of the key factors of Eq. (95) is that sensory pleasantness is not dominated by loudness. In fact, the effect of loudness on pleasantness is only strongly evident for sounds with significant strong loudness values. Zwicker and Fastl³⁶ suggest that the role of loudness in sensory pleasantness is only important when a sound has a calculated loudness greater than 15 sones.

13.9 Limitations

Each sound quality metric is based on using “curve-fit functions designed around sets of tests using jury listening evaluation of specific tones and developing empirical equations to match the juror response in each of the five categories. They are based on assumptions that approximations for each of the immeasurable factors can be made using one-third-octave filters and weighting functions to represent the cochlear response to auditory inputs. The question then arises as to whether this method can be applied to other sounds in general as they are not specific tones well defined by their frequency and amplitude. This brings to light the importance of at least some jury testing to compare with the results from the sound quality metrics.

14 NONLINEAR ACOUSTICS

This section provides an overview of nonlinear acoustics. All the theory and applications treated in this chapter thus far have relied on the fundamental assumption put forth in the wave equation section, which was that the acoustic perturbations are very small ($|\mathbf{u}|/c_0 \ll 1$). This supposition allowed us to keep only the first-order terms in the constitutive equations. However, there are certain situations in which this small-amplitude assumption breaks down and second-order (nonlinear) phenomena result. This section is a brief introduction into nonlinear acoustics theory and applications. It concludes with the description of data analysis tools that can be used to help in characterizing nonlinear phenomena.

14.1 Theory

It is first relevant to consider the basic effects of nonlinearity. In a linear system, an amplitude and phase change may occur, as is shown in Fig. 38,

Fig. 38 Example of linear system that induces amplitude and phase change.

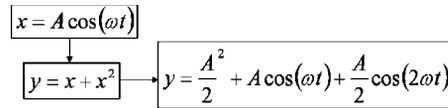

Fig. 39 Example of quadratic nonlinear system that produces dc and 2ω .

but the acoustic excitation remains at frequency ω . In a quadratically nonlinear system, however, such as $y = x + x^2$ shown in Fig. 39, the output contains energy not only at ω but also at zero frequency (dc) and at 2ω . If an input waveform that contains energy at ω_1 and at a greater frequency ω_2 is passed through $y = x + x^2$, trigonometric relationships demonstrate that the output of the nonlinear system will contain energy at dc, ω_1 , ω_2 , $2\omega_1$, $2\omega_2$, $\omega_1 + \omega_2$, and $\omega_2 - \omega_1$. The nonlinear generation of harmonics is called harmonic distortion and generation of sum and difference frequencies is called intermodulation distortion.

There are other classes of nonlinearities (e.g., cubic), but quadratic nonlinearities are emphasized here because they appear in the constitutive equations for sound propagation before they are neglected in first-order (i.e., linear) approximations. These nonlinearities culminate in an amplitude-dependent sound speed, expressed for one-dimensional propagation as

$$c = c_0 + \beta u \quad (96)$$

where u is the particle velocity, c_0 is the small-signal sound speed, and β is the coefficient of nonlinearity in the fluid ($\beta = 1.201$ in air). For general fluid or biological tissues, $\beta = 1 + B/2A$, where B/A is the “parameter of nonlinearity” of the medium. Measured values of B/A in a few other media are listed in Table 11. The tabulated values reveal that most media are significantly more nonlinear than air.

The significance of Eq. (96) is that the portions of the waveforms with positive particle velocities (or pressures) travel faster than those with negative particle velocities or pressures. For $|\mathbf{u}|/c_0 \ll 1$, $c \approx c_0$ and

Table 11 Parameter of Nonlinearity for Selected Media

Medium	B/A
Distilled water, 20°C	5.0
Sea water, 20°C	5.25
Liquid nitrogen, 90 K	9.00
Human liver, 30°C	7.6(±0.8)

the linear approximation is recovered. If we consider an initially sinusoidal waveform that propagates as a plane wave, the waveform will eventually steepen to the point that an acoustic shock forms. This distance is known as the shock formation or discontinuity distance and may be written as

$$\bar{x} = \frac{\rho_0 c_0^2}{\beta p_{\text{init}} k} \quad (97)$$

where p_{init} is the pressure amplitude of the initial sinusoid. We can also express propagation distance in terms of \bar{x} and define a dimensionless distance, $\sigma = x/\bar{x}$. The nonlinear evolution of an initially sinusoidal waveform is shown in Fig. 40 between $\sigma = 0$ and $\sigma = 3$. The time waveforms are expressed both as traditional pressure waveform traces in Fig. 40a and as longitudinal wave representations in Figs. 40b–d. At $\sigma = 1$ a discontinuity has just formed, and by $\sigma = 3$ the waves is essentially a fully developed sawtooth wave. The waveform steepening represents a transfer of energy from ω to higher harmonics that can eventually be expressed as the Fourier series of a sawtooth waveform that, in principle, contains an infinite number of harmonics to account for the discontinuous slope at the shock front.

The shock formation distance is an important parameter in determining the degree of nonlinearity of the propagation. However, another essential phenomenon to consider is the absorptive losses that occur in the propagation. The losses, which increase as a function of frequency, would “compete” with the nonlinear steepening that transfers energy to high harmonics. The importance of nonlinearity relative to absorption is expressed in the Gol’dberg number, a dimensionless quantity that can be written for an initially

sinusoidal plane wave in a thermoviscous medium as

$$\Gamma = \frac{1}{\alpha \bar{x}} \quad (98)$$

If $\Gamma \gg 1$, absorption and/or the shock formation distance is very small, which means that the propagation is highly nonlinear and that shocks will form. On the other hand, if $\Gamma \ll 1$, absorption and/or \bar{x} is very large, which means that nonlinear waveform steepening is negligible. Finally, $\Gamma \sim 1$ represents an intermediate case, where steepening is likely but an acoustic shock may not develop as the higher harmonic energy is absorbed. As a final note, the above description of the Gol’dberg number is only qualitative for any acoustic waveform besides a pure sinusoid in a thermoviscous medium; however, Γ demonstrates qualitatively the processes (e.g., amplitude, frequency, absorption) that determine when nonlinearity plays a significant role in sound propagation. In all cases, as propagation occurs, the effective Gol’dberg number gradually lessens as a function of distance as acoustic amplitudes are reduced through losses and possibly geometric spreading. This will eventually cause steepened waveforms to gradually unsteepen as the rate of absorption at high frequencies begins to exceed the nonlinear energy transfer rate.

14.2 Radiation Pressure and Streaming

Although their derivations are beyond the scope of this discussion, there are physical phenomena directly related with the nonlinear energy transfer to dc. The first is called acoustic streaming, which is a mean velocity that is set up in the fluid by the acoustic fluctuations. The second phenomenon is radiation pressure, which is a time-averaged pressure exerted on an object in the fluid or on a boundary. (Acoustic radiation pressure is analogous to the radiation pressure exerted by

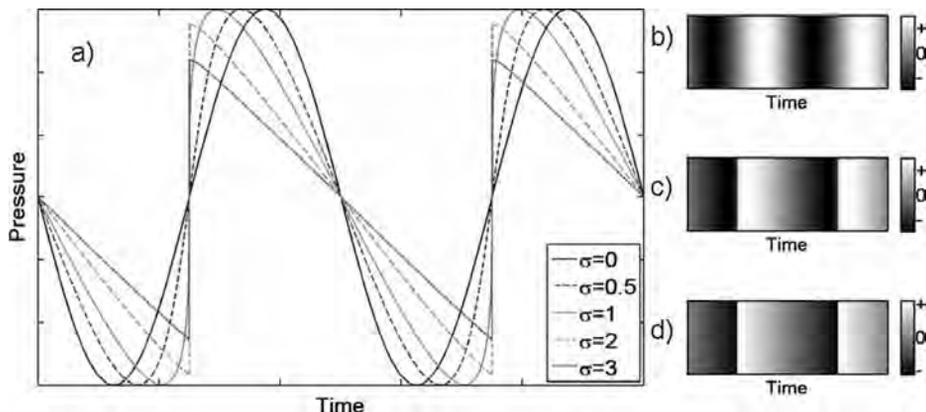

Fig. 40 (a) Nonlinear evolution of sinusoidal waveform into sawtooth wave. Longitudinal wave representation at (b) $\sigma = 0$, (c) $\sigma = 1$, and (d) $\sigma = 3$.

light waves.) One or both of these phenomena can be very relevant to applications of nonlinear acoustics, particularly in enclosed systems. For more detailed discussions, see Refs. 39 and 40.

14.3 Applications of Nonlinear Acoustics

Nonlinearity is often a factor in the atmospheric propagation of high-amplitude sources. For example, the nonlinear evolution of sonic boom waveforms is a problem that has been investigated in a variety of ways. The pressure fluctuation created by the supersonic aircraft travel at different speeds and the shocks that form often coalesce into two single shocks that form a wave called an N wave (see Fig. 41). The propagation of noise from explosions is also nonlinear, but unlike the sonic boom, there is typically a single shock front associated with the blast waveform. The last example of nonlinear atmospheric propagation is the noise radiated by military fighter jets and by rockets. The nonlinear interactions between spectral components as the shaped broadband noise waveform propagates result in a transfer of energy to high frequencies. The waveform steepening can lead to the formation of significant acoustic shocks. The excess high-frequency energy (relative to that linearly predicted) and its arrival in the form of shocks at discrete instances in time appear to have a significant impact on human perception of these sounds.⁴¹

Ultrasound is used in many applications of nonlinear acoustics that include the fields of audio, biomedical, and industrial acoustics. Parametric arrays have been investigated for audio applications for several decades. In its simplest form, the parametric array uses high-intensity ultrasonic transducers configured so as to produce a narrow primary beam of sound (in general, the larger the dimensions of the array, the narrower the beam). The array is driven at two closely spaced ultrasonic frequencies, ω_1 and ω_2 , at

high enough amplitudes to produce the difference frequency, $\omega_2 - \omega_1$. For proper selection of source frequencies, $\omega_2 - \omega_1$ will be in the audio range. Harmonics and sum frequencies are also generated, but atmospheric absorption at any of these ultrasonic frequencies is much greater than at the difference frequency. Consequently, the parametric array is unique in its ability to generate a narrow beam of low-frequency sound. Potential applications include audio complements to displays in museums, individualized stereo systems in vehicles, and other situations where spatially narrow audio is desired.

Applications of nonlinear acoustics in biomedical ultrasound are many, but a few are briefly summarized. The harmonic imaging technique in diagnostic ultrasound relies on harmonic distortion as waves propagate through human tissue (which is generally a nonlinearity-prone medium.) The ultrasonic transducer transmits a wave at ω , but then the ultrasonic sensors “listen” for the scattered signal at 2ω . The result is better spatial resolution of the tissue to be imaged. Other applications of nonlinear ultrasound include high-intensity focused ultrasound (HIFU). Shock wave lithotripsy uses focused ultrasonic waves that nonlinearly steepen into a shock wave to break up kidney stones. Although the physical mechanisms by which this occurs are still being researched, it is believed that cavitation, or the formation and subsequent violent collapse of bubbles due to large pressure changes in a fluid plays a significant role in breaking up of the stones. Because HIFU can lead to significant heating of internal tissue (which is ordinarily avoided), other applications of HIFU that are being investigated include ultrasonic treatment for cancer and stoppage of internal bleeding by wound cauterization.

Industrial applications of high-intensity ultrasound include ultrasonic cleaning, ultrasonic welding, and nondestructive evaluation (NDE).⁴³ There is a wealth

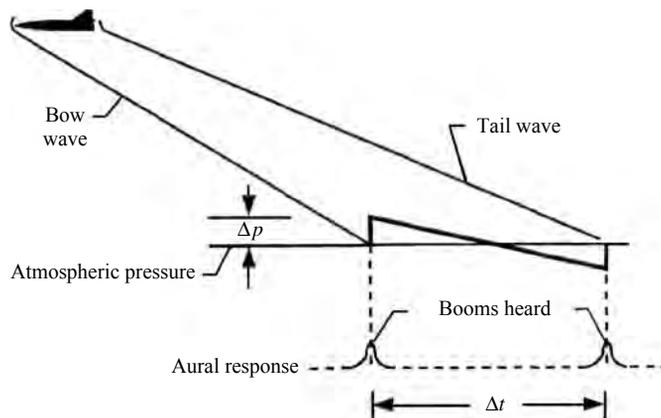

Fig. 41 N wave, characteristic of sonic booms.⁴²

of information on each of these topics that can be consulted. However, due to the brevity of the discussion, general principles of operation will be given. An ultrasonic cleaner is a fluid-filled chamber that is activated using one or more ultrasonic transducers. Although all the physical mechanisms behind the cleaning are not totally understood, microjets created by cavitating bubbles are believed to be largely responsible for the cleaning. One principal advantage of ultrasonic cleaning is that milder chemicals may be used in the cleaning process than other cleaning techniques. The use of ultrasonic cleaning is widespread and can be readily found in, for example, automotive, pharmaceutical, and medical applications.

Ultrasonic welding, which has been around since the 1960s, utilizes directional, high-intensity sound energy with typical frequencies ranging from 20 to 40 kHz. Although ultrasonic welding is most extensively used in the welding of plastics, it is also used in small-scale welding of metals (e.g., wires). The principle of ultrasonic welding is different for thermoplastics and metals. In thermoplastics, as the materials are pressed together and ultrasound is applied, the acoustic energy absorbed by the materials is transformed into heat, resulting in high temperatures in a localized area. This causes localized melting of the plastic surfaces and the formation of a bond. In ultrasonic welding of metals surfaces, studies have shown that the heat generated is insufficient to melt the metals at the interface. Rather, the mechanism is due to abrasive shear forces excited at the interface between the metals that disperse oxides and other contaminants. If the exposed metal surfaces are held together with sufficient pressure, a solid-state bonding takes place. Because the temperatures involved in an ultrasonic weld are

relatively low, embrittlement of the metals, which can occur with other welding techniques, is avoided.

Finally, ultrasound is a viable method within the broad field of NDE for testing material properties. Although some ultrasonic NDE, which typically involves frequencies in the megahertz range, employ linear acoustic techniques and processing, nonlinear phenomena can be used to readily identify defects in solids. Cracks and other defects exhibit high nonlinearity such that the amount of harmonic and intermodulation distortion increases significantly. Therefore, harmonic imaging or measurements of the amount of harmonic and intermodulation distortion in the scattered wave can be used to assess the properties of the solid. Examples of ultrasonic NDE include weld inspection, pipe wall inspection, assessment of concrete strength, and even recent examinations of the Space Shuttle wings and external fuel tanks.

15 THE HUMAN EAR AND HEARING

The human auditory system is complex from the standpoint of both how the nervous system responds to auditory inputs and the physical makeup of the human ear. This section first will discuss the structure of the ear, outlining the physical aspects of how humans hear, followed by a brief discussion of the nervous system response to auditory inputs and the role of the brain in hearing.⁴⁴

The human ear can be subdivided into three main parts, as illustrated in Fig. 42: the outer, middle, and inner ear. The outer ear consists of the pinna, which serves as a horn that collects sound and directs it into the auditory canal. The pinna is comparatively ineffective in humans. The auditory canal is essentially

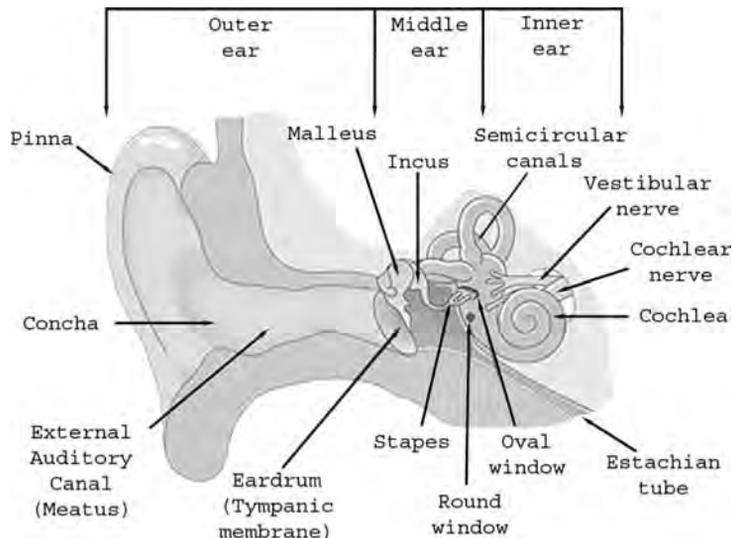

Fig. 42 Diagram of human ear.

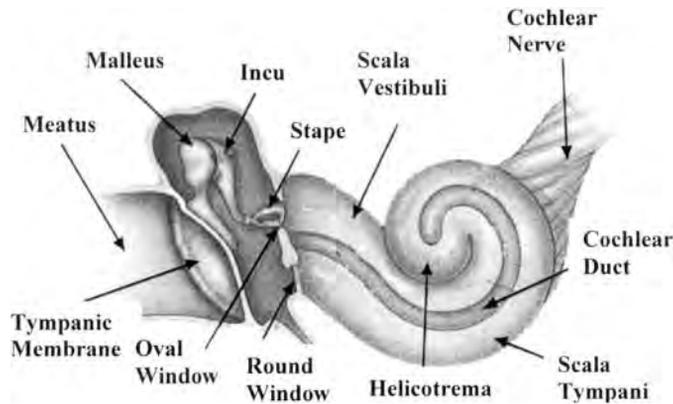

Fig. 43 Middle-to-inner-ear transition.

a straight tube about 0.7 cm in diameter and 2.5 cm long, open at one end and closed at the other, as seen in Fig. 43 in the section labeled outer ear.

There are resonances associated with this tube, the lowest resonance occurring at about 3 kHz. At this resonance frequency, the sound pressure level is about 10 dB higher at the closed end than at the open end. This is the most sensitive frequency region of the ear. Above this frequency, resonance phenomena can be observed, but resonance peaks tend to be relatively broad and flat

The outer ear is connected to the middle ear by the tympanic membrane, commonly known as the eardrum. This membrane forms a flattened cone with its apex facing inward. It is flexible in the center and attached to the end of the auditory canal at its edges. The middle ear is an air-filled cavity, with a volume of approximately 2 cm³, which contains three ossicles (bones): the malleus (hammer), the incus (anvil), and the stapes (stirrup). These bones form a mechanical linkage to amplify the force transmitted to the inner ear from the outer ear. The stapes is connected to the inner ear via the “oval window.” The area ratio of the eardrum to the oval window is about 30:1. This system combines to create an approximate impedance match between the auditory canal and the inner ear. This is controlled to some extent to protect the ear from high-intensity sounds, known as the acoustic reflex. Acoustic reflex takes about one-half of a millisecond to respond. Therefore, it is ineffective at protecting the ear from impulsive noise, for example, explosions, sonic booms, and gunshots. The middle ear is connected to the throat via the eustachian tube, also shown in Fig. 42. The purpose of the eustachian tube is to equalize the pressure on both sides of the eardrum. Normally it is closed, but it opens during yawning and swallowing.

The inner ear contains three significant parts, the vestibule (entrance chamber), semicircular canals, and the cochlea, as illustrated in Fig. 43. The semicircular

canals give humans their sense of balance and do not affect hearing. The vestibule is connected to the middle ear through the oval window and the round window. Both windows are sealed to prevent the inner ear fluids from escaping. Bone surrounds the remainder of the inner ear. The cochlea is a tube with an approximately circular cross section, which is curled in a shape similar to a snail shell. The tube makes approximately two and one-half turns with a length of approximately 3.5 cm. The total volume of the cochlear tube is approximately 0.05 cm³, with the cross section decreasing from entrance to termination. However, the average diameter is approximately 1.3 mm. The cochlear tube is divided by the cochlear partition into two channels, the upper gallery (scala vestibule) and the lower gallery (scala tympani). The two galleries are joined at the apex by the helicotrema. The other ends of the galleries are connected to the oval (upper gallery) and round (lower gallery) windows.

The cross section of the cochlear duct is presented in Fig. 44. There is a “bony ledge” which projects (from the right in the figure) into the fluid-filled tube, which carries the auditory nerve. At the termination of the bony ledge, the nerve fibers enter the basilar membrane, which continues across the tube and is attached to the spiral ligament on the opposite side of the tube. Above the basilar membrane is the tectorial membrane, which projects into the fluid in the scala media. Reissner’s membrane (vestibular membrane) runs diagonally across the tube from the bony ledge to the opposite wall, forming the pie-shaped cochlear sack, which is completely sealed. The cochlear sack is filled with endolymphatic fluid and the two galleries are filled with perilymphatic fluid. The organ of Corti is attached to the top of the basilar membrane. It contains four rows of hair cells, which span the entire length of the cochlear duct, giving roughly 30,000 cells. Several small hairs extend from each hair cell to the undersurface of the tectorial membrane.

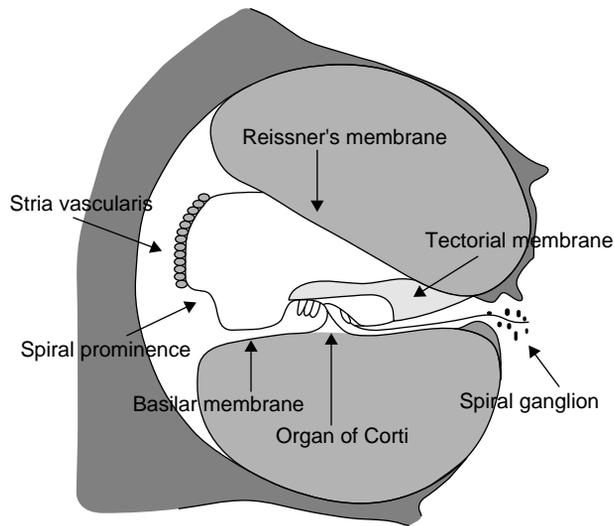

Fig. 44 Cross section of cochlear ducts.

When the ear is exposed to a sound, the eardrum's vibration is transmitted to the inner ear via the bones in the middle ear. The fluid of the inner ear in the upper gallery is disturbed by the motion of the stapes against the oval window. This fluid disturbance travels down the length of the upper gallery, through the helicotrema, then back down the lower gallery to the round window. The round window acts like a pressure release termination to the tube. The basilar membrane is driven by this fluid motion into highly damped motion with the peak amplitude increasing slowly with distance from the oval window. Once it reaches a maximum, it decreases rapidly. The location of the maximum amplitude is a function of frequency, with low frequencies causing the peak to occur close to the helicotrema and high frequencies reaching a peak much closer to the oval window. It is because of this behavior that low frequencies mask higher frequencies better than vice versa. As the organ of Corti is attached to the basilar membrane and the tectorial membrane is attached to the bony ledge, relative motion between the two flexes the hair follicles, which excite the nerve endings attached to these hair cells. This in turn creates an electrical impulse that is sent up the nerve fibers. As may be implicated by the complex physical nature of the inner ear, the individual nerves do not fire at the same frequency as that of the excitation sound. In fact, the nerves tend to fire in a quasi-random frequency that is dependent upon the stress on the individual hair cells, which is more closely related to the sound intensity. These pulses then travel to the auditory center in the brain. Here a complex decoding and processing process formulates the mental "picture" of the sound.

15.1 Psychoacoustic Effects

From the previous discussion, it is apparent that when a sound excites the basilar membrane a small group of cells at the point of maximum deviation has the maximum excitation, causing it to send the largest electrical impulse up the nerve, whereas the neighboring cells to either side of this point are also disturbed but to a lesser degree. As a result, they also fire impulses, but not as strongly. Each point of the basilar membrane is the point of maximum excitation for some frequency but will also join in the excitation when a different frequency excites one of its neighbors. Therefore, a sound at a given frequency excites nerves belonging to a range of frequencies. Any sound at a high level centered at a given frequency raises the hearing level threshold for frequencies in its vicinity. This phenomenon of some sounds rendering other sounds inaudible (or less audible) is termed masking. Studies have shown that tones or narrowband noise at a given frequency raise the audibility threshold of tones at neighboring frequencies. A broadband noisy sound, like a vacuum, a loud ventilation system, or a jet airplane engine, can therefore raise the hearing threshold of just about everything.⁴⁴

The segment of the basilar membrane that joins the excitement is called the critical band. The frequency range spanned by this section is called the critical bandwidth. It is important to note the difference between the two because they do not maintain a constant relationship. A frequency of 350 Hz stimulates a band of cells having a bandwidth of 100 Hz (300–400 Hz). However, a frequency of 4 kHz excites a critical band of cells having a bandwidth of 700 Hz (3.7–4.4 kHz). Thus, the critical bandwidth is much wider for higher frequencies than it is for lower frequencies.

Precisely where along the membrane this point of excitement occurs is another important aspect of the auditory system. As the frequencies of single-tone or narrowband noise are doubled, the point of excitement moves in equal increments. An equal length of basilar membrane is traversed to reach the points excited by 500 Hz, 1 kHz, 2 kHz, 4 kHz, 8 kHz, and so on. This corresponds to the human perception of pitch; individuals hear doubling of frequencies as a change of an octave. Other musical intervals are also based on the ratio of any two given frequencies, not the absolute distance between them. For example, a perfect fifth above some note is always a frequency ratio of 3:2: the E above A (440 Hz) is 660 Hz, an increase of 220 Hz and a ratio of 3 (660 Hz) to 2 (440 Hz). An additional fifth above 660 Hz is not, however, at 880 Hz (660 + 220), but rather at 990 Hz ($660 \times \frac{3}{2}$). Such a relationship, based on multiplication rather than addition, is logarithmic rather than linear.

From the example above, it is evident that the logarithmic relationship of the basilar membrane to the spectrum applies to the perception of pitch for human beings. A logarithmic relationship is also behind the changes in the sensitivity to frequency differences over the frequency spectrum. When two tones are played consecutively, the minimum frequency difference they must have in order for listeners to notice that difference is called the “just noticeable difference.” The just noticeable difference depends on a variety of factors, including frequency range and suddenness of the change. However, the just noticeable difference below 1 kHz is about 3 Hz, with the just noticeable difference for tones from 1 to about 4 kHz being 0.5% of the frequency. The just noticeable difference becomes larger above 5 kHz. Sine wave melodies transposed into that range tend to melt into a bunch of screaming, high beeps.

The auditory system is not completely egalitarian, however. Thus, the minimum sound pressure level required for a sound to be audible, called the threshold of audibility, is different for different frequencies. Lower frequencies must be produced at much greater sound pressure levels than higher frequencies in order for them to be perceived as having equal loudness, if perceived at all. The threshold is lowest for frequencies in the region of greatest importance for speech—hence giving the finest resolution of amplitude differences in this range. High frequencies excite the basilar membrane at points near the oval window, leaving points

that are more distant relatively undisturbed. Low frequencies, however, excite the membrane at points more distant from the oval window, creating waves in the membrane that have to travel past those closer points excited by higher frequencies. Therefore, when high and low frequencies are heard together, the low frequencies can, in some circumstances, interfere with the high frequencies.

In review, the main psychoacoustic effects are masking, critical bands, critical bandwidths, pitch, threshold of audibility, and just noticeable differences. Masking is caused by a high level of excitation at a particular point along the basilar membrane. This high level of excitation results in a change in the threshold of audibility for frequencies in the neighborhood of the masking tone. Critical bands are the bands of frequencies that humans recognize as an interference zone, which is nominally one-third-octave frequency band spacing. Pitch is related to the critical bands and the location along the basilar membrane where the maximum excitation occurs. Threshold of audibility is the sound pressure level where a tone is just audible; it is important to reiterate that it is not equal for all frequencies. This, however, is good because it prevents humans from hearing their own heartbeat and other low-frequency, low-amplitude sounds that would be disturbing but allows them to hear the spoken word very well. Just noticeable differences are the distances between two frequencies that are perceivable. It is this psychoacoustic effect, as well as that of masking, that is the basis of the principles of music compression for the MP3 format. The tones that would be masked or are not noticeably different from another simultaneously played tone are removed, allowing the file size to be greatly reduced without sacrifice in acoustic quality.

16 MICROPHONES AND LOUDSPEAKERS

A microphone is a transducing device which converts acoustic energy into electrical energy in the form of a time-varying voltage. The voltage should fluctuate so as to accurately represent the vibration of the air. The basic operation of a microphone can be represented as shown in Fig. 45. Sound impinging on a diaphragm causes the diaphragm to vibrate. The mechanical motion of the diaphragm is coupled to the transducer, producing the varying voltage. The original acoustic vibrations are thus preserved in the form of a time-varying voltage.

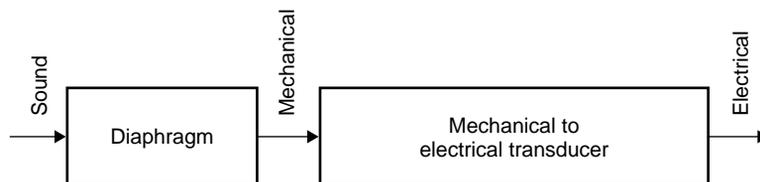

Fig. 45 Basic processes in a microphone.

A microphone can be classified as pressure-sensing, velocity-sensing, or some combination of these two types. In the pressure-sensing type sound is allowed to strike only one side of the diaphragm. Thus, the diaphragm is sensitive to pressure changes. Pressure microphones are said to be omnidirectional or nondirectional because they respond to sound coming from any direction. In velocity microphones both sides of the diaphragm are exposed to the sound. Velocity microphones respond mostly to sounds striking one side or the other of the diaphragm in a head-on fashion. Sound approaching the edge of the diaphragm exerts equal but oppositely directed pressures on each side of the diaphragm so that no motion is produced. A velocity microphone is said to be bidirectional.

The piezoelectric effect is the transducing principle employed in crystal microphones and ceramic microphones. Ceramic materials are more commonly used because they are less sensitive than crystal materials to mechanical shock, humidity, and temperature. Typical elements of a ceramic microphone are shown in Fig. 46. One end of the ceramic is attached to the microphone casing and the other end is coupled to the diaphragm by a drive pin. Conducting material is deposited on the two surfaces of the ceramic. When the diaphragm moves, the ceramic element is bent and a positive or negative (depending on the direction of bending) voltage appears on the electrical lead attached to one side of the ceramic. The principal disadvantage of a ceramic microphone is that relatively small output voltages are obtained for normal acoustic pressures. However, in modern designs this disadvantage is usually overcome by mounting a small preamplifier in the microphone casing. Microphones of this type have a fairly wide (20 Hz–10 kHz) but somewhat uneven

frequency response. They are small and relatively inexpensive and are widely used in hearing aids, public address systems, portable sound equipment, and tape recorders.

Typical elements of a *condenser microphone* are shown in Fig. 47. One conducting plate is fixed to the microphone casing, although it is electrically isolated from the casing. A metal or metallized plastic diaphragm is used and acts as the second (and movable) conducting plate of the capacitor. When the diaphragm vibrates, an oscillating voltage appears on the electrical leads attached to the plates. The principal disadvantage of these microphones is the need to have a bias voltage (200–400 V) across the plates and a preamplifier in close proximity to the plates. Condenser microphone designs have typically incorporated a preamplifier in the microphone casing. Condenser microphones are used in research, to produce high-fidelity recordings, and in hearing aids and portable sound equipment.

Electret condenser microphones (see Fig. 48) are now in wide use because they offer the advantages of a condenser microphone without the disadvantage of needing a polarizing voltage. The diaphragm consists of an electret plastic foil that has been permanently electrically charged and overlaid with a thin metallic layer. The electret condenser microphone typically employs a preamplifier. It is slightly less sensitive than the condenser microphone.

A *ribbon microphone* (see Fig. 49) consists of a very thin metallic ribbon set in a magnetic field. A current is caused to flow in the ribbon as it is pushed and pulled back and forth in the magnetic field by acoustic pressures. Maximum response occurs when the pressure is perpendicular to the face of the ribbon. Pressure coming from the edge pushes oppositely on the two

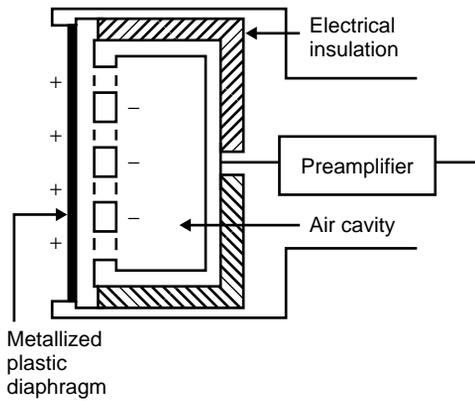

Fig. 48 Elements of an electret condenser microphone.

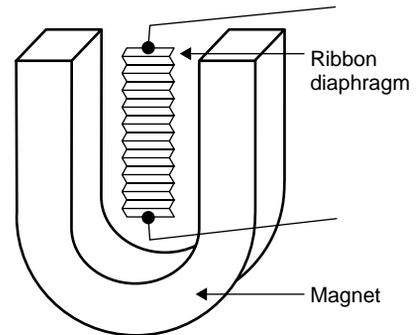

Fig. 49 Elements of a ribbon microphone.

sides of the ribbon and so little response results. A ribbon microphone is bidirectional in response and is an example of a velocity microphone.

A *dynamic microphone* has a coil of wire attached to its diaphragm as shown in Fig. 50. The transducing element is a coil that is free to move between the poles of a magnet. The electrons in the coil move with the coil and experience a force (as described by the magnetic force law) which produces a varying electric voltage across the ends of the coil. Dynamic microphones are capable of a relatively high power output. They are rugged and capable of a broad frequency response over a wide dynamic range. Because they are able to withstand the high-intensity sound levels often associated with popular music, they are widely used for live performances and for recording sessions.

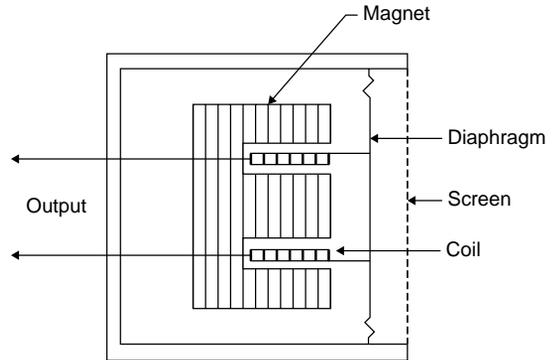

Fig. 50 Elements of a dynamic microphone.

A *loudspeaker* is a transducing device which converts electrical energy into acoustic energy. One common type of loudspeaker is the direct radiator dynamic loudspeaker. It operates on the same principle as the dynamic microphone, only in the opposite sense. Figure 50 illustrates a dynamic loudspeaker as well as a dynamic microphone. A voltage source is connected to a coil of wire situated in the magnetic field of a permanent magnet. A varying voltage produces a varying current in the coil. The coil experiences a force (because a magnetic field is present) which causes the coil to vibrate. The coil is attached to a diaphragm so the motion of the coil “drives” the diaphragm, causing the air to vibrate. Because of the simplicity of construction, the small space requirements, and the fairly uniform frequency response, this type of speaker is the most widely used.

1 ATOMIC STRUCTURE AND THE PERIODIC TABLE

Atoms. Atoms contain a dense, positively charged nucleus surrounded by a cloud of negatively charged orbital electrons that occupy discrete energy levels and orbital configurations. The nucleus consists of Z positively charged protons and $A - Z$ uncharged neutrons. Atomic number Z determines the name of the element and the number of orbital electrons in a neutral atom. Mass number A equals the number of protons plus neutrons in the nucleus. Gain or loss of electrons results in ionized atoms with a net charge. Chemical reactions are concerned only with electronic structure changes, while nuclear reactions involve changes in the constitution of the nucleus. Isotopes are atoms with the same atomic number, the same number of electrons, and the same chemical reactions but differing in mass number because the nucleus contains a different ($A - Z$) number of neutrons.

Atomic Weights of Elements. The mass of an element's naturally occurring distribution of isotopes is its atomic weight. This may be expressed in atomic mass units (amu) or in grams for an Avogadro number

(6.023×10^{23}) of atoms. Atomic weights are relative to 12.000 for the $^{12}_6\text{C}$ isotope of carbon, an atom whose $Z = 6$ and $A = 12$. Examples: Naturally occurring chlorine contains 75.53 atom % of $^{35}_{17}\text{Cl}$ and 24.47% of $^{37}_{17}\text{Cl}$; it is assigned an atomic weight of 35.453. Naturally occurring tin consists of a presumably geographically invariant distribution of 10 stable isotopes ranging from mass number 112 to 124. These yield a weighted average atomic weight of 118.69.

Atomic Radii. The radii of atoms, though nebulous and difficult to estimate, range from 0.4 to 2.5 Å ($1 \text{ Å} = 10^{-8} \text{ cm}$). The radii may be deduced from quantum mechanical calculations or from experimentally determined crystal radii. Ionic radius differs from atomic radius due to a greater or lesser occupancy of the outer electron orbitals.

Periodicity of Elements. The periodic table is an arrangement of elements in rows and columns in order of increasing atomic number according to similarity of chemical behavior. Differences in electron energy levels, deduced from transitions that absorb or emit

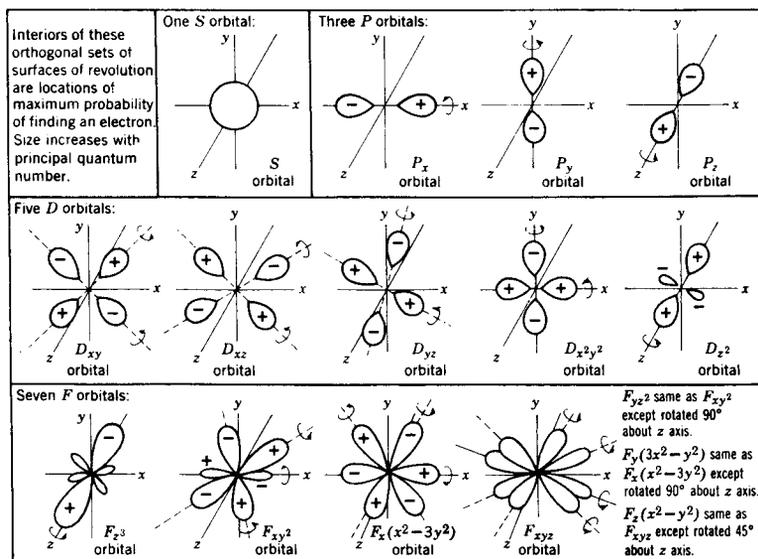

Fig. 1 Azimuthal characteristics of electronic orbitals.

spectral energy, yield a similar and consistent pattern of electron buildup in numbers and energy levels.

Electronic Orbitals. The rationalization of spectroscopic data via quantum mechanics leads to four types of quantum numbers for describing the building up of shells of electron orbitals with discrete energy levels for each orbital. This buildup, with electrons, individually occupying the lowest vacant energy level, results in calculated spectra that closely match the experimental. These four types of quantum numbers are:

- Principal quantum number* n represents a major grouping of energy levels, where n can be 1, 2, 3, ..., with 1 representing the lowest energy level.
- Azimuthal quantum number* l denotes different shapes of orbitals within the major grouping. These shapes are labeled s , p , d , and f for $l = 0, 1, 2$, and 3, respectively, where l may range from 0 to $n - 1$.
- Magnetic quantum number* m_l has $2l + 1$ possible values: $-l, -l + 1, -l + 2, \dots, 0, \dots, l - 1, l$.
- Spin magnetic quantum number* m_s may have a value of $+\frac{1}{2}$ or $-\frac{1}{2}$ depending on the direction of electronic spin.

Azimuthal Characteristics of s , p , d , and f Electronic Orbitals. Directionality of the most probable electronic position about the nucleus is provided by sets of mathematically symmetrical and

orthogonal orbitals shown in Fig. 1. Each orbital can contain two electrons of opposite spin. An electron has the highest probability of being located inside the surfaces of the revolution shown. The size of these surfaces (distance from the nucleus) increases with the principal quantum number.

Electronic Structure of Elements in the Ground State. As atomic number increases through the periodic table, the buildup of electronic structure follows a regular pattern. One s , three p , five d , and seven f orbitals can contain 2, 6, 10, and 14 electrons (with different magnetic and spin quantum numbers), respectively. Electron energy levels associated with quantum number designations are sequentially filled beginning with the lowest energy level available. Figure 2 shows the pattern of electron occupancy of orbitals for elements from hydrogen ($Z = 1$) to lawrencium ($Z = 103$) in their lowest, or ground, energy state.

Oxidation States of the Elements. The oxidation state of the elements is the atomic charge attainable by chemical methods. This is correlated with the systematic buildup of electrons in orbitals. The addition or loss of electrons is subject to energy barriers that become essentially insurmountable with filled shells exemplified by the noble-gas structures. In the discussion of groups of elements in each vertical column of the periodic chart, the known oxidation states are cited and related to electronic structure. This does not mean that all can exist as stable states in contact with oxygen, environmental moisture, or aqueous solution, for many of the oxidation states are particularly reactive. Electronic structure notation uses the structure of the

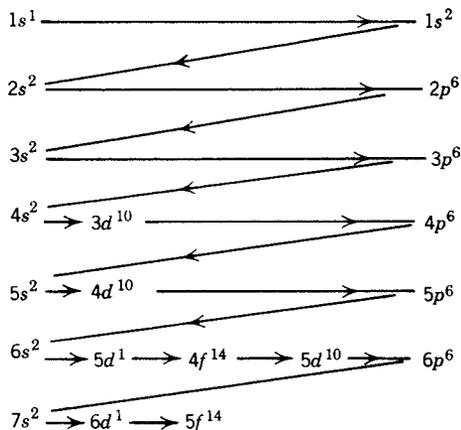

Fig. 2 Progressive filling of electron orbitals: $3d^{10}$ indicates 10-electron (complete) occupancy of the five d orbitals existent in principal quantum number 3 energy levels. These are filled after the $4s$ orbital is occupied by two electrons. Interruption of progressive buildup of the $5d$ sequence by 14-electron filling of $4f$ orbitals is partially explained by coulombic shielding of the positively charged nucleus by inner portions of the electron cloud.

prior noble gas plus the additional electronic orbitals that are filled for each element.

- (a) *Inert gases He, Ne, Ar, Kr, Xe, and Rn* have filled p orbitals, and this maximum-stability, minimum-energy configuration exists as a neutral atom with nuclear charge equaling orbital electron charge. The energy barrier for gain or loss of electrons is very high and the oxidation state is zero although a small number of compounds with fluorine and oxygen have been prepared such as XeOF_4 . With the exception of xenon (XeF_6) and radon compounds, where inner electrons shield the nuclear charge and reduce this potential barrier, stable compound formation has not been accomplished.
- (b) *F, Cl, Br, I, and At*, lacking one electron of filled p orbitals, readily gain one electron; can lose one p orbital electron, reaching stability of a half-filled orbital; can lose five p orbital electrons, leaving a filled s orbital below; or may further lose both of those s electrons. Oxidation states of $-1, 0, +1, +3, +5$, or $+7$ are possible.
- (c) *O, S, Se, Te, and Po* lack two p electrons of the inert-gas configuration and easily reach the oxidation state of -2 . Peroxides are a covalent combination of two oxygen atoms with -2 for the pair. Higher atomic number members of the group also can lose all four p electrons and may also lose the two s electrons lying beneath. Oxidation states of $-2, +4$, and $+6$ result.

- (d) *N, P, As, Sb, and Bi* with three p electrons can either gain or lose three and may also lose two s electrons beneath (exception: NO or NO_2 gases). Oxidation states of ± 3 and $+5$ exist for the group.
- (e) *C, Si, Ge, Sn, and Pb* with two p electrons can lose these plus two s electrons beneath, resulting in $+2$ and $+4$ oxidation states for the group. Carbon forms numerous covalent bonds with an oxidation state of -4 .
- (f) *B, Al, Ga, In, and Tl* lose their single p electron plus the two s electrons below for an oxidation state of $+3$. Thallium has an additional stable $+1$ oxidation state.
- (g) *Zn, Cd, and Hg*, with 10 electrons filling the d orbitals in stable configurations lose two s electrons, forming $+2$. Exception: mercurous dimer Hg_2^{2+} .
- (h) *Cu, Ag, and Au*, with filled d orbitals, can lose their one s electron, forming $+1$ oxidation state. Exceptions for the column are Cu^{2+} and Au^{3+} due to removal of additional d electrons over low energy barriers.
- (i) *Ni, Pd, and Pt*, with some overlap of d and s orbital energies, exhibit oxidation states of $+2, +4$, and $+6$.
- (j) *Co, Rh, Ir, and the Fe, Ru, and Os* transition groups tend to have two electrons in the s orbital at the expense of vacant d orbitals. Oxidation states of $+2, +3, +4$, and $+6$ occur, with the $+8$ oxidation state reached in Ru and Os .
- (k) *Mn, Tc, and Re*, with five-electron half-filled d orbitals and filled s orbital, tend to lose the s orbital electrons for $+2$ and any in the d orbitals for a maximum oxidation state of $+7$. Exception: Re also forms a -1 ion; it is the only transition element to do so.
- (l) *Cr, Mo, and W*, with four electrons in the d orbitals and two in the s orbital, can have oxidation states ranging from $+2$ to $+6$.
- (m) The *V, Nb, and Ta* group, with three or four electrons in the d orbitals and one or two in the s orbital, can have oxidation states ranging from $+2$ to $+5$.
- (n) The *Ti, Zr, and Hf* groups, with two d and two s electrons, tends to have an oxidation state of $+4$. Exception: Ti^{3+} also occurs.
- (o) The *Sc, Y, La, and Ac* group, with one d and two s electrons, can lose these for an oxidation state of $+3$.
- (p) The 14 *rare earths (lanthanides)*, following lanthanum and beginning with cerium, have the lanthanum $+3$ oxidation state and structure with approximately progressive filling of the seven $5f$ orbitals. Ce , Nd , Pr , and Sm form $+4$ ions while Sm , Eu , Tm , and Yb also form $+2$ ions.

- (q) The 14 *actinides*, beginning with thorium, paralleling cerium above, approximately repeat the structure of the rare earths with 14 electrons filling of $5f$ orbitals. Some exceptions occur, forming the half-filled orbital situation, and the +3 oxidation state can be increased to +6 due to much electronic shielding of the nuclear positive charge.
- (r) *Beryllium* and the *alkaline earth* group have two electrons filling the s orbital. Loss of these electrons results in a +2 oxidation state.
- (s) *Hydrogen* and the *alkali metals* have a single electron in the s orbital. Its loss results in a +1 oxidation state. Exception: Gain of an electron by hydrogen to fill the s orbital results in the hydride H^{1-} .

Excited Electronic States and Ionization Energy.

Excited electronic states are produced through energy absorption, which raises an electron's energy level to that of an unfilled orbital. Loss of energy by photoemission may be very fast (10^{-8} s) or very slow depending on the particular state. Energy absorption of magnitude greater than the highest available energy level is synonymous with having achieved an electronic escape velocity and ionization occurs. This ionization energy ranges from 3.9 eV (90 kcal/g atom) for cesium to 24.5 eV for helium.

Electron Affinity. The counterpart to ionization potential, electron affinity is energy released when an isolated monatomic gaseous atom gains an electron and becomes an anion. For halogens this energy is on the order of 3–4 eV; experimental problems have precluded measurement for many of the other elements that form negative ions.

Electronegativity. The electron-attracting power of the elements has been estimated from chemical bond energies and from average electron densities. The result is a consistent series of relative numbers based on zero for inertness of the noble gases and ranging from a maximum of 4.0 for fluorine (which readily forms the anion F^-) to 2.5 for carbon (which forms equally shared covalent bonds) to a minimum of 0.7 for cesium (which forms the cation Cs^+). Large differences in electronegativities of two chemically bonded atoms indicate an ionic bond with the more electronegative atom monopolizing the electron pair. Small differences in electronegativity indicate a covalent bond with approximately equal sharing of the electron pair.

2 MOLECULAR STRUCTURE AND CHEMICAL BONDING

Molecules. Molecules consist of groups of atoms held together in geometric arrangement by chemical bonds. Chemical bonds are based on electronic configuration of the individual atoms and electron occupancy of vacancies existent in the atomic orbitals. Mutual

occupancy of orbitals of two atoms by an electron pair constitutes a chemical bond between atoms and results in joint configuration of greater stability, or lower energy, than possessed by the individual atoms. The total charge on a molecule is zero, with the number of orbital electrons matching the summation of positive nuclear charges.

Chemical Bonds. Mutual occupancy of orbitals, the shared electron pair, leads to two general classification of chemical bonds. These are ionic and covalent. An ionic bond exists where the shared electron pair is monopolized by one atom, giving that portion of the molecule a net negative charge and leaving an electron deficiency or net positive charge, on the other. A covalent bond results when both atoms have approximately the same electronegativity or electron affinity the electron pair is shared without monopoly by either atom. One shared electron pair constitutes one chemical bond, commonly designated by a dash between symbols of the elements. The spatial geometry of molecules is related to orientation of the atomic orbitals involved in the bond.

Bond Energy. Energy liberated on bond formation, or energy required to rupture a bond, is the bond energy. This varies with the parent atoms and the particular molecular configuration involved (see Table 10 in Section 9). The summation of all bond energies is related to the heat of formation of a compound from its elements.

Chemical Compounds and Ions. Compounds can be classified into categories according to their ions in aqueous solution. Ionic compounds are those with ionic bonds between major atomic groupings, and these ionize in aqueous solution to form cations that are positive and anions that are negative. The naturally occurring combinations are used for inorganic chemical nomenclature. Metals, having low ionization potential, readily form positive cations, in agreement with their electronic configuration. Examples: Na^+ , Ca^{2+} , Al^{3+} , Fe^{2+} and Fe^{3+} , Zn^{2+} , Ag^+ , and so on. Halogens, having high electron affinity, form halide ions: F^- , Cl^- , Br^- , and I^- . Oxygen forms oxides and readily combines with other atoms to form MnO_4^- , $Cr_2O_7^{2-}$, SO_4^{2-} , SO_3^{2-} , NO_2^- , NO_3^- , PO_4^{3-} , CO_3^{2-} , SiO_3^{2-} , and similar ions.

Electrical Neutrality of Compounds. This results from summation of component oxidation states and permits assignment of an oxidation state to component atoms in the molecule.

Example 1. Determine oxidation state of Cr in $NaCrO_4$.

Sodium's electronic structure, revealed by its position on the periodic table, definitely assigns its ion as Na^+ . Oxygen, except in peroxides, assumes -2 oxidation state. Chromium's usual oxidation states are

+2, +3, and +6, as shown on the periodic table. Therefore, the oxidation state of Cr is +6, as required for compound electrical neutrality.

Inorganic Chemical Nomenclature. Systematic and unambiguous nomenclature for inorganic and organic compounds and ions is necessitated by proliferation of known species. Traditional (often trivial) names of common compounds are paralleled by more cumbersome names following rules of the International Union of Pure and Applied Chemistry (IUPAC). Traditional nomenclature for inorganic compounds (Table 1) uses simple prefix and suffix terminology.

Acids and Bases. Three acid–base definitions are recognized:

- The traditional Arrhenius definition that acids yield H^+ and bases yield OH^- suffices for inorganic reactions in aqueous solution.
- Brønsted introduced the broader definition that acids are proton (H^+) donors and bases are proton acceptors. Since H^+ in aqueous solution exists hydrated as the hydronium ion H_3O^+ , water is by definition a base because it can accept a proton. In nonaqueous media this definition recognizes hydrides, alcoholates, alkyl lithium compounds, and ammonia as the powerful bases they are. Brønsted broadens the traditional definition because OH^- does accept a proton.
- Lewis defines acids as molecules or ions capable of accepting electron pairs and bases as

molecules or ions capable of donating electron pairs. Thus $AlCl_3$, BF_3 , $FeCl_3$, $ZnCl_2$, and $SnCl_4$ are Lewis acids because they lack pairs of electrons from filled orbitals. These strong acids are important in nonaqueous organic reactions. Lewis bases have an uncoordinated electron pair available; for example, on the nitrogen atom of ammonia, $:NH_3$.

The Brønsted definition of proton donors and acceptors, broadened by the Lewis definition of electron pair donors and acceptors, is necessary to explain reactions in nonaqueous media. The remaining sections in inorganic chemistry utilize the traditional simplicity of acid H^+ and base OH^- because these ions do result when any of the more broadly defined acids and bases react with water.

Strong and Weak Acids and Bases. The strong or weak designation refers to extent of ionization; this does not refer to concentration in solution. Strong acids and bases are completely dissociated into their ions, in water, while weak ones are only slightly dissociated. A 1-*M* solution of a strong acid such as HCl yields a hydrogen ion concentration, H^+ , of 1 mol/l, while a 1-*M* solution of a weak acid such as acetic, CH_3COOH , yields a H^+ of only 4×10^{-3} mol/l. A similar classification of bases is made based on the extent of ionization in the solvent employed.

Complex Ions and Coordination Compounds. Unfilled electron orbitals of transition metal elements, those occurring in the center of the periodic table,

Table 1 Common Terminology

Cations (+ ions)	Anions (– ions)
<i>-ic.</i> Higher usual oxidation state of cation. Examples: Fe^{3+} is ferric and Cr^{3+} is chromic.	<i>-ide.</i> Usual oxidation state of anion in binary compounds. Examples: oxide O^{2-} , chloride Cl^- , and hydride H^- .
<i>-ous.</i> Lower usual oxidation state of cation. Examples: Au^+ is aurous and Cr^{2+} is chromous.	<i>-ate.</i> Higher usual positive oxidation state of major element in oxygenated acid anions. Examples: ZnO_2^{2-} is zincate, SO_4^{2-} is sulfate, and ClO_3^- is chlorate.
<i>-yl.</i> Oxygenated cation containing the <i>-ic</i> or higher usual oxidation state of the major element. Examples: UO_2^{2+} is uranyl, TiO_2^{2+} is titanyl.	<i>-ite.</i> Lower usual positive oxidation state of major element in oxygenated acid anions. Examples: NO_2^- is nitrite, SO_3^{2-} is sulfite, and ClO_2^- is chlorite.
No suffix is used for cations that form only one ion. Examples: Zn^{2+} is zinc and Na^+ is sodium.	<i>hypo -ite</i> or <i>-ous.</i> Lower oxidation state than <i>-ite</i> or <i>-ous</i> implies. Example: ClO^- is hypochlorite.
Instead of the prefix or suffix notation, oxidation states are also denoted by Roman numerals following the name, such as chromium(III), instead of Cr^{3+} or chromic.	<i>per- -ate</i> or <i>-ic.</i> Higher oxidation state than <i>-ate</i> or <i>-ic</i> implies. Example: ClO_4^- is perchlorate and MnO_4^- is permanganate.
	<i>pyro-.</i> Infers a dimeric structure (a di- <i>-ate</i>) of the oxygenated acid anion. Example: $P_2O_7^{4-}$ is pyrophosphate.
	<i>thio-.</i> Means single sulfur substitution for oxygen in oxygenated acid anions. Example: $S_2O_2^{2-}$ is thiosulfate (SO_4^{2-} with S replacing one O).

Table 2 Coordination Compound Ligands

F ⁻	NH ₃ , PH ₃	S ₂ O ₃ ²⁻ thiosulfate
Cl ⁻	NH ₂ -CO-NH ₂ (urea)	C ₂ O ₄ ²⁻ oxalate
Br ⁻		
CN ⁻	H ₂ O	S _x ²⁻ polysulfide
OH ⁻	CO, NO	
SCN ⁻	Various unsaturated hydrocarbons, including acetylide ion (HC≡C) ⁻ and cyclopentadienyl ion (C ₅ H ₅) ⁻	

permit forming complex ions and coordination compounds that appear inconsistent with the usual oxidation state of the metallic element. But complex ions are consistent with the metal's electronic structure; its unfilled orbitals are filled by the sharing of electron pairs to reach a stable configuration. Ligands (see Table 2) are groups attached to the central metal atom. Each ligand contributes an electron pair to be shared with and occupy vacant orbitals. Coordination number is the number of ligands surrounding the central metal atom. Solvation in water (hydration) or in liquid ammonia (ammoniation) and formation of hydrated and double salts and the numerous complex ions of inorganic and metal organic chemistry are examples of complex formation. The geometry of the complexes is spatially related to the hybridized orbitals involved. In the following examples, carbon monoxide, ammonia, and the cyanide ion are ligands:

Ni(CO) ₄	Nickel carbonyl
Cr(NH ₃) ₆ ³⁺	Hexamminechromium III ion
Fe(CN) ₆ ³⁻	Ferricyanide, or hexacyanoiron III ion

In nickel carbonyl, nickel has an elemental, or zero, oxidation state with one *4s* and three *4p* orbitals unfilled before reaching the next noble-gas structure, Kr. An oxygen from each of the four CO molecules provides an electron pair that effectively occupies one of the four equal *sp*³ hybrid orbitals to generate a stable compound.

The hexamminechromium III ion consists of Cr³⁺ symmetrically surrounded by six ammonia molecules, each providing an electron pair from its nitrogen atom. The resultant complex ion has gained stability by having all the *4d* orbitals filled and the *4p* orbitals half-filled. Further electron sharing with three negative ions will yield a hexamminechromium III salt; this effectively gives the chromium atom the stable electronic structure of Kr.

The ferricyanide ion consists of Fe³⁺ surrounded by six CN⁻ ions, each N of which shares an electron pair to occupy the six *d*²*sp*³ hybrid orbitals. Three of these same cyanide ions further share an electron to fill the remaining three vacancies and give the iron atom an effective Kr electronic structure. Charge on the remaining three CN⁻ ions gives the very stable ferricyanide ion its 3- charge.

A similar rationale can be applied to other coordination compounds composed of a central metal atom or ion and mixtures of ligands.

Chelate Compounds. Chelating (clawlike) ligands have a stereospecific configuration that permits multiple attachment to the metallic ion to form complexes. Examples are EDTA (ethylenediamine tetraacetate ion), the acetylacetonate ion, and ethylenediamine. Multiple attachment can consist of a chemical bond plus coordination with oxygen or nitrogen atoms of the ligands.

Dissociation of Complex Ions. The variable stability of complexes is represented by equilibrium constants for their dissociation. Many complexes are very stable, while others can exist only in specific environments.

3 CHEMICAL REACTIONS AND STOICHIOMETRY

Chemical Reactions. Chemical reactions fit into two broad categories: equilibrium-controlled conversions of reactants to products without changes in oxidation state and equilibrium control of oxidation-reduction reactions where changes in oxidation state occur.

Conversion of reactants to products can proceed only to an equilibrium condition because no driving force exists to go beyond equilibrium. Products can be maximized by continuously removing product from the reaction system so conversion can proceed without reaching equilibrium and stopping.

Le Chatelier's Principle. This principle is basic to the understanding of all chemical equilibria. It is universally applicable and states that systems adjust to reduce applied stress. For example, equilibrium of the reaction $aA + bB \rightleftharpoons cC + dD$ can be shifted to the right when excess concentration of reactants *A* or *B* are present, or when products *C* or *D* are removed from the reaction mixture. Conversely, equilibria may be shifted to the left by adjustment of reactant or product concentrations.

Equilibrium-controlled Conversions. Many chemical operations use processes that consist of a mixture of chemical species that proceed toward equilibrium and whose conversion to a desired product is governed by product removal from the reaction system. Product removal from the reaction system,

Table 3 Equilibrium-controlled Conversions

Product Removal Method	Example	Net Reaction of Example	Equilibrium Governing Conversion Completeness
Slightly ionized product	Acid–base neutralization, formation of weak acid or base	$H^+ + OH^- \rightleftharpoons H_2O$	Dissociation of water
		$H^+ + CH_3COO^- \rightleftharpoons$	Dissociation of weak acid or base
Slightly soluble products (least soluble product of several alternatives will prevail)	Precipitation reactions leaving uninvolved ions remaining in solution	CH_3COOH $Ca^{2+} + SO_4^{2-} \rightleftharpoons CaSO_4$	Solubility product of precipitate
Complete ion formation (most stable complex of several alternatives will prevail)	Removal of ions from solution (convert them to soluble species that do not participate in reaction)	$Ag^+ + 2CN^- \rightleftharpoons Ag(CN)_2^-$	Dissociation of complex ion
Volatile product formation	Loss of CO_2 from aqueous solution	$H_2CO_3 \rightleftharpoons H_2O + CO_2$	Solubility of gas at reaction temperature

as shown in Table 3, occurs through removal of ions by (a) forming slightly ionized products, (b) forming slightly soluble products, (c) complex ion formation, and (d) gas evolution.

Oxidation–Reduction (Redox) Reactions. Some chemical reactions change element oxidation states as molecular configuration and chemical bondings are rearranged. Redox terminology is given in Table 4. Electron transfer takes place from an oxidation source to a reduction sink. Electrons are not lost, only transferred. The number of electrons transferred determines the relative stoichiometry between their oxidation half-reaction source and their reduction half-reaction sink. Redox reactions are recognized by finding changes in oxidation state. Except in disproportionation, oxidation occurs for one atom and reduction occurs for another.

Changes in oxidation state are determined by considering the following:

- Elemental state of the elements; that is, S, O_2 , H_2 , Fe, and so on; oxidation state is 0.
- Oxygen in other molecules: Oxidation state is -2 (exception, when covalently bonded in peroxide, -1).
- Hydrogen in other molecules: Oxidation state is $+1$ (exception in hydride, -1).
- Other elements according to position on periodic table and list of usual oxidation states.
- Summation of oxidation states in any molecule is 0, and in any ion it equals the net charge on the ion.

Table 4 Redox Terminology

Oxidation	Process producing electrons; electron source; occurs at anode in electrochemistry; electron loss produces increase in oxidation state.
Oxidizing agent	Species that is reduced is electron sink and consumes electrons produced by oxidation of other species.
Oxidation half-reaction	Charge-balanced equation for electron source (reversing equation makes it reduction half-reaction).
Oxidation potential	Energetics of oxidation half-reaction, expressed thermally as free energy change or electrically as voltage, under standard conditions.
Disproportionation	Self-redox; reaction occurring when metastable oxidation state simultaneously oxidizes and reduces atom to more stable higher and lower oxidation states.
Reduction	Process consuming electrons; electron sink; occurs at cathode in electrochemistry; electron gain causes reduction in oxidation state.
Reducing agent	Species that is oxidized is electron source and produces electrons for reduction of other species.
Reduction half-reaction	Charge-balanced equation for electron sink.
Reduction potential	Energetics of reduction half-reaction. Positive sign means reaction can proceed spontaneously as written. Reversal of reduction half-reaction changes it to oxidation half-reaction and changes algebraic sign of potential.

- (f) Consult a table of reduction potentials (Table 10 later in the chapter) for typical half-reactions of the elements in acidic or neutral and in basic aqueous media.

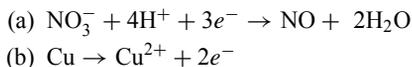

Stoichiometric Equations. Stoichiometric equations can be written for reactions relating initial reactants and final products without regard to details such as equilibria, steps in the reaction mechanism, kinetics, percentage of conversion in a closed system, intermediate products, excess reactants required in the process, process variables, solvents, catalysts, and so. The balanced stoichiometric equation relates mass and moles of each product species to mass and moles of each of the reactants, assuming that the reaction goes to completion as written. The stoichiometric equation is the balanced chemical equation.

Balanced chemical equations involve three basic principles: (a) a *mass balance*, based on conservation of mass, which requires that total mass in equal total mass out; (b) an *atom balance*, based on constant mass of each atomic species involved in ordinary nonnuclear reactions, which requires that there is no change in the numbers of each atomic species; and (c) an *electron balance*, based on conservation of the number of electrons involved in oxidation–reduction reactions.

Example 2

1. *Reaction not involving change in oxidation states* in a mixture of ions that may proceed to complete conversion because a product is removed from the reaction system. The stoichiometric equation $\text{CaCl}_2 + \text{Na}_2\text{SO}_4 \rightarrow \text{CaSO}_4 + 2\text{NaCl}$ can be written as a net ionic reaction: $\text{Ca}^{2+} + \text{SO}_4^{2-} \rightarrow \text{CaSO}_4$ for the formation of slightly soluble CaSO_4 , whose solubility is quantified by its solubility product (see Section 6). Atom balance and mass balance apply; but electron balance, although valid, is not required since no oxidation–reduction occurs.

2. *Reaction involving redox* requires atom, mass, and electron balances. A gross reaction for dissolving copper in concentrated nitric acid (with liberation of brown N_2O_4 gas resulting from air oxidation of NO , the reaction product) can be written as two half-reactions:

Charge balance requires electron balance so twice (a) provides $6e^-$ that match the requirement of three times (b) for the net result $2\text{NO}_3^- + 8\text{H}^+ + 3\text{Cu} \rightarrow 2\text{NO} + 4\text{H}_2\text{O} + 3\text{Cu}^{2+}$. It is apparent that 8H^+ must have come from 8HNO_3 , and the product 3Cu^{2+} must be accompanied by 6NO_3^- for charge balance. The final stoichiometric equation is $3\text{Cu} + 8\text{HNO}_3 \rightarrow$

$2\text{NO} + 4\text{H}_2\text{O} + 3\text{Cu}(\text{NO}_3)_2$. Equations (a) and (b) can be found among the equations in the table of reduction potentials (Table 10).

3. *Balance an unbalanced redox equation given* $\text{Ag}_2\text{S} + \text{CN}^- + \text{O}_2 \rightarrow \text{S} + \text{Ag}(\text{CN})_2^- + \text{OH}^-$. Atom, mass, and electron balances are required. Water can participate in the reaction, but H^+ cannot exist in alkaline solution. Determine which one element is oxidized and between which oxidation states. Do the same for the element reduced. (a) Reduction of O_2 from zero to -2 oxidation state in basic solution. (b) Oxidation of S from -2 to zero oxidation state in basic solution. Write net reactions for (a) and (b) or find those reactions in the table of reduction potentials.

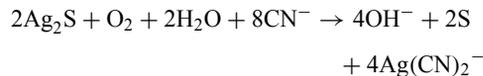

Note the need for H_2O inclusion to balance this half-reaction.

Equation (a) supplies $4e^-$, meeting the electron needs of twice Eq. (b) for the net result:

This matches that given, except it needs the CN^- added to give the $\text{Ag}(\text{CN})_2^-$ complex. The final stoichiometric equation is

A redox equation cannot be correctly balanced unless the electron balance requirement is first met. Trial and error on the basis of an atom balance usually leads to erroneous results.

4. *Balance the disproportionation:* $\text{ClO}^- \rightarrow \text{ClO}_3^- + \text{Cl}^-$. The oxidation state of chlorine changes from $+1$ to $+5$ and -1 . The simplified oxidation half-reaction is $\text{Cl}^+ \rightarrow \text{Cl}^{5+} + 4e^-$. The simplified reduction half-reaction is $\text{Cl}^+ + 2e^- \rightarrow \text{Cl}^-$. Electron balance equates the oxidation half-reaction with twice the reduction half-reaction. Addition produces a net skeleton reaction of $3\text{Cl}^+ \rightarrow \text{Cl}^{5+} + 2\text{Cl}^-$. The final redox equation is $3\text{ClO}^- \rightarrow \text{ClO}_3^- + 2\text{Cl}^-$ after oxygens are appropriately inserted to obtain the required mass and atom balance for the equation.

Molar Volume of Gases. At standard conditions of 0°C and 1 atm (32°F , 14.7 psia), the molar volume of ideal gases is approximately 22.4 l/g mol or 359 ft³/lb mol. Application of the ideal-gas law ($Pv = RT$) using ratios of absolute pressure and absolute temperature permits estimation of molar volumes at other temperatures and pressures. These molar volumes of gases can usefully elaborate the mass and molar quantities of gases directly available from the stoichiometric equations.

Material Balances. Material balances for processes can be written on many bases, for example, per ton mole of product, per hour of operation, and per batch. All are based on a stoichiometric equation for the process and on a definition of the system such that mass or molar balances may be made at the steady state using "out minus in equals no accumulation" as the guiding principle. Selection of the element(s) used in the material balance depends upon the system; for example, the nitrogen of air in combustion processes passes through unchanged and quantities of other gases may be related to it via gas analyses.

Example 3

- Determine the amount of CaO required to neutralize a short ton of 37 wt % H₂SO₄ waste.
 - Establish a balanced stoichiometric equation. Add the molecular weights of the species involved:

Note that a material balance exists.

- Determine the weight of 100% H₂SO₄ that must be neutralized:

$$2000(0.37) = 740 \text{ lb}$$

- Ratio reactants and products according to the stoichiometric equation:

$$\frac{\text{wt CaO}}{56} = \frac{740}{98} = \frac{\text{wt CaSO}_4}{136} = \frac{\text{wt H}_2\text{O}}{18}$$

$$\text{wt CaO} = 423 \text{ lb}$$

- Per 1000 standard cubic feet (scf) of methane, calculate maximum carbon black available from partial combustion, scf dry air required for that combustion, and composition of wet flue gas.

- Establish balanced stoichiometric equation. Add atomic and molecular weights of all reactants and products:

Note that 1 lb mol of CH₄ can produce 1 lb atom of carbon black.

- Convert 1000 scf CH₄ to pound moles and pounds (359 scf gas = 1 lb mol); therefore,

$$\frac{1000}{359} = 2.79 \text{ lb mol} \quad \text{or} \quad 44.7 \text{ lb, CH}_4$$

- Ratio reactants and products according to the stoichiometric equation:

$$\begin{aligned} \frac{44.7}{16} &= \frac{\text{lb O}_2}{32} = \frac{\text{lb mol O}_2}{1} = \frac{\text{lb C}}{12} \\ &= \frac{\text{lb mol H}_2\text{O}}{2} \end{aligned}$$

Obtain 2.79 lb mol O₂, 2.79 lb mol (or 33.5 lb) C, and 5.58 lb mol H₂O.

- Dry air composition is 21 vol% = 21 mol% oxygen and 79 mol % nitrogen and inerts:

$$\begin{aligned} \text{Dry air required} &= 2.79 \frac{100}{21} \\ &= 13.3 \text{ lb mol, or} \end{aligned}$$

$$13.3(359), = 4770 \text{ scf}$$

- Assume complete electrostatic precipitation of carbon black and no water condensation. Then the flue gases consist of nitrogen, inerts, and H₂O vapor (nitrogen + inerts in = nitrogen + inerts out):

$$13.3(0.79) = 10.5 \text{ lb mol N + inerts}$$

$$\frac{5.58 \text{ lb mol H}_2\text{O}}{\text{Total: } 16.08 \text{ lb mol}}$$

$$\text{N}_2 = \frac{10.5}{16.08} = 65.3 \text{ vol\%}$$

$$\text{H}_2\text{O} = \frac{5.58}{16.08} = 34.7 \text{ vol\%}$$

(Ideal-gas behavior has been assumed in the moles-to-volume conversion.)

- Products of hydrocarbon combustion analyzed on a dry basis are 10.34 vol % CO₂, 0.80 vol % CO, 5.16 vol % O₂, and the remainder N₂. Water is undetermined. Calculate the carbon/hydrogen weight ratio of the hydrocarbon fuel, assuming all hydrogen burns to water before any carbon is converted to other products, and the percentage of excess air entering the combustion zone.

- Establish 100 lb mol dry product as the basis of calculation. On a molar basis, the products are

$$10.34 \text{ lb mol CO}_2$$

$$0.80 \text{ lb mol CO}$$

$$5.16 \text{ lb mol O}_2$$

$$83.70 \text{ lb mol N}_2$$

$$\text{Total: } \frac{100.00 \text{ lb mol dry products}}$$

- Use a nitrogen balance to determine the O₂ entering the combustion zone:

$$83.70 \text{ lb mol N}_2 \text{ in} = 83.70 \text{ lb mol N}_2 \text{ out}$$

$$\begin{aligned} \text{O}_2 \text{ of air entering} &= 83.70 \frac{21}{79} \\ &= 22.25 \text{ lb mol} \end{aligned}$$

- (c) Determine the pound moles of oxygen accounted for in known products:

$$\begin{aligned} \text{in CO}_2: & 10.34 \text{ lb mol} \\ \text{in CO: } & \frac{0.80}{2} = 0.40 \text{ lb mol} \\ \text{as O}_2: & 5.16 \text{ lb mol} \\ \text{Total: } & \underline{15.90 \text{ lb mol}} \end{aligned}$$

- (d) Remainder of oxygen must exist as undetermined water:

$$22.25 - 15.90 = 6.35 \text{ lb mol O}_2 \text{ in water}$$

Therefore

$$2(6.35) = 12.70 \text{ lb mol H}_2\text{O} \text{ are in products}$$

- (e) Hydrogen in products = $12.70(1) = 12.70$ lb mol = 25.4 lb.
 (f) Carbon in products = $10.34(1) + 0.80(1) = 11.14$ lb atom = 133.5 lb; therefore

$$\text{C/H wt ratio} = \frac{133.5}{25.4} = 5.26$$

- (g) Percentage of excess air:

$$100 \times \frac{\text{(total O}_2 \text{ entering)} - \text{O}_2 \text{ required for complete combustion}}{\text{O}_2 \text{ required for complete combustion}}$$

- (h) Alternate method for calculating percentage of excess air:

$$\begin{aligned} & \text{Free oxygen in combustion products} \\ &= 5.16 \text{ lb mol, oxygen required to burn} \\ & \quad \text{CO to CO}_2 \\ &= \frac{0.80}{2} = 0.40 \text{ lb mol} \end{aligned}$$

Therefore excess O₂ beyond that required for complete combustion is 4.76 lb mol:

$$\begin{aligned} & \text{Percentage of excess O}_2 \\ &= \text{percentage of excess air} = 100 \times \frac{4.76}{17.49} \\ &= 27.2\% \end{aligned}$$

Mixture and Dilution Calculations. Mixtures with properties linearly dependent on mass, volume, or mole

fractions of components in the mixture can be handled by a simple summation:

$$P = \sum_i X_i P_i \quad (1)$$

where

$$1 = \sum_i X_i \quad (2)$$

X_i is the mass, volume, or mole fraction, as appropriate, of component i , and P_i is the property P of pure i . For example,

$$P \text{ of a binary mixture} = X_i P_i + (1 - X_i) P_i \quad (3)$$

Example 4

1. A mixture of density 3.6 is desired from components having densities of 2.6 and 7.5:

$$1(3.6) = (x)2.6 + (1 - x)7.5$$

$$x = \frac{3.9}{4.9} = 0.796$$

$$1 - x = 0.204$$

Since density is weight per volume, this is a weight summation when x is the volume fraction.

2. Dilute 37 wt % solution with a 3 wt % solution to make a 20 wt % solution:

$$1(20) = x(37) + (1 - x)3 \quad x = 0.50$$

$$(1 - x) = 0.50$$

Since $(\text{wt}) \times (\text{wt}\%) = \text{wt}$, this is also a weight summation when x is mass or weight fraction. Densities and assumption of volume additivity of ideal solutions are not required unless volume fractions are sought.

4 CHEMICAL THERMODYNAMICS

Chemical thermodynamics deals with work–energy relationships and the driving forces of chemical reactions. It is based on a wider variety of energy terms than the expansion–compression work, thermal, flow, kinetic, and potential energy terms of engineering thermodynamics. Basic relationships presented in the engineering thermodynamics section are augmented with other forms of work and energy that are applicable to the systems considered.

Energy Terms of Thermodynamics. Energy terms are the product of an intensive property (independent of quantity) and an extensive property (varies with amount) as shown in Table 5. When any of these

Table 5 Energy Terms of Thermodynamics

Kind of Energy	Intensive Property	Extensive Property	Energy Term
Expansion-contraction work	P , pressure	dV , volume	$P dV$
Thermal	T , temperature	dS , entropy	$T dS$
Mechanical	F , force	dX , displacement	$F dX$
Electrical	E , voltage	dQ , charge	$E dQ$ or $EF dn$
Magnetic	H , magnetic field intensity	dM , magnetization	$H dM$, work of magnetization
Surface	γ , surface tension	dA , area	γdA , work of increasing area
Chemical	μ , chemical potential (partial molal free energy)	dN , number of moles	μdN , energy due to undergoing reaction or crossing phase boundaries

terms are involved in a chemical thermodynamic system, they are included in the basic equations of engineering thermodynamics.

Chemical Potential μ . For a multicomponent system with N_i moles of component i ,

$$\mu_i = \left(\frac{\partial G}{\partial N_i} \right)_{T, P, N_{j \neq i}} = \left(\frac{\partial A}{\partial N_i} \right)_{T, V, N_{j \neq i}} \quad (4)$$

where G and A are the Gibbs free energy and the Helmholtz function, respectively.

Chemical Energy. As other forms of energy, all products of an intensive and an extensive property, chemical energy added to a system is $\mu_i dN_i$ for one component and $\sum \mu_i dN_i$ for all components of the system.

Chemical Thermodynamic Equations. Basic differential equations of engineering thermodynamics are expanded by adding the chemical energy and other appropriate energy terms. The thermal energy sign convention is used for chemical energy; positive terms are energy added and negative terms are energy removed from the system:

Relation of chemical potential to internal energy:

$$dU = T dS - P dV + \sum_i \mu_i dN_i \quad (5)$$

Relation to enthalpy:

$$dH = T dS + V dP + \sum_i \mu_i dN_i \quad (6)$$

Relation to Gibbs free energy:

$$dG = -S dT + V dP + \sum_i \mu_i dN_i \quad (7)$$

Relation to Helmholtz work function:

$$dA = -S dT - P dV + \sum_i \mu_i dN_i \quad (8)$$

For constant-temperature ($dT = 0$) and constant-pressure ($dP = 0$) reaction systems, Eq. (7) reduces to the most widely used relationship:

$$dG = \sum_i \mu_i dN_i \quad (9)$$

Standard Thermodynamic Data. Augmenting usual engineering sources of thermodynamic data (steam tables, gas tables, and special compilations for working fluids), useful tabulations of thermochemical data are available at 25°C (298 K).

ΔH_f° = heat of formation from elements, kcal/g mol
(ΔH_f° of all elements in standard state
arbitrarily taken as zero)

ΔG_f° = Gibbs free energy of formation from
elements, kcal/g mol
(some references use ΔF°)

S° = entropy, cal/g mol K

C_p° = heat capacity, cal/g mol K

New compilations may be expressed in joules rather than calories, where 1 cal = 4.184 J. The degree superscript designates standard state at 25°C and unit activity or 1 atm fugacity. For a pure compound with more than one allotropic form, this refers to the stable modification. Aqueous solution data are given at 1 molal activity. The standard state is independent of pressure or concentration variables because activity (as a thermodynamically corrected concentration) and fugacity (as a corrected pressure to give ideal-gas behavior) have been introduced as substitute variables.

Activity a . Activity is a thermodynamically effective concentration used in lieu of actual concentrations to compensate for deviations of gases from ideality, incomplete ionization of strong electrolytes in solution, and other discrepancies between calculated and experimental behavior.

Fugacity f . Fugacity deviations from the model behavior of a gas equals its activity. Fugacity is an effective partial pressure expressed in atmospheres.

For ideal gases fugacity f exactly equals partial pressure. Since real gases in the standard state (in their usual phase at 1 atm pressure and 25°C) deviate slightly from ideality, the activity of real gases is defined as the ratio of fugacity f to fugacity f° in a standard state where $f^\circ = 1$ atm. For all practical purposes, $f^\circ = 1$ atm pressure. Nonidealities of real gases at other temperatures and pressures are handled by an activity coefficient γ .

Activity Coefficient γ . Activity coefficient is the ratio of fugacity to partial pressure or the ratio of activity to molal concentration.

For ideal gases $\gamma = 1$.

For real gases γ varies with T and P and is the ratio f/p , where f is the fugacity of the gas and p is its partial pressure.

For ions in solution $\gamma = a/m$, where a is the activity of the ion and m is its molality in solution.

Activity of Gases in Mixtures. The activity of any gas in a mixture (Lewis and Randall rule) is calculated as

$$a_i = p_i \gamma_i \quad (10)$$

where p_i is the partial pressure in atmospheres and γ_i is the fugacity coefficient of pure i at the temperature and total pressure of the mixture.

Calculation of ΔG° at Elevated Temperatures.

The effect of temperature on ΔG° at constant pressure and at constant number of moles can be calculated from thermodynamic data at another temperature, which can be taken to be 298 K. At any temperature T ,

$$\Delta G_T^\circ = \Delta H_T^\circ - T \Delta S_T^\circ \quad (11)$$

$$\Delta H_T^\circ = \Delta H_{298}^\circ + \int_{298}^T \Delta C_P dT' \quad (12)$$

$$\Delta S_T^\circ = \Delta S_{298}^\circ + \int_{298}^T \frac{\Delta C_P dT'}{T'} \quad (13)$$

where ΔC_P is the difference in heat capacity between products and reactants. If any phase changes occur between T and 298 K, there are additional contributions to Eqs. (12) and (13). In the absence of any phase changes, Eqs. (11)–(13) can be combined to obtain

$$\Delta G_T^\circ = \Delta H_{298}^\circ - T \Delta S_{298}^\circ + \int_{298}^T \left(1 - \frac{T}{T'}\right) \Delta C_P dT' \quad (14)$$

If ΔC_P is represented by a power series in T' , the required integration in the last term is straightforward. (If ΔC_P is small and/or T is close to 298 K, the value of the integral is approximately zero.) An example is: Calculate ΔG_{298}° for the reaction: $\text{CO} + \frac{1}{2}\text{O}_2 \rightleftharpoons \text{CO}_2$ at unit fugacity and activity of all products and reactants at (a) 298 K and (b) 800 K:

(a) At standard conditions 25°C (298 K) and 1 atm

	CO	O ₂	CO ₂
ΔH_f° (kcal/mol)	-26.42	0	-94.05
ΔS° (cal/K mol)	47.30	49.00	51.06

Therefore,

$$\Delta H_{298}^\circ = \Delta H_f^\circ (\text{products}) - \Delta H_f^\circ (\text{reactants})$$

$$= -94.05 - (-26.42) - \frac{1}{2}(0)$$

$$= -67.63 \text{ kcal/mol}$$

$$\Delta S_{298}^\circ = 51.06 - 47.30 - \frac{1}{2}(49.00)$$

$$= -20.74 \text{ cal/K mol}$$

and

$$\Delta G_{298}^\circ = \Delta H_{298}^\circ - 298 \Delta S_{298}^\circ$$

$$= -67.63 - 298(-20.74/100)$$

$$= -61.45 \text{ kcal/mol}$$

(b) The heat capacity data are

$$\text{For CO: } C_p = 6.3424 + 1.8363 \times 10^{-3}T$$

$$- 0.2801 + 10^{-6}T^2,$$

$$\text{cal/g mol K}$$

$$\text{For O}_2: G_p = 6.0954 + 3.2533 \times 10^{-3}T$$

$$- 1.0171 + 10^{-6}T^2$$

$$\text{For CO}_2: C_p = 6.393 + 10.100 \times 10^{-3}T$$

$$- 3.405 \times 10^{-6}T^2$$

Here, ΔC_p for the reaction equals the C_p for products $-C_p$ for the reactants:

$$\Delta C_p = 1(C_{p,\text{CO}_2}) - \frac{1}{2}(C_{p,\text{O}_2})$$

$$= -2.997 + 6.637 + 10^{-3}T$$

$$- 2.716 \times 10^{-6}T^2$$

$$= \alpha + \beta T + \gamma T^2$$

At $T = 800$ K, one finds ΔG_{800}° from Eq. (14) and

$$\Delta G_{800}^\circ = -67.63 - 800 \left(-\frac{20.74}{1000} \right) + 0.19$$

$$= -50.85 \text{ kcal/mol}$$

Note that in this case the value of the integral, 0.19 kcal/mol, made a minor contribution to the net result.

Calculation of ΔG at Elevated Pressure*

At constant temperature and constant number of moles, $dT = 0$ and $dN_i = 0$, Eq. (7) reduces to $dG = +V dP$. The calculation of ΔG for ideal gases, real gases, solids, and liquids at any pressure is dependent only on an expression for V as a function of P .

For *ideal gases* $PV = RT$, and $dG = (RT/P) dP = RT d(\ln P)$. Integrating between limits gives

$$\Delta G = RT \ln \frac{P_2}{P_1} \quad (15)$$

For *real gases* more complicated equations of state relating V and P can be substituted for the ideal-gas law and the integration performed. Deviations from ideality can also be incorporated by the use of the fugacity f_i and

$$\Delta G = RT \ln \frac{f_2}{f_1} \quad (16)$$

For *incompressible liquids and solids* V is constant, so

$$\Delta G = V(P_2 - P_1) \quad (17)$$

using appropriate units. The magnitude of this change for all condensed phases is very small.

For *compressible liquids and solids* V is dependent on isothermal compressibility β , $V = V_0(1 - \beta P)$:

$$dG = V_0(1 - \beta P) dP = V_0 dP - \beta V_0 P dP \quad (18)$$

or

$$\Delta G = V_0(P_2 - P_1) - \frac{\beta V_0}{2}(P_2^2 - P_1^2)$$

Standard Gibbs Free-Energy Change and Reactivity. The ΔG_T° for a reaction is

$$\Delta G_T^\circ = \sum_i \nu_i G_{T_i}^\circ \quad (19)$$

where ν_i is the stoichiometric coefficient of species i , taken as positive for products and negative for reactants. Here, ΔG_T° is the standard Gibbs free-energy change for a reaction at temperature T when all reactants and products are at unit activity (unit fugacity for gases). The ΔG_T° is independent of pressure; its magnitude as a driving force for predicting reactivity is very important:

If ΔG_T° is negative	Reaction can occur as written; a forward driving force or chemical potential exists
If ΔG_T° is zero	No driving force exists; system is at equilibrium
If ΔG_T° is positive	Reverse reaction can occur; a reverse driving force or chemical potential exists

(20)

Since the rate of reaction is dependent on temperature and activation energy, the value of ΔG° provides no information about the rate.

Example 5

1. Reaction solid 1 CaO + gaseous 1 CO₂ = solid 1 CaCO₃

$$\begin{array}{rcc} \Delta G_f^\circ = & \Delta G_f^\circ = & \Delta G_f^\circ = \\ -144.4 & -94.26 & -269.78 \\ \text{kcal/gmol} & \text{kcal/gmol} & \text{kcal/gmol} \end{array}$$

where ΔG° for the reaction equals (1)(-269.78) - (1)(-144.4) - (1)(-94.26) = -31.1 kcal.

For the reaction as written at 298 K, the process is spontaneous.

2. Phase change:

$$\begin{array}{rcc} C_{\text{graphite}} = & C_{\text{diamond}} \\ \Delta G_f^\circ = 0 & \Delta G_f^\circ = +0.68 \end{array}$$

$\Delta G_{298}^\circ = 1(+0.68) - 1(0) = +0.68$ kcal for the reaction as written. The positive value of ΔG° indicates that the reaction as written cannot proceed at the standard condition, but the reverse reaction of diamond transition to graphite would be spontaneous if kinetic factors were favorable.

Thermodynamics of Equilibrium. At equilibrium the capability of any system for doing work is zero because there is no net energy available as the driving force to modify the status quo. In chemical systems at constant temperature and pressure, the change in the Gibbs free energy, ΔG , is zero at equilibrium between reactants and products; it is negative when a thermodynamic driving force for forward reaction is existent. (For equilibrium at constant temperature and constant volume, the change in the Helmholtz work function ΔA is zero.) Since most significant chemical equilibria are at constant temperature and pressure, this section contains only the relationships involving Gibbs free energy. The conditions for chemical equilibrium are

$$\begin{array}{l} dG = \begin{cases} 0 & \text{at constant } T, P \\ \sum_i \mu_i dN_i = 0 \end{cases} \\ dA = \begin{cases} 0 & \text{at constant } T, V \\ \sum_i \mu_i dN_i = 0 \end{cases} \end{array} \quad (21)$$

*Note: ΔG is not the same as the pressure-independent ΔG° introduced in the preceding.

Standard Gibbs Free-Energy Change and Equilibrium Constant. The magnitude of the driving force ΔG_T° at unit activity or unit fugacity of reactants and products, available to cause the reaction to proceed, was calculated for temperature T . The standard free energy ΔG_T° was considered pressure independent because unit activities or fugacities were involved.

Here, ΔG_T° is related to the equilibrium constant K , where K is expressed using activities (or fugacities of gases). This K is pressure independent because the product of any set of equilibrium fugacities, each to the power of its stoichiometric coefficient is a constant:

$$\Delta G_T^\circ = -RT \ln K \quad (22)$$

where K is expressed using activities (or fugacities) of gases.

Temperature Dependence of Equilibrium Constant.

The temperature dependence of ΔG_T° directly affects K . The temperature dependence of K can be obtained by combining Eqs. (11) and (22) to yield

$$\ln K = -\frac{\Delta H_T^\circ}{RT} + \frac{\Delta S_T^\circ}{R} \quad (23)$$

If T is close to 298 K and/or ΔC_P for the reaction is approximately zero,

$$\ln K = -\frac{\Delta H_{298}^\circ}{RT} + \frac{\Delta S_{298}^\circ}{R} \quad (24)$$

Pressure Dependence of Equilibrium Constant.

For an equilibrium constant expressed in activities and fugacity, the effect of pressure is introduced through change of activity and fugacity terms.

For *gases*: Fugacity equals the partial pressure of ideal gases and corrects for nonlinearities in the partial pressure of real gases.

For *liquids* or *solids*: Activities of solids and liquids are essentially invariant. The change in ΔG with pressure for these condensed phases, calculated from Eq. (17) [$\Delta G = V_0(P_2 - P_1)$] is of small magnitude.

For *solutes*: The changes of activity coefficient and equilibrium constant with pressure are given by

$$\frac{d(\ln \gamma_i)}{dP} = \frac{\bar{v}_i}{RT} \quad (25)$$

where \bar{v}_i is the partial molal volume of component i . The magnitude of pressure dependence of the equilibrium constant is extremely small:

$$\frac{d(\ln K)}{dP} = \frac{\sum_i \nu_i \bar{v}_i}{RT} \quad (26)$$

where $\sum \nu_i \bar{v}_i$ is the difference in the partial molal volumes of products and reactants.

Thermodynamics and Phase Equilibria. Phase equilibrium exists, as with other equilibria, when change in Gibbs free energy $\Delta G = 0$. Since the chemical potential, μ_i of component i is defined as $(\partial G / \partial N_i)_{T, P, N_j \neq i}$, μ is the partial molal free energy G_i . At constant temperature and pressure, $\Delta G = 0 = \sum_i \mu_i dN_i$. Phase equilibrium exists (with dN_i moles of component i transferred between phases) when the partial molal free energy \bar{G}_i or chemical potential μ_i of each component is the same in all phases:

$$\mu_i \text{ (phase 1)} = \mu_i \text{ (phase 2)} \quad (27)$$

Since $\bar{G}_i = \bar{G}_i^\circ + RT \ln a_i$, or $\mu_i = \mu_i^\circ + RT \ln a_i$, it follows that activities in each phase can be used with standard free energies to determine chemical potentials. For liquid phases, activities can be related to concentrations, and for vapor phases, activities are related to partial pressures. These relationships allow calculation for the effects of changes in temperature, pressure, and concentrations.

Partial Molal Quantities. Mixture nonidealities are often empirically treated by summing partial molal quantities contributed by each component. Partial molal quantities, such as molal volume or molal free energy, are of interest in phase equilibria:

$$dV = \sum_i \bar{v}_i dN_i \quad dG = \sum_i \bar{G}_i dN_i \quad (28)$$

where the overbar indicates partial molal quantities.

5 THERMOCHEMISTRY

ΔH° Standard Heats of Reaction and Formation.

Energy is transferred in all reactions and phase changes. The enthalpy change during an endothermic reaction is positive, in agreement with the basic sign convention of thermodynamics. Conversely, the enthalpy change in an exothermic process is negative.

Data at a standard condition of 25°C (298 K) and 1 atm (or at unit fugacity of gases and unit activity of solutes) are designated by the $^\circ$ superscript. Standard heats of formation of compounds from their elements are available, all based on a reference state of $\Delta H^\circ = 0$ for elements in their stable phase at the standard condition. These data are given in kilocalories per gram mole.

Example 6

$$\Delta H_f^\circ = -57.80 \text{ kcal/g mol water(g)}$$

$$\Delta H_f^\circ = -68.32 \text{ kcal/g mol water(l)}$$

Parentheses enclose the phase of each species involved.

Additivity of Extensive State Functions. Extensive properties that are state functions, such as H , G , and S , are additive over successive reactions carried out at constant temperature and pressure according to the principle known as Hess's law:

$$\Delta X = \sum_i (v_i X_i)_1 + \sum_i (v_i X_i)_2 + \dots \quad (29)$$

where v_i is the stoichiometric coefficient of species i . Thus ΔX for a reaction may be obtained from the summation of a series of simpler or better known reactions that give the same overall chemical balance. Thus the heat of a reaction may be obtained from the heats of combustion or formation of the compounds involved in the reaction. If X is any extensive property of the system and X_i is the corresponding molal property of pure i for the reaction,

$$\Delta X = \sum_i v_i X_i \quad (30)$$

In simultaneous or successive reactions, where the numerical subscripts refer to the different reactions,

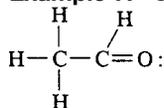

$$dN_i = (dN_i)_1 + (dN_i)_2 + \dots \quad (31)$$

and

$$N_i = N_i^\circ + (v_i \Delta N)_1 + (v_i \Delta N)_2 + \dots \quad (32)$$

Estimating Heat of Formation and Reaction from Bond Energies. In the absence of heat-of-formation data for organic compounds, the standard heat of formation can be estimated by summing average nonpolar energies for each of the bonds of the compound. These energies are for gaseous molecules and are to be used with caution since bond strengths are influenced by molecular configuration being reduced in resonance structures and increased in polar compounds. Heats of formation can be expected within $\pm 10\%$ of the experimentally determined values using the values of Table 6.

Example 7. Heat of formation of acetaldehyde

Energy evolved to make products bonds:

$$\begin{array}{r} 4 \text{ C-H bonds at } 98.7 \quad = -394.8 \\ 1 \text{ C-C bond} \quad \quad \quad = -82.6 \\ 1 \text{ C=O aldehyde type bond} = -176 \\ \hline -653.4 \text{ kcal/mol} \end{array}$$

Energy added to break reactant bonds:

$$\begin{array}{r} 2 \text{ H-H bonds at } 104.2 \quad = +208.4 \\ \frac{1}{2} \text{ O=O bond at } 119.1 \quad = +59.6 \end{array}$$

Table 6 Bond Energies, kcal/g mol at 25°C^a

H-H	104.2	C-N	72.8

^aFor all elements of higher molecular weight use an average value of 6.4 cal/g atom K

Example: Ag₂CO₃ = 2(6.4) + 1.8 + 3(4.0) = 26.6 cal/g mol K, (actual 26.8).

atomic C_p° values for constituents. Average values are given in Table 8.

C_p of Solutions and Mixtures. In lieu of experimental data, the heat capacity of a solution or mixture can be estimated by

$$C_{p,\text{mixture}} = \sum_i y_i C_{pi} \quad (36)$$

where y_i is the mole fraction and C_{pi} is the molar heat capacity of component i .

Effect of Temperature on Heat of Reaction.

Consider the reactants as one state and the products as another and that thermodynamically one can proceed from one state function to another regardless of the path. From reactants at temperature T , one can change temperature (using heat capacities and the enthalpies of any phase changes) to 25°C, then utilize the standard heat of reaction at 25°C and 1 atm, and then change products back to temperature T .

Example 8. Calculate the heat of the ammonia synthesis reaction, $N_2 + 3H_2 \rightarrow 2NH_3$, as a function of temperature T . Given is the standard heat of reaction $\Delta H^\circ = -22.08$ kcal for the equation as written at 25°C (298 K) and 1 atm.

The heat capacity equations for reactants and products are

$$H_2: \quad 6.62 + 0.0081 T(\text{K}) \text{ cal/g mol K or}$$

$$6.62 + \frac{0.00081}{1.8} T(^{\circ}\text{R}) \frac{\text{Btu}}{\text{lb mol}^{\circ}\text{R}}$$

$$N_2: \quad 6.50 + 0.00100 T \text{ K}$$

$$NH_3: \quad 6.70 + 0.00630 T \text{ K}$$

1. Cool reactants from T down to 298°K:

$$\begin{aligned} \Delta H_1 &= \sum \int_T^{298} C_P dt = 1 \left[(6.50)(298 - T) \right. \\ &\quad \left. + 0.00100 \left(\frac{298^2 - T^2}{2} \right) \right] \\ &\quad + 3 \left[(6.62)(298 - T) + 0.00081 \right. \\ &\quad \left. \times \left(\frac{298^2 - T^2}{2} \right) \right] \\ &= 26.36(298 - T) + 0.00343 \\ &\quad \times \left(\frac{298^2 - T^2}{2} \right) \\ &= -26.36(T - 298) - 0.00343 \\ &\quad \times \left(\frac{T^2 - 298^2}{2} \right) \end{aligned}$$

- Standard heat of reaction $\Delta H^\circ = -22.08$ kcal/g mol quantities for $\text{N}_2 + 3\text{H}_2 = 2\text{NH}_3$ at the 298 K. Given is $\Delta H^\circ = -11.04$ kcal for $\frac{1}{2}\text{N}_2 + \frac{3}{2}\text{H}_2 = \text{NH}_3$ in tables. Doubling the stoichiometric quantities doubles heat of reaction. Multiply by 1000 to convert the Btu/lb mol quantities.
- Heat products from 298 K up to T K:

$$\begin{aligned}\Delta H_2 &= \int_{298}^T C_p dt \\ &= 2 \left[6.70(T - 298) + 0.00630 \right. \\ &\quad \left. \times \left(\frac{T^2 - 298^2}{2} \right) \right] \\ &= 13.40(T - 298) + 0.01260 \\ &\quad \times \left(\frac{T^2 - 298^2}{2} \right)\end{aligned}$$

- Algebraically sum the three ΔH values to get ΔH_T for the reaction at temperature T K:

$$\begin{aligned}\Delta H_1 &= -26.36(T - 298) \\ &\quad - 0.00343 \left(\frac{T^2 - 298^2}{2} \right) \\ \Delta H^\circ &= -22.08 \\ \Delta H_2 &= +13.40(T - 298) \\ &\quad + 0.01260 \left(\frac{T^2 - 298^2}{2} \right) \\ \hline \Delta H_T &= -22.08 - 12.96(T - 298) \\ &\quad + 0.00917 \left(\frac{T^2 - 298^2}{2} \right)\end{aligned}$$

kcal/g mol quantities for the equation as written.

- Convert to Btu and lb mol units for T °R since 298 K = 537°R

$$\begin{aligned}\Delta H_T &= -22.08(1000) - \frac{12.96}{1.8}(T - 537) \\ &\quad + \frac{0.00917}{1.8} \left(\frac{T^2 - 537^2}{2} \right)\end{aligned}$$

Btu/lb mol quantities for the equation as written.

Combustion Calculations

1. For purposes of combustion calculations *dry air* is assumed to have a molecular weight of 29 and the following composition:

$$\begin{aligned}\text{Oxygen, 21 vol\%} &= 21 \text{ mol\%} \\ \text{Nitrogen, 79 vol\%} &= 79 \text{ mol\%}\end{aligned}$$

(The nitrogen includes 1% argon and traces of carbon dioxide.) This composition allows combustion calculation on the basis of 100 lb mol (2900 lb) dry air entering a reaction zone with 21 lb mol oxygen available for reaction and 79 lb mol nitrogen and inerts that pass through unreacted.

2. The *moisture* in ambient air entering a combustion zone can often be ignored in approximate combustion calculations; however, it cannot be ignored in the exhaust gases. Gases saturated with water vapor contain a partial pressure of water vapor equal to the vapor pressure of water at that temperature. Saturation is 100% relative humidity; and the dew point, being the temperature of condensation initiation, is then the ambient temperature. The vapor pressure of water is available from steam tables.

Example 9. At a dew point of 77°F, the vapor pressure of water from steam tables (saturated steam, temperature table) is 0.459 psia. Applying Dalton's law of partial pressures, the mole fraction of water vapor in gases at 1 atm is 0.459 psia/14.7 psia = 0.031. At a dew point of 160°F, the vapor pressure is 4.739 psia and the mol fraction of water vapor in gases at 28 in. Hg pressure is

$$\frac{4.739 \text{ psia}}{\frac{28}{30}(14.7 \text{ psia})} = 0.347$$

3. *Psychrometric charts*, useful for air conditioning and humidification calculations, express moisture content in grains of water per pound of dry air (7000 grains = 1 lb) and utilize wet-bulb (essentially dew point) and dry-bulb (ambient) temperatures as variables for determining percentage relative humidity.

4. *Percentage excess air.* Stoichiometric air is the amount of air theoretically necessary to burn all hydrogen in fuels to water and to burn all carbon to carbon dioxide. With insufficient air, hydrogen is preferentially oxidized to water and carbon may be released as elemental carbon (soot), carbon monoxide, or mixtures of carbon monoxide and dioxide. Significant amounts of excess air and residence time in the combustion zone are required for complete combustion of fuel-contained carbon to carbon dioxide.

5. *Basis for calculation.* All stoichiometric calculations should be preceded by a basis of calculation in order to readily permit scale-up or scale-down of the result. Examples of usual bases are per 100 lb of fuel, per 100 lb mol of a reactant, and per ton of a product.

6. *Heat balances.* Thermal calculations for reaction systems are most easily made for steady-state conditions involving an accounting calculation that equates all forms of energy in plus heat of reaction to all forms of energy out plus losses. Forms of energy involved are thermal, chemical, electrical, and mechanical in the form of shaft work, kinetic, potential, and flow energies plus enthalpies of all phase transitions

involved. Heat balances are necessarily predicated on valid material balances, and vice versa. Calculation can be based on mass flow of some component, a unit of operating time, or any other useful basis chosen to simplify calculation and utilize available thermal data.

6 CHEMICAL EQUILIBRIUM

Equilibrium Constant. The equilibrium condition for any reaction $aA + bB + \dots = cC + dD + \dots$ is defined by the expression

$$K = \frac{[C]^c [D]^d \dots}{[A]^a [B]^b \dots} \quad (37)$$

The exponents are stoichiometric coefficient of the equation as written, and bracketed terms are the activities of each species existent at equilibrium. The wide numerical range of K encountered has promoted usage of $pK = -\log_{10} K$ for tabulated data. The equilibrium constant is an expression relating activities of reactants and products such that the net chemical potential is zero at the temperature and pressure of reaction. The standard free energy of a reaction is based on the unit activity of all reactants and products. The K varies with temperature and has a pressure dependence introduced via fugacity of gaseous species, being derived from the relationship $\Delta G_T^\circ = -RT \ln K$ [see Eq. (22)].

For reactions where equilibrium constant data are unavailable, combining K 's from other known reactions will yield the one desired. This is a consequence of the additivity of reactions and their thermodynamic state functions.

Example 10 See the tabulation for Example 10 below.

The activities of solids and solvents are substantially invariant, each in its own phase; they are assigned numerical values of 1. The activity of gases is their fugacity in atmospheres. Fugacity is related to partial pressure via a fugacity coefficient $\gamma = f/p$ that varies with pressure and temperature. The fugacity coefficient of ideal gases is 1, but the deviations of real gases necessitate its consideration. For real gases

it is expedient to divide K , based on activities, into two parts:

$$K = K_\gamma K_p \quad (38)$$

where K_γ is an activity coefficient product and K_p is the pressure product.

Equilibrium Composition of Reaction Mixtures.

The effects of pressure and temperature on equilibrium composition, qualitatively predicted by Le Chatelier's principle (Section 3), are increased conversion with pressure rise if moles of reactants exceeds moles of products and decreased conversion with temperature rise in an exothermic reaction. Quantitatively, equilibrium composition may be calculated from the equilibrium constant.

Sample Calculation of Equilibrium Composition for Gaseous Reactions

$$K = \frac{[\text{NH}_3]^1}{[\text{H}_2]^{3/2} [\text{N}_2]^{1/2}} \\ = 0.0431 \text{ atm}^{-1} \quad \text{at } 600 \text{ K}$$

Note that the equilibrium constant is dimensional, and its units are useful in reconstructing the equilibrium constant expression and the reaction equation on which it is based.

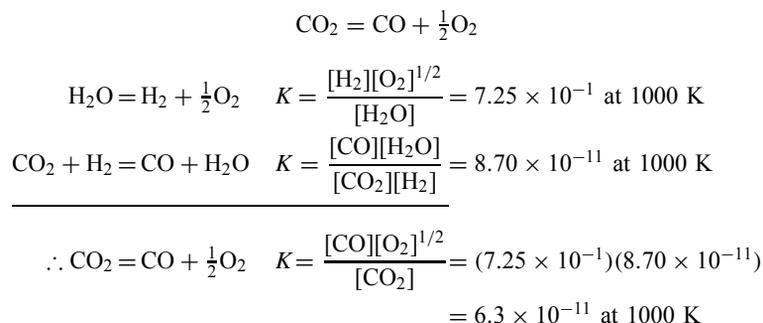

Example 11

$$K = \frac{(f_{\text{NH}_3})^1}{(f_{\text{H}_2})^{3/2} (f_{\text{N}_2})^{1/2}} = 0.0431 \text{ atm}^{-1}$$

applies for NH_3 synthesis. For a stoichiometric ratio of hydrogen and nitrogen without inerts, calculate the mole fraction of ammonia in the equilibrium mixture at (a) 1 atm and (b) 100 atm.

At 1 atm total pressure, where the assumption of ideal-gas behavior for this system may be valid, the

Tabulation for Example 10

Tabulation for Example 11

	P_C (atm)	T_C (K)	T_R	P_R at $P = 100$ atm	$\gamma = f/p$ at $P = 100$ atm	P_R at $P = 1$ atm	$\gamma = f/p$ at $P = 1$ atm
NH ₃	111.3	405.5	0.90	1.48	ca~0.92	0.009	~1
H ₂	12.8	33.3	7.8	18.	ca~1.1	0.078	~1
N ₂	33.5	126.2	2.98	4.76	ca~1.0	0.030	~1

$$K_\gamma = \frac{(0.92)^1}{(1.1)^{3/2}(1.0)^{1/2}} = \frac{0.92}{(1.16)(1.0)}$$

$$= 0.79 \text{ at } 100 \text{ atm}$$

$$= 1.02 \text{ at } 1 \text{ atm}$$

activity coefficient γ is assumed and confirmed to be 1 for all species. At 100 atm γ should be estimated for each species by entering the $\gamma = f/p$ chart (see Section 7) using reduced temperature and pressure based on the reaction temperature and total pressure. Significant deviation of K_γ from 1 signals the necessity of its inclusion in the calculation. See the tabulation for Example 11 above.

Calculation of mole fraction NH₃: At total $P = 1$ atm, $K_\gamma = 1$. Let

X = partial pressure of N₂ in the reaction mixture

$3X$ = partial pressure of H₂

$1 - 4X$ = partial pressure of NH₃

$$K = K_\gamma K_p = 0.0431 \text{ atm}^{-1} = \frac{1 - 4X}{(3X)^{3/2}(X)^{1/2}}$$

$$1 - 4X = 0.0431(5.2X^2)$$

This is solved by the quadratic formula or successive approximation to give $X \cong 0.246$:

$$\text{Mole fraction } y_{\text{NH}_3} = \frac{p_{\text{NH}_3}}{p_{\text{total}}} = \frac{1 - 4X}{1} = 0.014$$

At total $P = 100$ atm, $K = 0.79$. Let

$$X = p_{\text{N}_2}$$

$$3X = p_{\text{H}_2}$$

$$K = 0.0431 = \frac{0.79(100 - 4X)}{(3X)^{3/2}(X)^{1/2}}$$

$$100 - 4X = p_{\text{NH}_3}$$

$$100 - 4X = \frac{0.0431}{0.79}(5.2X^2)$$

$$X = 13.0$$

$$\text{Mole fraction } y_{\text{NH}_3} = \frac{p_{\text{NH}_3}}{p_{\text{total}}} = \frac{100 - 4X}{100} = 0.48$$

Applications to Solution Chemistry. Equilibrium constants have important quantitative applications in solution chemistry, and specific K 's are given appropriate subscripts:

K_A = ionization constant for weak acids

K_B = ionization constant for weak bases

K_W = dissociation constant for water

K_D = dissociation constant for complex ions

K_{sp} = solubility product for slightly soluble species

Solutions and Solution Concentrations. Solutes are smaller amounts of any phase dissolved in larger amounts of liquid or solid solvents, resulting in single-phase solutions.

Solution concentrations are expressed in three ways:

1. *Molar* concentration M is gram moles of solute per liter of solution. Small temperature dependence exists due to density changes.
2. *Molal* concentration m is gram moles of solute per kilogram of solvent. Molal concentrations are not temperature dependent. Since volume of solution = (grams solute + grams solvent)/(solution density), molality m approximately equals molarity M only in dilute aqueous solutions.
3. *Mole fraction* x is the ratio of moles of component i to total moles of all species present in that phase:

$$x_i \text{ or } y_i = \frac{N_i}{N_{\text{total}}} \quad (39)$$

where N is number of moles.

Activity–Concentration Relationship for Solutes.

Activity coefficient γ is the ratio of activity a to molality m . At infinite dilution $\gamma = 1$ for all solutes, but γ varies with temperature, concentration, and the species involved (see Section 9). Activity is correctly used for equilibrium calculations, although molar concentrations are widely used as approximations.

Hydrogen Ion Concentration pH. The pH is an exponential notation using the operator p meaning $-\log_{10}$ to express a wide range of $[\text{H}^+]$. At $10^{-7} M [\text{H}^+]$, resulting from dissociation of water at ambient temperature, $\text{pH} = 7$.

7 PHASE EQUILIBRIA

Temperature–Pressure Phase Diagrams. Pure chemical species, in the absence of thermal decomposition, have temperature–pressure phase diagrams of the same general shape exemplified by Fig. 3. In this figure changes of state occur along transition lines, that is, sublimation along AB , fusion along BC , and vaporization along BD . Each phase transition is accompanied by volume, enthalpy, and entropy changes. Phase equilibrium exists at any T, P condition on a transition line. If multiple solid phases exist, transition occurs at T, P along lines such as EF .

Excepting material ($\text{H}_2\text{O}, \text{Bi}$) which expand on solidification BC slopes only slightly to the right. For different species the coordinates of triple and critical points differ, but the diagram retains the same general form. Logarithmic compression of scales is often helpful. The normal boiling point occurs along transition curve BD at $P = 1$ atm. The normal freezing point occurs approximately at the temperature of the triple point because of the almost vertical slope of line BC .

Equations of State. The PVT relations for gases are most simply expressed by the ideal-gas law $Pv = RT$, where v is molar volume, applicable with small error at pressures well below the critical pressure and

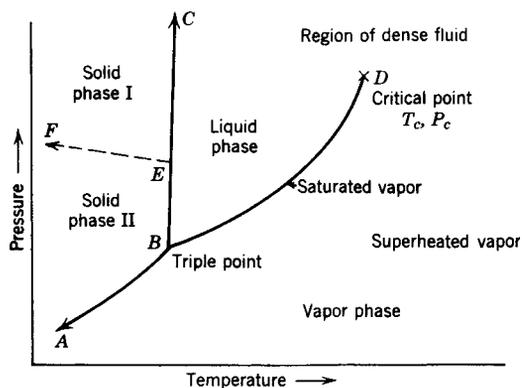

Fig. 3 Generalized temperature–pressure phase diagram.

at temperatures well above the condensation temperature. More precise equations of state are necessary for gases near their condensation conditions where atomic size becomes important and interaction must be considered. Several modifications are used, and all contain additional terms to improve precision near the liquid state. One of the several historical and more precise equations of state is the van der Waals equation

$$\left(P - \frac{a}{v^2}\right)(v - b) = RT \quad (40)$$

where a and b are dimensional and specific van der Waals constants applicable to individual gases. Constant a is a measure of the attractive force between molecules, and constant b is due to incompressibility and finite molecular volume.

The Redlich–Kwong equation is another example:

$$P = \frac{RT}{v - b} - \frac{a}{T^{1/2}v(v - b)} \quad (41)$$

where a and b are constants calculated from P_c and T_c available in Table 9.

Virial coefficients are used in more easily computed power series expansion used as equations of state:

$$Pv = RT + \frac{\beta}{v} + \frac{\gamma}{v^2} + \frac{\delta}{v^3} \quad \text{and}$$

$$Pv = RT + BP + CP^2 + DP^3 + \dots \quad (42)$$

where β, γ, δ , and B, C, D are second, third, and fourth virial coefficients

Reduced Equations of State. Coefficient of van der Waals equation of state, a and b , vary for individual gases and also vary to some extent with temperature. Coefficient a and b and the gas constant R can be generalized and expressed in terms of the critical constants for all gases using consistent units:

$$a = 3V_c^2 P_c = \left(\frac{3}{4}\right)^3 \frac{R^2 T_c^2}{P_c} \quad (43)$$

$$b = \frac{V_c}{3} = \frac{RT_c}{8P_c} \quad (44)$$

$$R = \frac{8 P_c V_c}{3 T_c} \quad (45)$$

Using reduced variables P_R, V_R , and T_R , the van der Waals equation of state yields a dimensionless reduced equation of state:

$$\left(P_R + \frac{3}{V_R^2}\right)(3V_R - 1) = 8T_R \quad (46)$$

This infers that all gases have the same V_R at equal values of P_R and of T_R . This reduced equation of state is generally applicable at elevated pressures and near the critical point.

Table 9 Critical Constants; Latent Heat of Vaporization at Normal Boiling Point

Corresponding States. The reduced equation of state, similar shapes of the basic T, P phase diagrams, maximum ΔH_v and ΔS_v at the triple point, and the disappearance of ΔH_v and ΔS_v at the critical point have led to the use of reduced pressure, volume, and temperature for correlation of other properties. These reduced variables $P_R, V_R,$ and T_R are defined as ratios of the existent to the critical variable:

$$P_R = \frac{P}{P_c} \quad V_R = \frac{V}{V_c} \quad T_R = \frac{T}{T_c} \quad (47)$$

Two gases are in corresponding states when they have the same values for two of the three reduced variables. Corresponding states permit property estimation by relating gases or liquids to comparable species where more complete PVT data are available.

Compressibility. The PVT relations of any gas may be expressed as

$$Pv = ZRT \quad (48)$$

where Z is the compressibility factor or ratio of the volume of a real gas to that of an ideal gas. If the parameters P and T are replaced by their ratios to the corresponding critical values, called reduced properties, all gases are in corresponding states and can be approximately represented by a general chart (Fig. 4) of Z versus P_R on lines of constant T_R .

Most individual gases deviate from such a general graph by 2–7%. Hydrogen and helium, however, deviate so much that the reduced properties for them are computed by adding 8 atm to the critical pressure and 8 K to the critical temperature.

Generalized Fugacity Chart. A generalized fugacity chart can be constructed from the compressibility chart by integration, along each isotherm, of

$$\ln \frac{f}{P} = \int_0^{P_R} (Z - 1) d(\ln P_R) \quad (49)$$

The result of these integrations is shown in Fig. 5.

Gas Mixtures. Mixtures of ideal gas have a compressibility $Z = 1$ at low pressures; however, mixtures of real gases deviate from ideality as pressure is increased. A compressibility factor for the mixture can be determined to simplify calculation. At pressures below 50 atm Dalton's law of additive partial pressures can be used for calculating mixture pressure, while above 300 atm Amagat's law of additive molal volumes allows better calculation of mixture volume. The pseudocritical point method may be used

to estimate mixture compressibility between 50 and 300 atm.

Dalton's Law of Additive Partial Pressures. For real gases below 50 atm, where the actual volume of the molecules is small relative to the volume occupied and where molecular interaction does not have a large effect, Dalton's law is valid:

$$P = \sum_i p_i \quad (50)$$

where $p_i = Py_i$ and P is total pressure, p_i is partial pressure of species i , and y_i is the mole fraction of species i .

Amagat's Law of Additive Molal Volumes. Amagat's law is valid at pressures above 300 atm:

$$V = \sum_i v_i \quad (51)$$

where $v_i = Vy_i$ and v_i is the molal volume of species i .

Molal Average Compressibility

$$Z = \sum_i y_i Z_i \quad (52)$$

where Z_i is determined using T_R and P_R for species i at the temperature of the mixture and at p_i for low total pressures (50 atm maximum) or at P for high total pressures (300 atm minimum).

Pseudocritical Point. In the absence of experimentally determined critical conditions for gas mixtures, pseudocritical temperature and pressures can be estimated as molal average values derived from components:

$$T_{pc} = \sum_i y_i T_{ci} \quad \text{and} \quad P_{pc} = \sum_i y_i P_{ci} \quad (53)$$

where T_{ci} and P_{ci} are critical temperature and pressure of pure component i and the subscript pc refers to pseudocritical. These values may be used for determining a reduced temperature and pressure for the mixture, from which a compressibility may be estimated.

Examples of Gas Mixture Calculations. Calculate molal volume at 100°C (373 K) of a mixture containing 30 mol % CO₂ and 70% N₂ at (a) 20 atm, (b) 70 atm, and (c) 400 atm.

- (a) At 20 atm use Dalton's law and molal average compressibility:

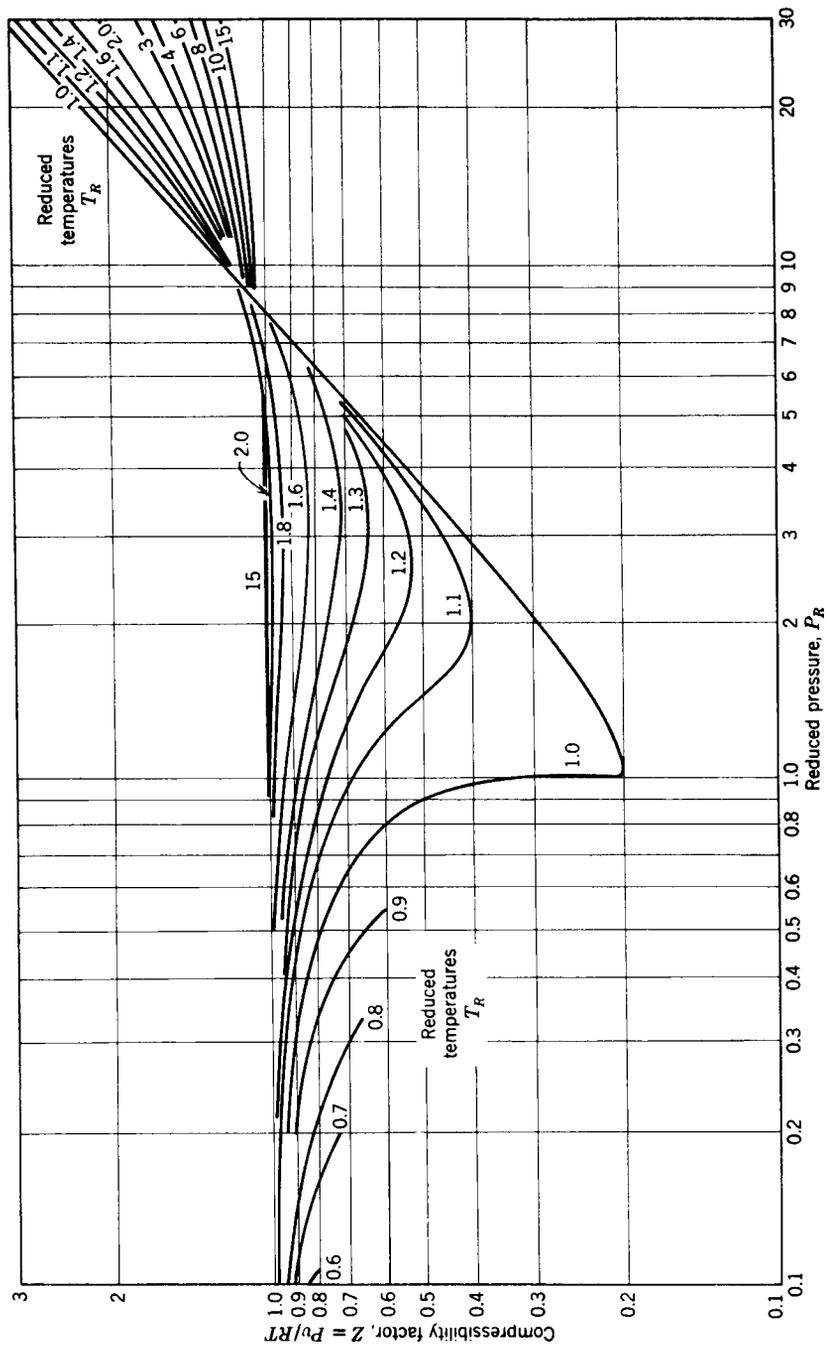

Fig. 4 Compressibility factor. (Reprinted by permission from M. Souders, *Engineers Companion*, Wiley, New York, 1966).

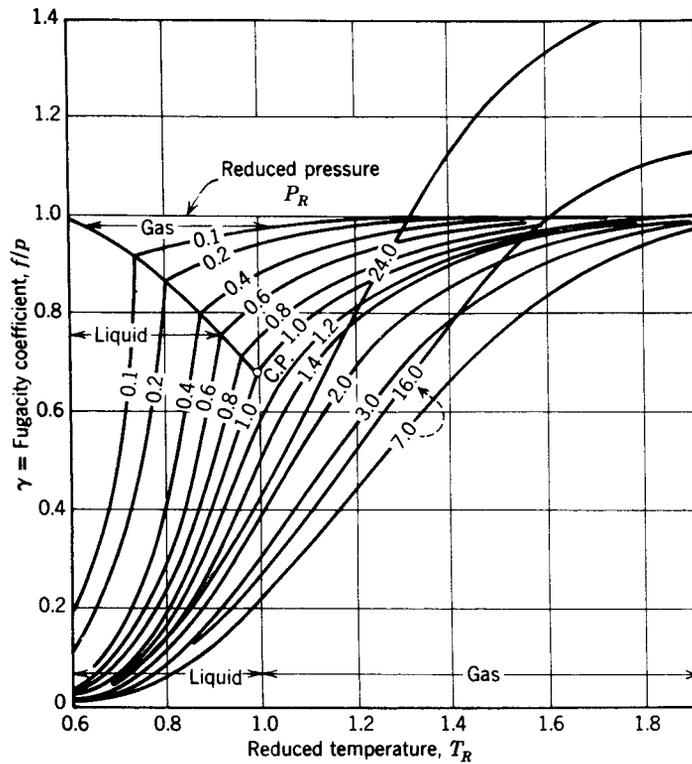

Fig. 5 Fugacity of gases and liquids. (Reprinted from O. A. Hougen, K. M. Watson, and R. A. Ragatz, *Chemical Process Principles*, Wiley, New York, 1959.)

For CO ₂	For N ₂
$y_i = 0.3$	$y_j = 0.7$
$p_i = 20(0.3)$ $= 6 \text{ atm}^a$	$p_j = 20(0.7)$ $= 14 \text{ atm}$
$T_c = 304 \text{ K}$	$T_c = 126 \text{ K}$
$P_c = 72.9 \text{ atm}$	$P_c = 33.5 \text{ atm}$
$T_R = \frac{373}{304}$ $= 1.23$	$T_R = \frac{373}{126}$ $= 2.96$
$P_R = \frac{6 \text{ atm}}{72.9}$ $= 0.082$	$P_R = \frac{14 \text{ atm}}{33.5}$ $= 0.42$
$Z_i = 0.98$	$Z_j = 0.99$
$Z_{\text{mixture}} = (0.3)(98) + (0.7)(99)$ $= 0.987$	
$v = \frac{ZRT}{P}$	

$$= \frac{(0.987)(0.0821)}{(20) \text{ atm}} 1 \text{ atm} (373) \text{ K/g mol K}$$

$$= 1.5 \text{ l/mol mixture}$$

^aThis assumes that Dalton's law holds.

- (b) At 70 atm use pseudocritical point to determine mixture compressibility:

$$\text{Mixture } T_{pc} = 0.3(304) + 0.7(126) = 179 \text{ K}$$

$$\text{Mixture } P_{pc} = 0.3(72.9) + 0.7(33.5) = 45.3 \text{ atm}$$

$$T_R = \frac{373}{179} = 2.08$$

$$P_R = \frac{70}{45.3} = 1.54$$

$$Z_{\text{mixture}} = 0.980$$

$$v = \frac{ZRT}{P} = \frac{(0.980)(0.0821)(373)}{70}$$

$$= 0.43 \text{ l/mol mixture}$$

- (c) At 400 atm use Amagat's law and molal average compressibility:

For CO ₂	For N ₂
$T_R = \frac{373}{304}$	$T_R = \frac{373}{126}$
= 1.23	= 2.96
$P_R = \frac{400}{72.9}$	$P_R = \frac{400}{33.5}$
= 5.49	= 8.38
$Z_i = 0.76$	$Z_i = 1.08$
$Z_{\text{mixture}} = (0.3)(0.76) + (0.7)(1.08)$	
= 0.984	
$v = \frac{ZRT}{P} = \frac{(0.984)(0.0821)(373)}{400}$	
= 0.075 l/ mol mixture	

Ideal Solutions. The activity of each constituent of ideal-liquid solutions is equal to its mole fraction under all conditions of temperature, pressure, and concentration. The solution volume exactly equals the summation of component volumes. The enthalpy of mixing of components is zero. The total vapor pressure is the summation of the contribution of individual components following Raoult's law. This also applies to solutions containing nonvolatile components. The freezing point of solvent in ideal solutions occurs at that temperature where the vapor pressure of the solution equals the vapor pressure of the solid solvent.

Real Solutions. Actual liquid solutions deviate from the preceding conditions of ideality. Most significant are positive or negative vapor pressure deviations from direct summation of component contributions; these affect behavior on distillation for separating the components. Deviations from ideality increase with solute concentration; that is, dilute solutions behave reasonably ideally.

Henry's Law. The solubility, and hence activity, of gaseous solute in liquid solvent is directly proportional to the partial pressure (fugacity) of the solute vapor phase in equilibrium with the solution. If the solution and vapor phases behave ideally, the molal fraction of the gas solute in solution at low concentration equals solute activity ($X_i = a_i$). Henry's law is

$$P y_i = h_T x_i \quad (54)$$

where y_i and x_i are mole fractions of i in the vapor and liquid phases, P is total pressure, and h_T is Henry's law of coefficient for i at temperature T . The solubility of gases in liquids is inversely proportional to temperature, and frequently chemical similarity between solute and solvent leads to a higher solubility. Henry's law applies to the same molecular species of solute in the solution and in the gas phases. For example, for

NH₃, CO₂, SO₂, H₂S, Cl₂, HCl, and so on, in water it applies to the unhydrated, undissociated species in equilibrium.

For nonreactive, unhydrated, and undissociated gases such as O₂, N₂, H₂, CO, and CH₄ in water, h_T is on the order of 10^{-5} atm⁻¹ between 0 and 80°C. Similar data of different magnitudes are existent for nonaqueous solvents, but a wider range of this type of data is presented in vapor-liquid equilibrium diagrams.

Raoult's Law. For ideal-vapor and ideal-liquid solutions at any temperature, the equilibrium partial pressure of any component of a liquid solution equals the product of the vapor pressure of that pure component and its mole fraction in solution:

$$P y_i = p_i^\circ x_i = p_i \quad (55)$$

where y_i and x_i are the mole fractions of i in the vapor and liquid phase, P is total pressure, p_i° is the vapor pressure of pure i , and p_i is the actual partial pressure of i , all at temperature T . For ideal solutions Raoult's law holds for all mole fractions of a component, while for real solutions it can be assumed valid only for mole fractions near unity. Interaction between dissimilar species in the liquid phase leads to large deviations from ideal solution behavior and hence divergence from conformity with Raoult's law. Raoult's law can be considered a special case of Henry's law where Henry's law coefficient h_T is equal to the vapor pressure of pure component i , p_i° at that temperature.

Nernst Distribution Law. The equilibrium distribution of solute between two immiscible liquid phases at temperature T is constant regardless of concentration and is equal to the ratio of solute activities in the two phases:

$$K = \frac{a_1}{a_2} \quad (56)$$

where a_1 is the activity in phase 1 and a_2 is the activity in phase 2. In dilute solutions molar concentrations can be used to replace activities.

Gibbs Phase Rule. The phase rule gives the relationship to define heterogeneous phase equilibria:

$$P + F = C + 2 \quad (57)$$

where P is the number of separate phases involved, C is the number of components (minimum number of chemical species necessary to define composition of all phases), and F is the number of degrees of freedom or number of variables, such as temperature, pressure, or concentration, of each component that can be varied independently without changing the number of phases.

Example 12

1. *Water at the triple point.* Solid, liquid, and vapor phases are in equilibrium. A pure compound is a single component, and its concentration in each phase is determined to be 100 mol %. Therefore $P = 3$, $C = 1$, and F is to be determined by substituting these values in Eq. (57):

$$3 + F = 1 + 2$$

Hence $F = 0$, and the system is invariant; temperature and pressure are fixed, and a shift in either will reduce the number of phases in equilibrium.

2. *For a three-component system, defined by T , P but not composition,* determine the number of phases present; $F = 2$, $C = 3$, and P is to be determined:

$$P + 2 = 3 + 2$$

Therefore $P = 3$ phases. Further define the concentration of one of the three components raises F to 3 and reduces the number of phases to 2. Define the concentration of two components also establishes the concentration of the third, raises F to 4, and reduces the number of phases to 1.

3. *Two-component system at liquid–vapor equilibrium (two phases).* The concentrations in the two phases are not independent; $P = 2$, $C = 2$, and F is to be determined:

$$2 + F = 2 + 2$$

Two of the three independent variables (T and P , or concentration of only one component) are required to define the system; the third is fixed

Colligative Properties of Solutions. Colligative properties depend on the number, rather than the nature, of particles in solution: nonelectrolytes, being undissociated, yield one particular per molecules unless they are dimerized. Strong electrolytes ionized to an extent indicated by their activity yield several ions. Colligative properties are (a) boiling point elevation as a direct consequence of vapor pressure reduction; (b) freezing point depression, also as a direct consequence of vapor pressure reduction; and (c) osmotic pressure. Since ideal solutions are expected at low concentrations, changes in these colligative properties are predictable.

Binary Solution Vapor–Liquid Equilibria. In the vapor phase

$$P_{\text{total}} = p_i + p_j$$

$$N_{\text{total}} = N_i + N_j$$

$$y_i = \frac{p_i}{P_{\text{total}}}$$

$$y_i + y_j = 1 \quad (58)$$

where p_i is the partial pressure, y_i is the mole fraction, and N_i is the number of moles of i .

In the liquid phase

$$x_i = \frac{N_i}{N_{\text{total}}}$$

$$x_i + x_j = 1$$

$$N_{\text{total}} = N_i + N_j \quad (59)$$

where x_i is the mole fraction of i .

- (a) *Ideal Solutions.* Each component of an ideal solution obeys Raoult's law [Eq. (55)], relating concentrations in vapor and liquid phases.

- (b) *Real Solutions.* Numerical distillation calculations often use a vapor–liquid equilibrium ratio K for each component:

$$K_i = \frac{y_i}{x_i} = \frac{f \text{ of pure } i \text{ at its vapor pressure at } T \text{ of system}}{f \text{ of pure } i \text{ at } T, P \text{ of system}} \quad (60)$$

The volatility ratio between components of binary solutions is

$$\alpha = \frac{k_i}{k_j} = \frac{y_i x_i}{x_i y_j} \quad (61)$$

where α is the volatility ratio. For ideal binary solutions, where α is constant, manipulation of Eqs. (60) and (61) relates the mole fraction in the vapor phase y_i to the volatility ratio α and the mole fraction in the liquid phase x_i :

$$y_i = \frac{\alpha x_i}{1 + x_i(\alpha - 1)} \quad (62)$$

Binary Solution Vapor Pressure–Composition Diagrams

- Ideal solutions follow Raoult's law [Eq. (55)]. As shown in Fig. 6a, the vapor pressure of each component is linear and proportional to the mole fraction, and the vapor pressure of the mixture is the simple sum of the component vapor pressures. The diagrams shown represent one fixed temperature.
- Real solutions show significant deviations from linearity of individual vapor pressures with the mole fraction. At low mole fractions in the liquid phase, Henry's law [Eq. (54)] is followed, while at high mole fractions, Raoult's law tends to be followed. These deviations from linearity are shown in Figs. 6b, c.

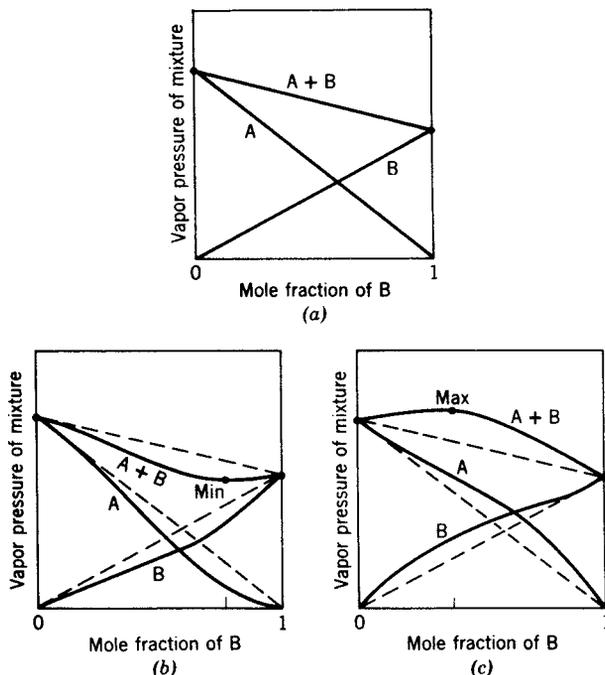

Fig. 6 Binary solution vapor pressure-composition diagrams.

Boiling Point-Composition Diagrams. Figure 7 shows three types of boiling point-composition diagrams. These are drawn for a single pressure. Figure 7a is the usual case for ideal solutions; it corresponds with the vapor pressure diagram 6a. At any given temperature, vapor composition y is in equilibrium with liquid composition x . This ideal type of boiling point diagram exists for many combinations of chemically similar materials.

Figures 7b,c correspond to the vapor pressure diagrams in Figs. 6b,c.

Azeotropes (constant-boiling mixtures) exist at 1 and 2. Their composition can be altered by changing pressure. These arise from nonideality of the solutions. For collected data on azeotropes, see *Handbook of Chemistry and Physics*.²

Freezing Point-Composition Diagrams. The freezing point is essentially independent of pressure, and the binary freezing point-composition diagrams of Fig. 8 apply over an extended pressure range. The usual case of two similar and mutually soluble components is to form a continuous series of solid and liquid solutions as shown in Fig. 8a. At any one temperature the composition of the liquid phase differs from that of the solid phase in equilibrium with it. Nonidealities in the liquid and solid solutions can give rise to a composition of minimum freezing point typified by Fig. 8b. Where components of the binary mixture

have limited mutual solubility, a eutectic composition exists, and this is a mechanical mixture of the two components. A phase diagram idealized by Fig. 8c then occurs. Maximum-melting-point mixtures are rare, and the existence of a maximum is due to formation of a definite compound. Figure 8d shows the existence of an equimolar compound A_1B_1 . The resultant phase diagram then shows two eutectic diagrams placed side by side. One of these eutectics exists for component A and compound A_1B_1 ; the other exists for compound A_1B_1 and component B.

Numerous proliferations of these basic types of phase diagrams exist. All may be interpreted on the basis of the temperature and composition range for mutual solubility, the existence of nonideal solutions, and the formation of compounds stable over an often limited temperature range.

8 CHEMICAL REACTION RATES

Process Kinetics and Conversion. The kinetics of chemical reactions vary widely, ranging from a rapid approach to equilibrium for ionic reactions in aqueous media (primarily limited by diffusion and mixing) to a much slower approach to equilibrium for organic reactions involving covalent bonds. The net reaction rate at equilibrium is zero, and further conversion of reactants to products depends upon the rate of product removal from the reaction system so the

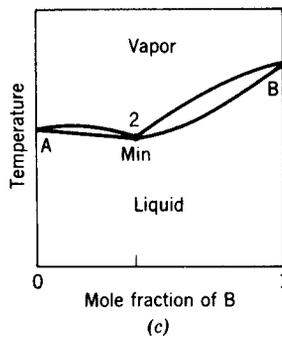

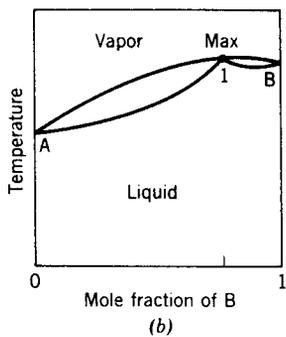

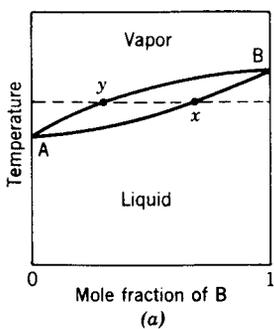

Fig. 7 Binary solution boiling point-composition diagrams.

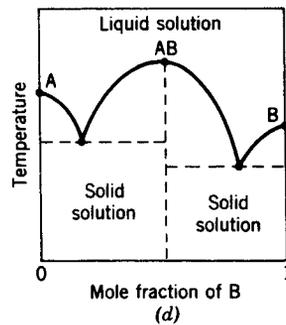

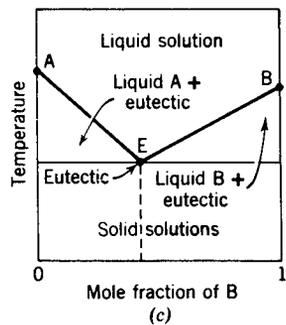

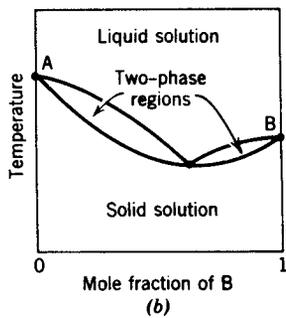

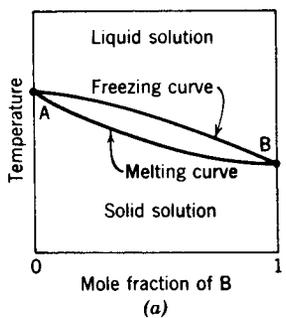

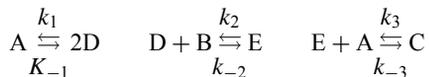

Fig. 8 Binary solution freezing point-composition diagrams.

reaction can again proceed at a finite rate toward equilibrium. Only temperature can shift the equilibrium constant of the reaction system; however, the physical control of reactant and product concentrations can allow a reaction to proceed to complete conversion of reactants to product despite an equilibrium situation that may permit a maximum of a few percent of product in the system at any instant.

Kinetics of Reaction. This is concerned with the rate of approach to a temperature-dependent equilibrium condition. The rate varies with the following:

- Displacement from Equilibrium. This is dependent on the reactant and product concentrations.
- Temperature. In addition to changing the numerical value of the equilibrium constant and altering the diffusional mobility, increased temperature raises the fraction of molecules with enough energy to react.
- Catalysis. This modifies the reaction mechanism and may provide a lower energy path from reactants to products and vice versa. Catalysis has no effect on equilibrium.
- Inhibition. Inhibitors block an existent low-energy path between reactants and products, for example, by an essentially irreversible reaction with a catalytic surface.

Reaction Mechanism and Reaction Rate. Most reactions proceed via a sequence of several reversible steps. For example, the net reaction $aA + bB \rightleftharpoons cC$ might actually involve the following elementary steps:

where D and E are intermediates. The rate law for each of the species follows directly from the mechanism, for example,

$$\frac{d[E]}{dt} = k_2[B][D] - k_{-2}[E] - k_3[A][E] + k_{-3}[C]$$

where the brackets denote the concentration of the species. (There are analogous expressions for, for example, $d[A]/dt$.) Determination of the overall rate of reaction requires the solution of the set of coupled differential equations for all of the species, and the resulting rate law will be a complex function of $[A]$, $[B]$, $[C]$, and the k 's. While the expression for the equilibrium constant K is related to the stoichiometry of just the net reaction, the time dependence of the approach to equilibrium depends on the details of the mechanism.

Activation Energy. An enthalpy-versus-reaction diagram (Fig. 9) can be ideally drawn for any reac-

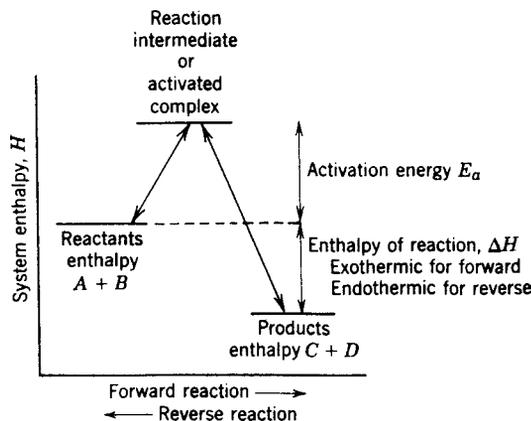

Fig. 9 Enthalpy-reaction diagram.

tion. An activation energy barrier exists between reactants and products, and enthalpy of reaction ΔH separates the enthalpies of reactants and of products. Reactant molecules must receive a minimum activation energy E_a before they are energetic enough to react. For the reverse reaction, product molecules must receive $E_a + \Delta H$ before they can react in the reverse direction. Catalysts modify the intermediate condition and result in a reduced activation energy by providing a lower energy path between reactants and products; by so doing, they effectively speed both forward and reverse reactions without affecting the equilibrium condition.

Collision Theory. Energy of activation results from the statistical probability that some molecules, after collision with others, conserving momentum, have energy enough for reaction to occur. An elevated temperature increases the Maxwell-Boltzmann energy distribution of molecules and raises the number of molecules having the energy required for the reaction.

Rate Dependence on Temperature. The population of high-energy molecules is directly correlated with the temperature dependence on the reaction rate using the Arrhenius equation (which has a form similar to the dependence of the equilibrium constant on temperature)

$$\frac{d \ln k}{dT} = \frac{E_a}{RT^2} \quad (63)$$

where E_a is the activation energy, R is the gas constant, and T is the absolute temperature. Integration of Eq. (63) yields $\ln k = -E_a/RT + \text{const}$. A plot of $\ln k$ versus $1/T$ is a straight line with slope equal to $-E_a/R$, from which the activation energy can be obtained. It shows that a rate at 25°C will double for a 10°C temperature rise when the activation energy is 12.5 kcal/g mol . A lower activation energy gives a

smaller rate increase, and a higher energy gives a larger rate increase. *Caution*: Changes of mechanism, via catalysis or otherwise, will alter the E_a of a reaction.

Reaction Mechanisms. The low statistical probability of trimolecular collisions essentially precludes the possibility that any reaction can proceed in one step according to the stoichiometric equation. More probable is a sequence of bimolecular reactions forming intermediate species, some of which may be too short-lived to isolate. Each of these stepwise reactions has its equilibrium constant and rates dependent on species concentrations. Usually one step is limiting and becomes the rate-determining factor for the entire reaction. The intermediate species may be an activated complex that rearranges to produce the reaction products.

Different reaction mechanisms have been postulated and proved for many reactions:

1. Simple bimolecular collision.
2. Chain reaction for polymerization, with initiation, propagation, and termination steps.
3. Free-radical, photoinitiated reactions.
4. Acid- or base-catalyzed intermediate steps.
5. Activated complex on a heterogeneous catalyst surface, with adsorption-desorption contributing to the overall rate.
6. Solvolysis participation in the reaction sequences.

Many processes have been studied in detail, with reaction sequences, proven or postulated, consistent with experimentally determined kinetics.

Initial Rate Equation. A reaction rate equation can be experimentally deduced and, from this, a reaction mechanism postulated. The initial rate equation has the generalized form

$$-\frac{dC_A}{dt} = kC_A^a C_B^b \dots \quad (64)$$

where $-dC_A/dt$ is the rate of decrease of reactant A and is dependent upon a product of concentration terms. The order of a reaction is the sum of the exponents of concentration terms in the rate equation. It need not be a whole number; it may be $0, \frac{1}{2}, 1, \frac{3}{2},$ or 2. There is no necessary relationship between the reaction order and the form of the overall stoichiometric relation. Where one of the reactants is a solvent, its concentration does not effectively change, and it will not appear in the rate equation.

Heterogeneous (Contact) Catalysis. Contact catalysis for gas-phase reactions involves surface adsorption and reaction at active sites. Adsorption can be either physical, with a mono- or multimolecular gas layer, or chemical (chemisorption), with a monomolecular layer in some activated state. A large surface area is required. Steps involved in a catalyzed reaction are

1. Adsorption of reactants (favored at low temperature)
2. Activation
3. Reaction
4. Desorption of products (favored at high temperature)

For monolayer coverage, the amount of adsorption from the gas phase can be represented by the Langmuir adsorption isotherm

$$y = \frac{ap}{1 + bp} \quad (65)$$

where y is the fraction of area covered, p is pressure, and a and b are empirical constants applicable at one temperature only.

Adsorption from the liquid phase is represented by the Freundlich equation

$$y = aC^{1/b} \quad (66)$$

where C is the concentration of the solute and a and b are empirical and applicable at one temperature only.

Catalyst poisoning involves blocking active sites on the catalyst surface by adsorbed material that is not readily desorbed.

Photochemical Reactions. Many reactions proceed via ultraviolet (UV) energy absorption. Photons from mercury vapor at $2536 \text{ \AA} \cong 113 \text{ kcal/g mol}$ are absorbed, one maximum per molecule, and have energy sufficient to disrupt chemical bonds (usual range of 80–100 kcal) and form reactive free-radical species. Photons of infrared (IR) wavelength $9000 \text{ \AA} \cong 31.8 \text{ kcal/g mol}$ do not have sufficient energy for bond disruption, although they do increase the overall thermal energy of a system.

An Einstein is an Avogadro number (6.02×10^{23}) of photons.

9 ELECTROCHEMISTRY

Chemical Energy of Redox Reactions. The chemical energy of redox reactions can be equated at constant T, P with Gibbs free energy using Eq. (7):

$$dG = -S dT + V dP + \sum_i \mu_i dN_i$$

Since dT and dP are both zero at constant T, P , then $dG = \sum_i \mu_i dN_i$. Gibbs free energy then can be manifest as electrical energy by an electron flow through an external conductor provided there is electrical isolation of the oxidation reaction (electron source) and reduction reaction (electron sink). The external conductor transfers electrons from source to sink, and a liquid junction permits internal migration of ions for preservation of charge neutrality of the system as a whole.

Chemical energy at constant T, P can be considered convertible to electrical and/or thermal energy, for it can be shown by conservation of energy that $\sum_i \mu_i dN_i = -E dq - T dS$. In the absence of $T dS$ thermal energy,

$$dG = -E dq \quad (67)$$

where E is in volts, dq is in coulombs per gram mole, and dG is energy in joules per gram mole. Joules are convertible to calories by $J = 4.185 \text{ J/cal}$.

Without source-sink electrical isolation, an internal short circuit results in energy conversion to thermal. Thus at constant T, P

$$dG = -T dS \quad (68)$$

where T is in degrees Kelvin and dS is in calories per gram mole per degrees Kelvin.

Faraday F. This is the 96,500 C charge carried by 1 g equivalent or an Avogadro number of electrons. Hence

$$dq = F dn \quad (69)$$

where dn is the number of gram equivalents.

Standard Potential, E° Volts. The superscript refers to the standard conditions of 25°C (298 K), 1 atm fugacity (pressure), and 1 M activity of reactants and products, the same conditions as for ΔG° , thus establishing dimensionally correct conversion of energy terms at the standard thermodynamic reaction condition:

$$dG^\circ = -\frac{dnFE^\circ}{J} \quad \text{or} \quad \Delta G^\circ = -\frac{nFE^\circ}{J} \quad (70)$$

in integrated form. If the equilibrium constant for the reaction is known at 298 K, $\Delta G_T^\circ = -RT \ln K$ can be used to calculate ΔG° , which can then be related to E° via Eq. (70). ΔG° indicates the magnitude of displacement from equilibrium that exists at 298 K when all reactants and products are at unit activity:

$$\Delta G^\circ = RT \ln(1) - RT \ln K = -RT \ln K = -\frac{nFE^\circ}{J} \quad (71)$$

Potential E_T° at Temperatures Other Than 298 K.

The ΔG_T° calculated for reactions at other temperatures [via. Eq. (11)] can be directly related to E_T° . Similarly, experimental values of the equilibrium constant K can be related to ΔG_T° [via Eq. (23)] and then to E_T° using

$$\Delta G_T^\circ = -RT \ln K = -\frac{nFE_T^\circ}{J} \quad (72)$$

Potential E at Other Concentrations—Nernst Equation. No driving force exists at equilibrium where $\Delta G = 0$, and the driving force is directly related to displacement from equilibrium. Therefore, an E value can be corrected for reactant and product activities other than 1 at 298 K by using the general equation

$$G = RT \ln K' - RT \ln K = \frac{-nFE}{J} \quad (73)$$

where K' has the form and exponents of the reaction equilibrium constant but uses actual activities of products and reactants in the system rather than those existent at equilibrium.

Combining Eqs. (71) and (73) yields the Nernst equation

$$E = E_0 - \frac{JRT}{nF} \ln K' \quad (74)$$

At $T = 298 \text{ K}$, this equation reduces to the usual equation

$$E = E^\circ - \frac{0.0592}{n} \log_{10} K' \quad (75)$$

Both equations reduce E to zero at equilibrium concentrations. At temperatures other than 298 K, E_T° instead of E° may be used in the general equation to obtain E actual.

Standard Reduction Potential E° . Being related to both ΔG° and to equilibrium constant K at standard conditions, E° is a measure of the chemical energy available from redox reactions. Tabulated potentials for a number of half-reactions in aqueous solution can be combined to give the standard potential of all possible combinations of these half-reactions. Table 10 gives the standard potentials for reduction half-reactions in 1 M acid and neutral media and in 1 M base media because the reactions and their potentials change in many cases. The table is reversible because a reduction half-reaction (with its E°), on reversal, becomes an oxidation half-reaction (with the same numerical E° but of opposite sign).

Example 13 See the tabulation for Example 13 on page 1236.

- Sign Convention.* Since E° for $2\text{H}^+ + 2e^- = \text{H}_2$ is taken as a zero reference potential, all positive E° values indicate the reaction can proceed as written, and all negative E° values indicate that the reverse reaction (with a positive E° value) can occur.
- Oxidation Potential.* Reversal of any reduction half-reaction and change of sign of the reduction potential generates an oxidation half-reaction with its oxidation potential.

Table 10 Reduction Potentials

Acid Solution	E^0	Basic Solution	E°_B
Aluminum			
$\text{Al}^{3+} + 3e^- \rightarrow \text{Al}$	-1.66	$\text{H}_2\text{AlO}_3^- + \text{H}_2\text{O} + 3e^- \rightarrow \text{Al} + 4\text{OH}^-$	-2.35

$\text{Zr}^{4+} + 4e^- \rightarrow \text{Zr}$	-1.53	$\text{H}_2\text{ZrO}_3 + \text{H}_2\text{O} + 4e^- \rightarrow \text{Zr} + 4\text{OH}^-$	-2.36

Tabulation for Example 13

Reduction	$\text{Zn}^{2+} + 2e^- \rightarrow \text{Zn}$	$E^\circ = -0.76 \text{ V}$ in neutral or acid
Oxidation	$\text{Zn} \rightarrow \text{Zn}^{2+} + 2e^-$	$E^\circ = +0.76 \text{ V}$ in neutral or acid
Reduction	$\text{ZnO}_2^{2-} + 2\text{H}_2\text{O} + 2e^- \rightarrow \text{Zn} + 4\text{OH}^-$	$E_B^\circ = -1.22 \text{ V}$ in base
Oxidation	$\text{Zn} + 4\text{OH}^- \rightarrow \text{ZnO}_2^{2-} + 2\text{H}_2\text{O} + 2e^-$	$E_B^\circ = +1.22 \text{ V}$ in base

Reduction Potentials for Other Than Tabulated Half-Reactions. These may be obtained by adding or subtracting known half-reactions provided correction is made for the different numbers of electrons involved. This is done by summing voltage equivalents nE° and dividing by n , the number of electrons involved in the final derived equation.

Example 14

$\text{Fe}^{2+} + 2e^- \rightarrow \text{Fe}$	$E^\circ = -0.44 \text{ V}$	$nE^\circ = -0.88$
$\text{Fe}^{3+} + e^- \rightarrow \text{Fe}^{2+}$	$E^\circ = +0.77 \text{ V}$	$nE^\circ = +0.77$
$\text{Fe}^{3+} + 3e^- \rightarrow \text{Fe}$		$nE^\circ = -0.11$

Therefore, $E^\circ = -0.11/3 = -0.04 \text{ V}$.

Doubling stoichiometric coefficients of an equation does not change E° since E° is a molal quantity.

Relationship of Tabulated Reduction Potentials to "Electromotive Series." A compilation of standard reduction potentials, in acid, of metal-to-ion reduction half-reactions arranged in order of decreasing E° values comprises the usual abbreviated electromotive series tabulations.

Table of Standard Reduction Potentials in Aqueous Solution. The potentials listed are derived from Latimer with additions from the recent literature. The E° values in volts for the reduction equations as written are based on a zero-reference voltage for the

hydrogen couple at 25°C. Not all reactions are physically reversible or achievable as written under usual laboratory conditions. They are for 1 M activities for water-soluble species, for 1 atm fugacity for gases, and do not take into account overvoltages necessary for gas evolution at electrodes. Within the limitations imposed, these remain one of the most reliable sources of relative potential for reaction, although they infer nothing about reaction rate.

Significance of Reduction Half-Reactions and Potentials for Predicting Chemical Reactivity

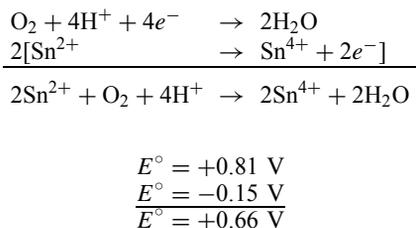

1. Reaction with acids, water, and bases. Stability of solutions to air oxidation.
2. Redox reactions. A source of balanced half-reactions that may be added to give balanced redox reactions.
3. A systematic guide to descriptive inorganic chemistry and usual oxidation states.
4. Compound disproportionation (self-oxidation and reduction).

Reactions with Acids, Bases, Water, or Air.

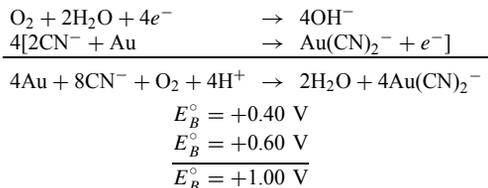

Such reactions add complexity to all chemical reactions and offer competing reactions. If a potential exists to oxidize or reduce water (consider the pH of the system), that oxidation or reduction can proceed. Atmospheric oxygen is easily reduced (is a moderately strong oxidizing agent), and its reactions in systems exposed to air may be significant. These important potentials, listed under hydrogen and oxygen in the reduction potential table, are pH dependent and are summarized in Table 11.

Example 15

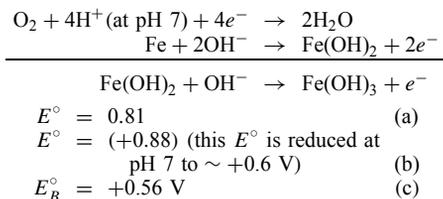

1. Air can oxidize Sn^{2+} to Sn^{4+} in neutral solution:

2. Gold is dissolved by dilute cyanide solution with air oxidation in alkaline solution:

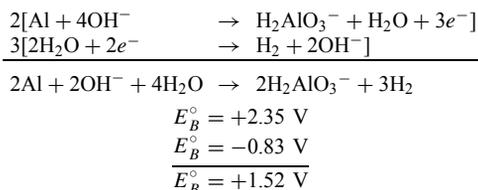

3. Iron rusting in neutral solution:

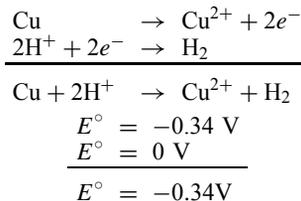

The reduction of oxygen reaction (a) and the oxidation of iron reaction (b) are followed by further reactions (a) and (c). An alkaline solution reduces potential (a) to +0.40 and an acid solution increases it to +1.23. Many reaction schemes are postulated for rusting; this one is plausible. Overall corrosion rate is increased at low pH and is dependent on oxygen diffusion rate.

4. Aluminum dissolves in a base to liberate hydrogen:

5. Copper will not dissolve in a nonoxidizing acid:

and reaction cannot proceed spontaneously

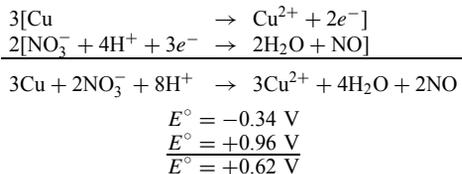

Table 11 Summary of Air and Water Reduction Potentials

Acidic Solution, pH 0	Neutral, pH 7	Basic Solution, pH 14
$\text{O}_2 + 4\text{H}^+ + 4e^- \rightarrow 2\text{H}_2\text{O}$ $E^\circ = +1.23 \text{ V}$	$\text{O}_2 + 4\text{H}^+ + 4e^- \rightarrow 2\text{H}_2\text{O}$ $E^\circ = +0.81 \text{ V}$	$\text{O}_2 + 2\text{H}_2\text{O} + 4e^- \rightarrow 4\text{OH}^-$ $E_B^\circ = +0.40 \text{ V}$
$2\text{H}^+ + 2e^- \rightarrow \text{H}_2$ $E^\circ = 0 \text{ V}$	$2\text{H}^+ + 2e^- \rightarrow \text{H}_2$ $E^\circ = -0.41 \text{ V}$	$2\text{H}_2\text{O} + 2e^- \rightarrow \text{H}_2 + 2\text{OH}^-$ $E_B^\circ = -0.83 \text{ V}$

Tabulation for Example 17

Reactions at Anode		Reactions Possible at Cathode	
$\text{Fe} \rightarrow \text{Fe}^{2+} + 2e^-$	$E^\circ = +0.44 \text{ V}$	At low concentrations:	
$\text{Cu} \rightarrow \text{Cu}^{2+} + 2e^-$	$E^\circ = -0.34 \text{ V}$	$\text{Fe}^{2+} + 2e^- \rightarrow \text{Fe}$	$E^\circ = -0.44 \text{ V}$
$\text{Ag} \rightarrow \text{Ag}^+ + e^-$	$E^\circ = -0.80 \text{ V}$	At high concentrations:	
		$\text{Cu}^{2+} + 2e^- \rightarrow \text{Cu}$	$E^\circ = 0.34 \text{ V}$

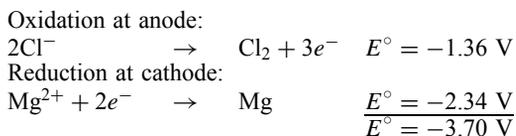

6. Copper will dissolve in oxidizing acids (example: nitric):

Electrolytic Cells. Electrolysis cells and the charging of batteries are comparable because an external applied voltage is used, depending on polarity, to augment the rate or to reverse the direction of spontaneous reaction. For example, charging a lead storage battery requires an opposing voltage greater than that of the spontaneous discharge reaction to reverse the direction of the oxidation and reduction reactions. Electrolysis cells can be operated using either molten salts or aqueous solutions, both of which are conductive.

(a) *Molten Salt Cells.* These cells are simple and straightforward in their operation.

Example 16. Electrolysis of fused MgCl_2 (with NaCl added to reduce melting point) liberates chlorine at the anode and magnesium metal at the cathode:

Possible competitive reactions do not occur because the minimum applied potential of 3.70 V (plus IR losses) reduces the magnesium ion more easily than the sodium ion:

Although E° is not directly applicable because of the nonaqueous media, elevated temperature, and high ionic concentrations, it can be helpful as a very crude approximation.

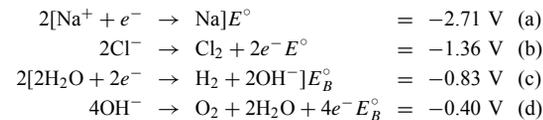

(b) *Aqueous Solution Electrolysis Cells.* These cells are used for electroplating, electrolytic copper purification, and many chemical reactions. Competing reactions such as electrolysis of water and overvoltages

required for oxygen and hydrogen bubble formation and evolution are complications encountered.

Example 17. Electrolysis in Aqueous Solution of Electrolytic Copper. Purification of impure copper requires its separation from Fe, Ag, Ni, Sb, and As metals. An electrolytic cell with an impure copper anode, CuSO_4 solution as electrolyte, and a pure copper cathode is used. See the tabulation for Example 17 above.

By application of a low voltage, Cu and the more easily oxidized metals Fe, Ni, Sb, and As are selectively dissolved at the anode, leaving Ag and metals that are more difficult to oxidize. Copper metal is deposited at the cathode and the more easily oxidized (less easily reduced) ions Fe^{2+} , Ni^{2+} , Sb^{3+} , and As^{3+} remain and accumulate in solution, replacing the Cu^{2+} of the electrolyte.

Overvoltage for Gas Evolution. Gaseous products can be formed and react with an anode at voltages consistent with their E° values; however, bubble formation and evolution from inert anodes require an overvoltage. Overvoltage is experimentally dependent upon anode surface and current density. The approximate values in Table 12 show the large potentials required and the facts that hydrogen and halogen have very low overvoltages on platinum black and that oxygen, though high, is minimum on that particular surface. Reaction with noninert electrodes occurs whenever possible. The effect of overvoltage on the selection of alternate reactions that may occur is shown in the following example: Electrolysis of NaCl (basic aqueous solution) forms H_2 and Cl_2 on graphite electrodes:

Reduction reactions (a) or (c) can occur; (c), the easiest reaction, occurs and liberates hydrogen (despite the hydrogen evolution overvoltage). Oxidation reactions (b) or (d) can occur; they are dependent on the low concentration of OH^- , the high concentration of Cl^- , and the much lower overvoltage for Cl_2 than for O_2 evolution, and Cl_2 is preferentially evolved. The net result is that reactions (b) and (c) occur.

Table 12 Approximate Overvoltages for Gas Evolution

	At 0.01 A/cm ²			At 0.1 A/cm ²			At 1 A/cm ²		
	O ₂	H ₂	Cl ₂	O ₂	H ₂	Cl ₂	O ₂	H ₂	Cl ₂

Definitions

Anode.

Oxidation occurs at this electrode; site where reducing agent is oxidized; source of electrons to external circuit whether battery or electrolytic cell; electrode labeled negative terminal on batteries (physically labeled for condition of discharge); anode of a discharging battery becomes its cathode during charging (or acting as an electrolytic cell); name of electrode connected to positive terminal of external voltage source for charging a battery or for electrolytic cell; anions (negative ions) migrate toward it in an electrolytic cell.

Cathode.

Reduction occurs at this electrode. Its characteristics are reversed from those of the anode.

Refer to redox terminology of Table 4.

Batteries. Batteries are redox cells that are physically arranged for external flow and internal ion mobility. When different electrolytes are used, gel structures or a porous membrane prevent mixing. The electrolyte(s) must permit ionization of the reactant species and be conductive. Mobility of ions in solution provides the mechanism for maintaining a charge balance and electrical neutrality within the electrolyte. By convention, batteries are labeled negative at the anode of the spontaneous discharge reaction.

(a) *Voltage.* Open-circuit terminal voltage is concentration and temperature dependent due to changes in chemical potential and is reduced by internal *IR* drop under current flow conditions. The current available depends on the reaction rate, which is a function of temperature and is not directly predictable from E° values. For practical battery configuration E° provides a reasonable voltage estimate.

(b) *Polarization.* Polarization is a localized accumulation of reaction products at an electrode until their concentration is reduced by diffusion, precipitation, formation of complexes, or further reaction to form new species not involved in the electrode reaction. Depolarization is the process of reducing the localized high concentration of reaction products; if depolar-

ization is by a diffusional process, the cell may be reversible because the products retain their chemical identity and physical availability.

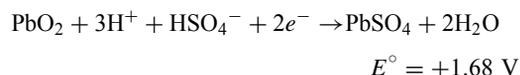

(c) *Irreversibility.* Although all redox reactions are ideally reversible near equilibrium, many cells operate far from equilibrium and with secondary reactions or physical configuration that render the cell partially, if not completely, irreversible for practical purposes. This situation results in having many cells that can convert their chemical energy to electrical and a limited few that are reversible for use as practical and economic storage batteries.

(d) *Battery Reactions.* Battery reactions on discharge are listed in what follows. Only a few are designed for reversibility.

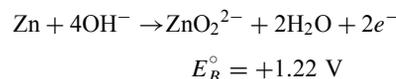

1. *Lead Storage Battery* (H₂SO₄ Electrolyte) (Reversible). Oxidation reaction at lead plates, labeled electrically negative:

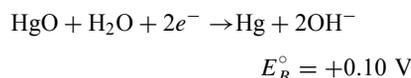

Reduction reaction at lead dioxide plates, labeled electrically positive:

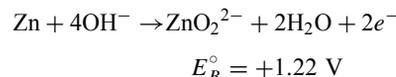

2. *Mercury Cell* (KOH Electrolyte Saturated with ZnO). Oxidation (negative terminal):

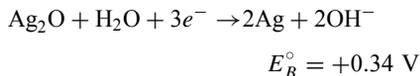

Reduction (positive terminal):

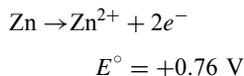

3. *Zinc-Silver Peroxide Cell* (KOH Electrolyte Saturated with ZnO). Oxidation (negative terminal):

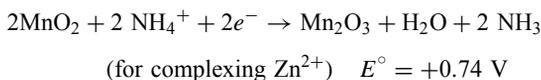

Reduction (positive terminal):

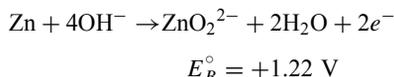

4. *LeClanche Cell* (Flashlight Battery, NH_4Cl Electrolyte). Oxidation (negative terminal):

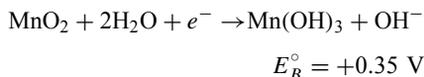

Reduction (positive terminal):

5. *Alkaline Zinc Manganese Dioxide* "Alkaline Flashlight Battery" (KOH Electrolyte). Oxidation (negative terminal):

Reduction (positive terminal):

6. *Nickel-Cadmium Storage Battery* (KOH Electrolyte) (Reversible). Oxidation (negative terminal):

Reduction (positive terminal):

10 ORGANIC CHEMISTRY

Tetrahedral Carbon. The electronic orbitals of carbon are consistent with the formation of four covalent bonds. Symmetry leads to a tetrahedral spatial orientation. The ability of carbon to bond to carbon leads to a multiplicity of organic compounds based on linear, branched chain, and ring sequences of carbon atoms.

Carbon-Carbon Bonds. Saturation refers to carbon-carbon single bonds, with the remaining three bonds to another carbon, to hydrogen, or to substituent groups. Double and triple bonds between carbon atoms are strained and quite reactive; compounds containing these are termed *unsaturated* because each double bond replaces two substituents.

10.1 Classes of Compounds Based on Structure of Carbon Chain

Aliphatic Compounds. Chains and branched chains of tetrahedral carbon atoms covalently bonded to each other give rise to a proliferation of aliphatic compounds. Bonds between carbon atoms forming the backbone chain may be single, double, or triple, and the remaining bonds available at each carbon atom are made to hydrogen or other substituent groups. Compounds have backbone and branch combinations ranging from C_1 to C_{40} or more. Since substituent groups other than hydrogen are possible at the carbon atoms and can be placed in different sequences along the backbone, the numbers of organic compounds become very large—before considering the effect of spatial configuration that often permits one part of the molecule to combine with another reactive part of the same or a kindred molecule.

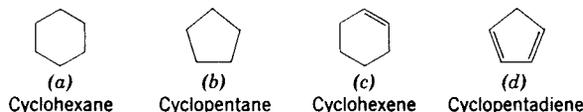

Cyclic Compounds. Ring structures of aliphatic compounds exist subject to bond strain and the possible three-dimensional configuration of the carbon atom chain. Cyclohexane, C_6H_{12} (Fig. 10a), and cyclopentane, C_5H_{10} (Fig. 10b), most commonly exist as the backbone structures. These consist of tetrahedral carbon atoms connected by single bonds and with two hydrogen atoms existent at each apex. Double bonds between carbon atoms can occur: cyclohexene, C_6H_{10} (Fig. 10c) and cyclopentadiene, C_5H_8 (Fig. 10d), are examples.

Note that these can be variously oriented on paper just as the molecules can be in space, so there is no correct or preferred orientation. The presence of a double bond limits the number of hydrogen atoms or substituent groups to one at the double-bonded carbon atoms.

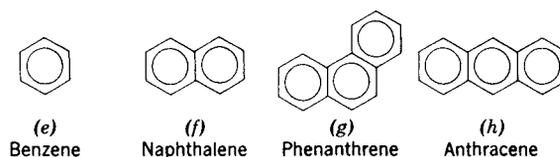

Aromatic Compounds. A particularly stable minimum-energy configuration of six carbon atoms (Fig. 10e) consists of equivalent carbon atoms in planar configuration with single bonds to a substituent at each apex of the hexagon. The absence of other substituent groups infers the presence of hydrogen, and the figure drawn signifies benzene, C_6H_6 . Other groups may replace any or all hydrogen atoms subject to steric (space) considerations; two or three large groups or six small groups may each replace a hydrogen. Higher analogs of benzene (e.g., Figs. 10f–(h)) are condensed planar ring structures containing H atoms at the protruding corners that are subject to similar space-limited substitutions.

Heterocyclic Compounds. Heterocyclic compounds are ring structures with O, S, or N substituted for one or more of the carbon atoms. Bonds at these substituent atoms are those expected from their electronic structure. Examples are furan, $\text{C}_4\text{H}_4\text{O}$ (Fig. 10i), thiophene, $\text{C}_4\text{H}_4\text{S}$ (Fig. 10j), pyridine, $\text{C}_5\text{H}_5\text{N}$ (Fig. 10k), a nitrogen analog of the aromatic hydrocarbon benzene, and piperidine, $\text{C}_5\text{H}_{10}\text{NH}$ (Fig. 10l), an alicyclic amine.

Cyclic Compounds

Aromatic Compounds

Heterocyclic Compounds

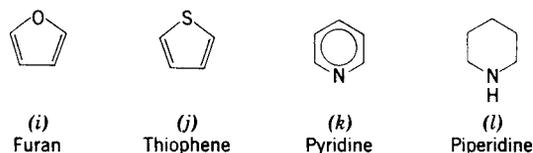

Fig. 10 Cyclic, aromatic, and heterocyclic compounds.

10.2 Abbreviated Organic Chemical Nomenclature

Organic nomenclature is systematic and dependent upon an extensive set of rules of the IUPAC that discourages use of older trivial names. Use of the structural formula is encouraged because it is unambiguous. A few of the simpler rules are helpful: Ring compounds are considered the basic unit and all appendages as secondary. If required, positions around ring compounds are numbered sequentially. Carbon atoms of linear and branched-chain compounds are numbered along the longest string, starting at the end nearest a substituent group or branch. The positions of substituents and side chains are located by the number of the carbon atom where they are attached. Multiple bonds are located by the lowest numbered of the two numbered carbon atoms involved. Some of the prefix and suffix terms used in organic nomenclature are listed in Table 13.

Common usage of trivial names that are unrelated to structure will continue. The only recourse in a practical situation is to locate the compound and its physical constants in the *Merck Index*³ or the *Handbook of Chemistry and Physics*.²

10.3 Classification of Compounds into Unreactive and Functional Groups

Although the number of known organic compounds is astronomic, the number of inexpensive and commer-

cially available ones is drastically limited. Their chemistry ranges from complete oxidation (during combustion) to conversion into specific compounds with academic or commercial application.

Reactivity of organic compounds occurs only at selected sites on the molecule. Synthetic procedures attack substituent groups, more reactive-than-normal hydrogen atoms, and multiple bonds in the carbon chains; the remainder of the molecule remains unchanged in the process. This permits classification of compounds into a reactive portion of the molecule and one that is unaffected by the synthetic process. The reactive portion is a substituent or functional group. The unaffected portion is the remainder of the compound and is called an aliphatic (alkyl), cyclic aromatic (aryl), or a heterocyclic R group according to its structure; this R group is the backbone that carries the reactive substituent group (Tables 14 and 15).

10.4 Organic Reactions

Organic reactions make changes in the bonding to carbon atoms; their course is greatly influenced by reaction conditions that are experimentally established on the basis of reaction mechanism studies. Complications arise because several different reactions may occur simultaneously accompanied by cyclization, molecular rearrangements, and oxidation-reduction. All occur in the direction of minimum energy and increased stability. An encyclopedic literature is replete with tens of thousands of reactions, several hundred of which are generally useful in synthesis and are "name reactions"

Table 13 Organic Chemical Nomenclature

-ane	Saturated hydrocarbon compound
-ene	Unsaturated hydrocarbon compound with double bond
-yne	Unsaturated hydrocarbon compound with triple bond
-yl	Hydrocarbon group as substituent (see next section)
<i>cis-</i>	Refers to stereochemistry
<i>trans-</i>	Refers to stereochemistry
ortho-	1,2 positions on benzene ring (abbreviated <i>o-</i>)
meta-	1,3 positions on benzene ring (abbreviated <i>m-</i>)
para-	1,4 positions on benzene ring (abbreviated <i>p-</i>)
<i>d-</i>	Dextro-rotatory optical isomer
<i>l-</i>	Levo-rotatory optical isomer
<i>r-</i>	Racemic, mixture of <i>d</i> and <i>l</i> isomers
<i>n-</i>	Normal or linear chain
iso-	Branched chain; usually with isopropyl group
<i>t-</i>	Tertiary, three carbons attached to one
<i>sec-</i>	Secondary, two carbons attached to one
neo-	Four carbons attached to one
di-	Two
tri-	Three
cyclo-	Ring structure

Three parts of a simple compound name are:

1. A position number
2. Name of substituent group (see next section)
3. Name of parent structure

Examples:

honoring their early investigators. Studies of rate, catalysis, stepwise mechanism, and stereochemistry have coalesced much of the accumulated information into a few generalized categories of related mechanisms.

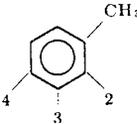

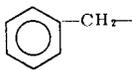

Substitution. In substitution reactions a group attached to a carbon atom is removed and another enters in its place. Reactions are designated S_{N1} , S_{N2} , S_{E1} , or S_{E2} dependent on the nucleophilic or electrophilic nature of the reagent and the unimolecular or bimolecular dependence of the reaction rate. Nonpolar substitutions are dependent on a free-radical mechanism. Solvolysis reactions, such as hydrolysis of esters or amides, and organic acid-base neutralizations are substitution reactions. Other reactions occur at both saturated and unsaturated carbon atoms. Intra- and intermolecular substitutions are the mechanism for rearrangements and cyclization (ring formation).

Addition. Addition of functional groups occurs at unsaturated carbon atoms, increasing the number of groups attached at those positions. The reagent species may be nucleophilic, electrophilic, or free radical.

Elimination. Reducing the number of functional groups bound to one carbon atom necessitates the formation of an unsaturated carbon bond to the adjacent carbon. Elimination thus involves removal of two functional groups from contiguous carbon atoms and is the reverse of addition reactions. Elimination reactions often occur simultaneously and competitively with substitution reactions at saturated carbon atoms.

Rearrangement. Many reactions are encountered where functional groups migrate within the molecule and result in products other than anticipated. These migrations tend to occur at adjacent carbon atoms; they

Table 14 Alkyl and Aryl R Groups

<i>Alkyl Groups</i>

<i>Cyclic groups</i>		
C ₆ H ₁₁ –		cyclohexyl-

may involve five and six-membered heterocyclic ring intermediates or neighboring group participation in the reaction. The driving force for any rearrangement, as for any reaction, is increased stability of the resultant product species.

Oxidation–Reduction. Redox reactions are selectively applied to carbon–hydrogen bonds and carbon–carbon multiple bonds, but few oxidative procedures allow selective breaking of a specific carbon–carbon single bond without disrupting the entire molecule. The removal of hydrogen to form multiple carbon–carbon bonds or to make new bonds between carbon and oxygen, sulfur, nitrogen, or halogens is called oxidation. Primary alcohols are oxidized to carboxylic acids, and acids are reduced to alcohols.

10.5 Reagents of Organic Reactions

Further classification is made according to classes of reagent, the species which attacks a substrate to produce products. Reagents are collected into three classes based on their electronic structure:

- Nucleophilic. Lewis bases can donate unshared electron pairs, reducing agents.
- Electrophilic. Lewis acids can accept unshared electron pairs, oxidizing agents.

- Free Radical. A reactive transient fragment that has one or more unpaired electrons. Examples: Cl·, ≡C·, and =C: are chlorine, carbon, and carbene radicals, respectively.

The more common reagents are summarized in Table 16.

10.6 Catalysis

Catalysis is absolutely dependent on the reaction mechanism; other than transition metal participation in intermediate species, acid and base catalyses are most important:

- Acid catalysis facilitates production of electrophilic reagent species. Lewis acids provide acid catalysis.
- Base catalysis facilitates production of nucleophilic reagent species. Lewis bases provide base catalysis.
- Free-radical initiation: Heat, light, or peroxide can initiate free-radical formation, independent of both solvent and acid or base catalysis.

10.7 Solvents

The solvent for reactions may be one of the reactants or be introduced to facilitate mutual contact via solution.

Table 15 Functional Groups

$-\text{OH}$	Alcohol when attached to alkyl R, phenol when attached to aryl R		Sulfoxide
$-\text{O}-$	Ether		Sulfone
$-\text{O}-\text{O}-$	Peroxide		Sulfonic acid
$-\text{O}-\text{OH}$	Hydroperoxide		Carboxylic acid
$-\text{O}-\text{N}=\text{O}$	Nitrite		Acid anhydride
	Nitrate		Ester
	Nitro compound		Amide
$-\text{NH}_2$	Primary amine		Acid halide
	sec-Amine		Ketone
	tert-Amine		Aldehyde
$=\text{NH}$	Imide		
$-\text{C}\equiv\text{N}$	Nitrile		
$-\text{X}$	Halide, where X = F, Cl, Br, or I		
$-\text{H}$	Hydrogen		
	Double bond		
$-\text{C}\equiv\text{C}-$	Triple bond		
$-\text{SH}$	Thioalcohol, mercaptan		
$-\text{S}-$	Sulfide		
$-\text{S}-\text{S}-$	Disulfide		

Table 16 Nucleophilic and Electrophilic Reagents

Nucleophilic Reagent, Bases and Reducing Agents, Donors of Unshared e^- Pair		Electrophilic Reagent, Acids and Oxidizing Agents, Acceptors of e^- Pair	
I^-	Iodide ion	H_2O^+	Hydronium ion
OH^-	Hydroxyl ion	$\left\{ \begin{array}{l} \text{R}_2\text{C}=\text{OH}^+ \\ \text{R}_2\text{C}^+-\text{OH} \end{array} \right\}$	These occur after protonation of ketones
RO^-	Alcoholate ion	BF_3	Boron trifluoride
RS^-	Mercaptide ion	AlCl_3	Aluminum chloride
CN^-	Cyanide ion	Cl_2	Their cleavage forms X^+ and X^- ; X^+ is actual electrophilic reagent
$\text{H}_2\ddot{\text{O}}:$	Water	Br_2	
$\text{R}\ddot{\text{O}}\text{H}$	Alcohol	I_2	
$:\ddot{\text{N}}\text{H}_2$	Ammonia	NO_2^+	Nitronium ion (formed after protonation of nitric acid)
Br^-	Bromide ion		
Cl^-	Chloride ion		
$\text{>C}^-:$	Carbanion	>C^+	Carbonium ion

Table 17 Solvents for Organic Reactions

Polar	Nonpolar
Water	Hydrocarbons
Formic acid	Acetone — will dissolve some ionic species
Dimethylsulfoxide	Ethers
Dimethylformamide	Ethylene glycol dimethyl ether (diglyme)
Methanol	Tetrahydrofuran (THF)
Ethanol	Dioxane
Acetic acid	
Nitromethane	
Acetonitrile	
Liquid ammonia	

The choice is necessarily dependent on reaction conditions to avoid undesired solvent participation:

- (a) Polar solvents are chosen to solubilize ionic species.
- (b) Nonpolar solvents dissolve un-ionized molecules.

Table 17 summarizes the more widely used polar and nonpolar solvents.

1 INTRODUCTION

Engineering economics is a necessary field for practicing engineers and those studying to become engineers because it helps students prepare for real-world situations and provides professionals with valuable conceptual and mathematical tools for implementing cost analysis. Cost analysis and project selection in a cost-efficient manner are important factors impacting economies and business competitiveness. Companies must respond to increased competition with lower cost operations. Thus, the purpose of engineering economics is to formulate economic studies for the proper allocation of financial resources. Just as operations research or other management sciences deal with the allocation of human or material resources in a methodical and calculated manner, engineering economics focuses on the distribution of financial resources in the best manner to maximize financial payback. This type of analysis is intricately intertwined with engineering since many problems can be easily solved with engineering solutions, but it is only when we add

the economic constraint that we realize the solution is not necessarily feasible. As Eugene Grant¹ said, engineering “involves a realization that quite as definitely a body of principles governs the economic aspects of an engineering decision as governs its physical aspects.” For example, the problem of excessive carbon dioxide emissions could easily be solved by giving everyone an alternate-fuel car. However, it is only when we add the economic constraint that alternate-fuel cars are too expensive for most people that the real engineering begins. Thus, this chapter on engineering economics discusses the kinds of entrepreneurial decisions that engineers need to make in choosing among competitive design alternatives or in deciding which business case or project they or their company should pursue.

2 CASH FLOWS AND TIME VALUE OF MONEY

Money makes (or loses) value as it changes hands over time. Transactions, where money moves from one entity to another, are called cash flows and can happen

at any point in time. Whether these transactions, or cash flows, are from lender to borrower or personal investor to bank, the details of cash flow cost one person some part of the wealth and increase the other's wealth. In contrast to taking dollars and putting them under a mattress, called hoarding, in a transaction, or cash flow, scenario, one is modifying wealth via the transaction, whereas in the hoarding example one is not modifying wealth.

In the hoarding scenario, money, or the future value of money, can only be lost. This is so since inflation causes the purchasing power of today's dollars to decrease over time. Add the interest lost by putting the money under the mattress instead of a simple savings account, and we can see that under the mattress money is not standing still but instead is losing value at a rather quick rate. Contrast that to funds and put in a bank account, certificate of deposit, or money market account. This investment would earn some money through the interest rate on the account—this might at least keep pace with inflation.

But what is the value of money used to purchase something such as a home or a car? For example, a person takes out a mortgage for a specific time period (e.g., 30 years) at some rate of interest. To pay back the mortgage, the person generally pays the same mortgage payment in year 1 as in year 30. But what is this payment really worth in year 1? And what is it worth in year 30? Are they the same value? The answer is that the values of the two amounts, though the same in dollar amount, are not the same in value. The first payment is made in today's dollars and the last payment, 30 years later, is made when the value of those future dollars is less. Using numbers to illustrate: When your parents first took out their mortgage in the last quarter of the twentieth century, a monthly payment of \$1000 was a hefty monthly mortgage payment for a young couple to meet. By the time you were out of college and your parents were making their last mortgage payment, that same \$1000 monthly payment was just a drop in the bucket. This is because inflation went up while purchasing power went down, making the future value of that same \$1000 less after 30 years.

Thus, not only is a transaction, or cash flow, necessary to modify the value of money, but the time line on which the transaction occurs also needs to be known. For, as can be seen above, a dollar in a future transaction is not worth as much as a dollar today. To equate the two without correcting for the "time value of money" would be as incorrect as adding pounds to kilograms without first converting the items into the same units. This is the basis for engineering economics—equating sums of money from different periods of time (i.e., the *time value of money*) based on the risk associated with the investment, which is normally expressed in terms of the interest rate.

3 EQUIVALENCE

Economics is basically the moving of money from some point in time to some other point in time. For

example, if one loans money to someone else, money could be made later. However, there are many things to consider. For example, there is a risk the borrower will not pay back the loan, the borrower is getting to use the money when you are not, there is a risk of inflation over the life of the loan, and the dollars you get back, even if more than you loaned, may not buy as much as they would have if you had just kept the money. In addition to these concepts surrounding the loan, one must consider what else could be done with the money if it was not lent. By considering these factors, an agreement between lender and borrower will say that if one is going to lend money, the borrower will have to pay back more than what was borrowed. One might think of this extra amount as rental income charged for the use of the money. To account for these types of issues, we use an interest rate to indicate the value of money on the time continuum. Thus, the concept of *equivalence* within economics is that today's and tomorrow's dollars are related to each other by some interest rate and time period.

In order to make sensible comparisons between present and future sums on this time continuum, we must bring all the sums being compared into the same moment of time. This moment can be either present or future, but not both. The value of present money increases as we move it into the future, while the value of future income falls as we move it back to the present.

The central notion here is that of equivalence. Present and future sums of money are equivalent if a rational person would be indifferent as to which he or she received. Thus, for example, if one won the lottery, the payout is typically either one cash payment today or multiple payments over a specific time period in the future. At some interest rate, both of these payouts are equivalent. Assuming the winner could only reinvest the winnings at the same interest rate at which the lottery is paying out, the winner would be indifferent to the options. Or put more simply, if the best available interest rate is 5%, one should be indifferent between receiving \$100 now or \$105 this time next year. Similarly, we should now see the principle that \$100 this time next year is worth less than \$100 today. (These concepts do not include specific exceptions such as when income taxes may affect a decision to accept money today.)

3.1 Cash Flow Diagrams

Sometimes one has to use money now and pay it back later or vice versa. In order to move money from one point in time to another, the units of the time line need to be specific along the time line, or the planning horizon of the project, on a cash flow diagram. Similarly, the equations need to be specified. Within these equations are standard notations for the quantities involved. The five most needed quantities are P , present worth; F , future worth (or "compound amount²"); A , annual worth; i , interest rate per period; and N , number of time periods we are considering.

Cash flow diagrams are a way to define and visualize the problem. Similar to other engineering and science concepts which use concepts such as the free-body diagram, cash flow diagrams are an important step in taking a problem from words to one that can be easily analyzed using mathematical techniques. And within the time line, or cash flow diagram, standard conventions are similarly employed. On a cash flow diagram the x axis represents the time period up to the duration of the project, N . The y axis represents the monetary amount where up is a positive inflow of money (i.e., revenues) and down is a negative outflow of money (i.e., expenditures). Also note that an arrow means that money is changing hands. However, a key assumption within the cash flow diagram is that all interest occurs at the end of the time period. See Figs. 1a, b for examples of typical cash flow diagrams as well as the information usually presented on the diagram. It should be noted that the *end-of-year* convention is the generally accepted format for cash flow diagrams. What this means is that any cash flows within the year will be shown as occurring at the end of the year.

3.2 Solving the Problem

The steps to solving a typical cash flow problem are simple. First one would want to draw a picture, or cash flow diagram, in order to visualize the entire cash flow within the problem. Second, one should identify all the known components and unknowns within the problem. Third, one needs to convert all

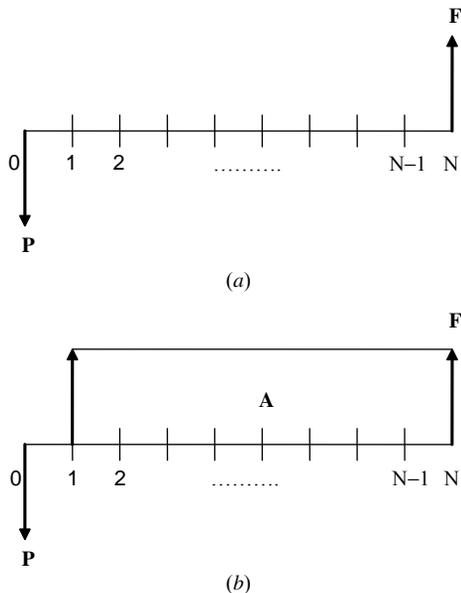

Fig. 1 Typical cash flow diagrams: (a) single sum; (b) uniform series.

known components to the same units of time. Lastly, one needs to identify the correct equation and solve the problem using engineering economic techniques. The general equations used in engineering economics are shown in Table 1.

Factor notation can be used to represent the necessary equations (see the notation column of Table 1) and is available in tabular form, such as Table 2, in the literature,² or on the Internet.³ The tables used will depend upon which factor is used (designated in columns within the tables) and which interest rate is needed (designated by separate tables). Normally each table is based on one interest rate or minimum attractive rate of return (MARR). Thus, one would need to find the table with the appropriate interest rate for the problem at hand. Common mathematical operations would tell one to multiply by a factor which would “cancel out” the variable on the right side of the equation and leave the variable you are looking for on the left. This is not what actually happens. However, it allows one to easily determine which factor should be used as located across the top row of the table. In addition to determining the factor and interest rate, one would also need to determine the period, N , which would be located down the left side of the table. The tables all work this way, and when used in place of the formulas, they make calculations very simple. Interest table use is not always possible if the interest rate is not listed in the provided tables. (Tables normally run only in whole numbers from 1 to 50%.) In situations where the interest table is not available, one needs to use the formulas to calculate the answer the long way. See Table 1 for factor functional formats as well as formulas.

In addition, it should be noted that the interest rate is assumed to be *compound interest* where the money within the account is compounded monthly, quarterly, or yearly. Also the interest rate used must be the effective rate per period, N . Thus the basis of the rate, whether monthly, quarterly, or yearly, must agree with the period used for N . So, for example, one cannot use an annual interest rate when the time period N is in months.

Lastly, there are different kinds of interest rates. The effective interest rate is the rate that would yield the accrued interest at the end of the year. The nominal rate (r) equals the rate per period times the number of periods in the year (m). (For example, $m = 12$ for monthly compounding.) Thus, if the interest rate were 1% per month, the nominal rate would be 12% per year. Thus, the effective interest rate is simply r/m . The nominal and effective rates differ as the effective rate is the yield from the *continuous* compounding process. Thus, for the effective rate, if the interest rate was 1% per month, the effective rate would actually be greater than 12% due to the power of compounding. Generally speaking, one can assume the rate given in a problem is the effective rate if the compounding is annual. If, however, the compounding is not annual, the rate given is the nominal rate.

Table 1 Engineering Economy Symbols, Notation, and Formulas

Type of Factor	Factor Symbol	Factor Notation	Formula
<i>Present Worth</i>			
Single payment	P/F	$P/F, i, N$	$\frac{1}{(1+i)^N}$
Annuity	P/A	$P/A, i, N$	$\frac{(1+i)^N - 1}{i(1+i)^N}$
Gradient	P/G	$P/G, i, N$	$\frac{(1+i)^N - 1}{i^2(1+i)^N} - \frac{N}{i(1+i)^N}$
Geometric gradient		$P/A, i, g, N$	$\frac{1 - [(1+g)/(1+i)]^N}{i-g}$
<i>Future Worth</i>			
Single payment	F/P	$F/P, i, N$	$(1+i)^N$
Annuity	F/A	$F/A, i, N$	$\frac{(1+i)^N - 1}{i}$
Gradient	F/G	$F/G, i, N$	$\frac{(1+i)^N - 1}{i^2} - \frac{N}{i}$
<i>Annuity</i>			
Capital recovery	A/P	$A/P, i, N$	$\frac{i(1+i)^N}{(1+i)^N - 1}$
Sinking fund	A/F	$A/F, i, N$	$\frac{i}{(1+i)^N - 1}$
Gradient	A/G	$A/G, i, N$	$\frac{1}{i} - \frac{N}{(1+i)^N - 1}$

4 SINGLE SUM AND UNIFORM, GRADIENT, AND GEOMETRIC SERIES

When one is considering two investment opportunities, if you are indifferent to one or the other in making a choice between them, they are said to be equivalent. For example, two values, P occurring in the present and F occurring at some future time N , are equivalent at some interest rate. The most common conversion is that which reduces the cash flow pattern to a single sum at year zero. This is referred to as the present worth (P).

But another common conversion reduces the cash flow to a future single sum. This single sum can occur at year N , the end of the cash flow, or at any time in the middle. This is referred to as the future worth (F). (Note: There is a special function of F called salvage value (S) which occurs only at year N at the end of a project.) The parameters P , F , and S are all equivalent single sums within a given time period. See Fig. 1a.

Another common conversion is to reduce a cash flow pattern to a uniform series that runs without

change in amount from year 1 to year N . This is the annual worth (A). This is an equivalent uniform series within a given time period. For an example, see Fig. 1b.

Another common conversion is a series which increases or decreases in magnitude by a uniform amount, G , from one period to the next. This is called a gradient, where G increases starting with the end of the second period until the end of year N , at which time its cash flow is calculated as $(n - 1)G$. Note that the value of the gradient G at year 1 is zero. This kind of gradient calculation would be common in replacement studies where expenses such as maintenance are assumed to increase by a fixed amount each year. See Fig. 2a. A final common conversion is a series which increases or decreases in magnitude at a constant rate or percentage from one period to the next. This is called a geometric gradient (g), where g increases starting with the end of the second period. A common example of a geometric gradient is inflation. See Fig. 2b.

The conversion patterns, singly or in combination, represent most of the situations where money is

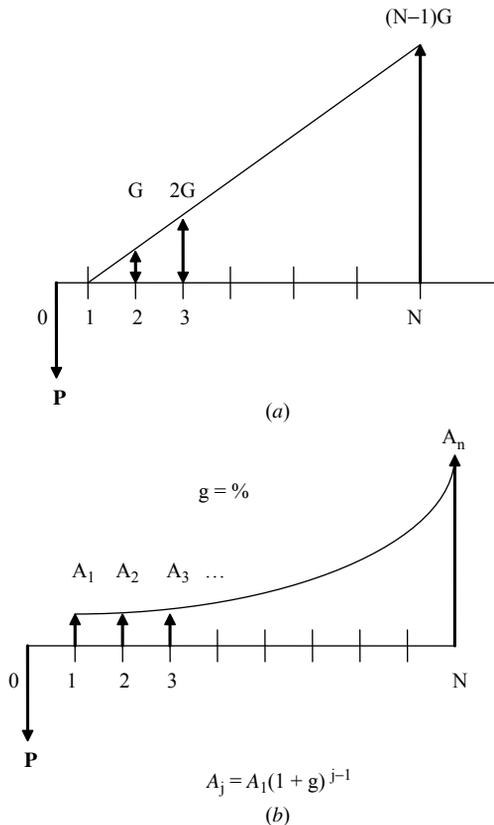

Fig. 2 (a) Arithmetic gradient cash flow Diagram. (b) Geometric gradient cash flow diagram.

exchanged whether in one's personal finance or within a company (e.g., selection, insurance, pensions, loans, funding, and replacements). These conversions are critical since they allow the comparison of investment opportunities whose cash flow patterns differ. With the conversions, all the cash flows are reduced to a common level in which direct comparisons can be made. A common calculation is switching between present dollars (PW), annual dollars (AW), and future dollars (FW). Table 3 shows which factors to multiply by to yield a needed worth conversion. Thus, any worth can be converted to any other worth by multiplying it by the proper factor, as shown in the table. For example, a present worth can be converted to a future worth simply by multiplying by F/P or to an annuity by multiplying by A/P . In essence, any of the "worths" (A, F, P) can be readily converted into the others.

Up to this point we have discussed all the notation in the equations in Table 1 except for i , the interest rate. Present and future values, annual and present values, and so on, are all related through this interest rate or the MARR one will accept. To determine whether or not a project should be undertaken, its rate of return should be compared to the MARR or the required rate of return for the project. The more risk one is willing to accept, the greater the MARR will be. Stated another way, MARR is the rate of return that one will accept for giving up the money now in favor of future purchasing power. If after engineering economic calculations the rate of return is shown to be higher than the MARR, the investment should be undertaken. Conversely, if the rate of return is shown to be lower than the MARR, the investment should not be undertaken since it is assumed that the money can be invested elsewhere at a rate at least equal to the MARR.

Finally, while working to make cash flows equivalent, a few items must be kept in mind. Cash flow that occur at the same point in time can be added or subtracted from one another. Time horizons must be aligned so that every problem starts at year 0 with income or expenses starting at year 1. If expenses are incurred prior to the start of the project, or time zero, they are called sunk costs and are not relevant to the problem unless they have tax consequences. Lastly, gradients may need to be manipulated.

Table 3 Conversion of Worth Factors

If you are given →	P	F	A	G
To solve for	P	F/P	F/A	F/G
Use factors in table	A/P	A/F	A	A/G

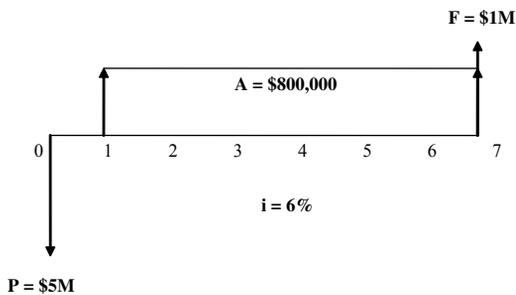

- P = PW = present worth (NPV = net present value)
- F = FW = future worth
- A = AW = annual worth

Note: There is commonly no P/G factor. Therefore to get P/G , simply multiply $(A/G)(P/A) = P/G$.

Example 1 provides a problem encompassing the basics of engineering economics described thus far.

Example 1 Basic Engineering Economics Problem. A company wants to purchase equipment today which costs \$5 million. During each year of ownership of the equipment, the company estimates that an additional \$800,000 in revenues will be brought in. The company plans to hold the equipment for seven years and estimates it will be able to sell the equipment in year 7 for \$1 million. The interest rate is estimated at 6%.

- Draw a cash flow diagram.
- Is this a profitable enterprise and should it be undertaken?

Identify the items from the word problem and list them with appropriate notation:

$$\begin{aligned}
 P &= -\$5,000,000 \\
 A &= \$800,000 \\
 S \text{ (also called } F) &= \$1,000,000 \\
 i &= 0.06 \\
 N &= 7
 \end{aligned}$$

Solution

1. Solving the problem using the equations in Table 1 gives

$$\begin{aligned}
 PW &= -P + A \left(\frac{P}{A}, i, N \right) + F \left(\frac{P}{F}, i, N \right) \\
 &= -5,000,000 + 800,000 \left(\frac{P}{A}, 6, 7 \right) \\
 &\quad + 1,000,000 \left(\frac{P}{F}, 6, 7 \right) \\
 &= -5,000,000 + 800,000 \times \frac{(1+i)^N - 1}{i(1+i)^N} \\
 &\quad + 1,000,000 \times \frac{1}{(1+i)^N}
 \end{aligned}$$

$$\begin{aligned}
 &= -5,000,000 + 800,000 \times \frac{(1+0.06)^7 - 1}{0.06(1+0.06)^7} \\
 &\quad + 1,000,000 \times \frac{1}{(1+0.06)^7} \\
 &= -5,000,000 + 800,000 \times 5.5824 \\
 &\quad + 1,000,000 \times 0.6651 \\
 &= -5,000,000 + 4,465,920 + 665,100 \\
 &= \$131,020
 \end{aligned}$$

This is a profitable project which should be undertaken since the present worth of the project is positive.

2. Solving the problem using factors from interest tables such as Table 2 yields

$$\begin{aligned}
 PW &= -P + A \left(\frac{P}{A}, i, N \right) + F \left(\frac{P}{F}, i, N \right) \\
 &= -5,000,000 + 800,000 \left(\frac{P}{A}, 6, 7 \right) \\
 &\quad + 1,000,000 \left(\frac{P}{F}, 6, 7 \right) \\
 &= -5,000,000 + 800,000 \times 5.5824 \\
 &\quad + 1,000,000 \times 0.6651 \\
 &= \$131,020
 \end{aligned}$$

This is a profitable project which should be undertaken since the present worth of the project is positive.

5 COMPARING ALTERNATIVES: DEFINING OPTIONS

The object of an economic evaluation is to select the most cost-effective solution among several alternatives. Comparing engineering design alternatives can take many forms: assessment of technology, risk, quality, safety, serviceability, and so on. But in engineering economics the comparison of engineering design alternatives revolves around the monetary aspects and the economic impact of the various projects to determine which project best serves the financial interest of the firm or individual. Thus, it is often worthwhile to be able to rank engineering projects or investment opportunities not only from a technological perspective but also from a monetary perspective. Engineering economics provides us with this ability through its financial criteria, called figures of merit, numerical quantities based on the monetary attributes of the projects. Thus, through engineering economics, one can rank and compare investment opportunities, solve design problems, and make business decisions based on their financial impact as expressed through the figures of merit.

There are two steps to ranking projects: technological and financial. For both steps one needs to determine

the set of alternatives from which a project will be chosen. There are many stories of how “pet” projects are chosen. But to be a truly adequate selection process, tests of feasibility, both technical and financial, need to occur. Under technical feasibility one might consider technical limitations (e.g., of material or production capability) or political, administrative, or other physical hindrances that disqualify alternatives from further review. For financial feasibility one must consider the amount of available funding and how that funding will be allocated to the projects under review.

As mentioned, the steps for calculating an engineering economic problem are simple. First draw a cash flow diagram for each project to outline what is occurring in the project. The cash flow diagram, by means of its layout, would indicate the time line on which the entire problem was occurring from time zero to N , the cash flows and the points of time of their occurrence, and the specific interest rate, or MARR. In many instances a “do nothing” alternative will also be examined that represents the concept of passing on the project and reinvesting the project funds as would usually be done.

Cash flow often need to be estimated because, just as stock analysts cannot accurately predict the future stock market level, economists cannot always predict the future of the economy. Variations in cash flow can be understood from concepts such as whether projected income from a project is only what is anticipated and, if the salvage value of an asset depends heavily on what is occurring in the economy N years later at the end of the project life, whether inflation can impact the variability of the direct and overhead costs.

In addition to the time line (N) and the cash flows (P , F , and/or A), interest rate i , also called MARR, must be estimated for each project. As already discussed, the MARR indicates the level of risk one is willing to accept to undertake the project. Or put more simply, MARR is the rate of return that one will accept for giving up the money now in favor of future payout from the project. This interest rate is used to convert the cash flows into figures of merit that allow one to compare the engineering alternatives. The selection or estimation of MARR can be based on various factors, including but not limited to the current interest rate, the rate of inflation, the risk of defaulting on the loan, and the risk of failing to achieve the project outcome. In essence, the greater these factors, the higher the MARR should be for the project. Another way of calculating MARR is to simply estimate the current return in the market for other investments of similar profile and risk.

6 COMPARING ALTERNATIVES THROUGH FIGURES OF MERIT

The most common figures of merit for comparing and ranking alternative investment opportunities are as follows:

Present value or present worth or net present worth (PV, PW, NPW)

Annual worth (AW), which if negative is also known as equivalent uniform annual cost (EUAC) or annual cost (AC)

Future value or future worth (FV or FW)

Internal Rate of Return (IRR)

Benefit–cost ratio (BCR)

The first three items are commonly called “the three worths.” As mentioned previously, any worth can be converted to any other worth simply by multiplying it by the correct factor (see Table 3). These worths are often useful in problems that involve comparing projects directly at present costs (present worth), mortgages or auto loans (annual worth), or life insurance or pensions (future worth), for example.

The last two items, IRR and BCR, cannot be compared directly or converted into each other. IRR is used by investors to ease the comparison of outcomes to market rates or other investment opportunities such as standard bank options (i.e., CDs, bonds, and money market funds). BCR is used mostly in the public sector in major investment projects involving capital expenditures with little or no projected profit from the undertaking (i.e., roads, bridges, and municipal buildings).

6.1 Present Worth

The present worth of a cash flow is the discounted value of future cash flows at time zero at some interest rate. To maximize benefit of the projects under consideration, one would choose the projects with the highest present worth. However, when the projects all entail costs (with no benefits) then one would want to minimize costs and choose the alternative with the least cost. (i.e., the smallest negative number). See Example 2 for a demonstration of calculating the present worth.

6.2 Annual Worth

The annual worth converts the cash flows in a project into an equivalent uniform annual series based on the interest rate. The rules for choosing the best alternatives are the same as those for the present worth. In a maximum-benefit case, one wants the highest annual worth. In a least-cost case, one wants to choose the alternative with the smallest negative number. Example 2 converts worths from present to annual.

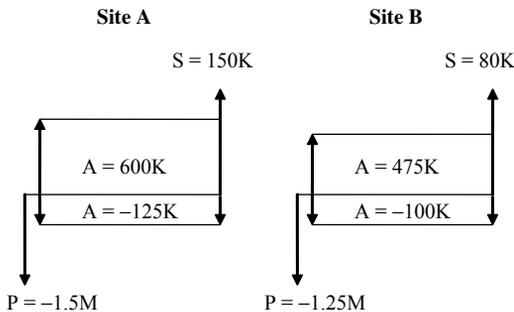

6.3 Future Worth

The future worth is the compounded value of cash flow in a project at time N at some interest rate. As previously stated for the other worths, the project having the greatest future worth is the one to be selected in a maximum-benefit problem, while the project having the lowest future worth is the one to be selected in a least-cost problem. Example 2 converts worths from present to future.

Example 2 American Mirror Company is looking into expanding its operations and incorporating another site. The two business alternatives, sites A and B, are as follows:

Description	Site A	Site B
First cost, P	\$1,500,000	\$1,250,000
Annual revenue, $+A$	\$600,000	\$475,000
Annual expense, $-A$	\$125,000	\$100,000
Salvage value, S	\$150,000	\$80,000
Life, N	10	10
MARR, i	12%	12%

(a) Draw a cash flow diagram for each opportunity:

(b) Calculate the present worth for both sites:

$$PW = A \left(\frac{P}{A}, i, N \right) + S \left(\frac{P}{F}, i, N \right) - P$$

$$\begin{aligned} PW \text{ site A} &= (600,000 - 125,000) \\ &\quad \times \left(\frac{P}{A}, 12\%, 10 \right) + 150,000 \\ &\quad \times \left(\frac{P}{F}, 12\%, 10 \right) - 1,500,000 \\ &= (600,000 - 125,000) \times 5.6502 \\ &\quad + 150,000 \times 0.322 - 1,500,000 \\ &= \$1,232,145 \end{aligned}$$

$$\begin{aligned} PW \text{ site B} &= (475,000 - 100,000) \\ &\quad \times \left(\frac{P}{A}, 12\%, 10 \right) + 80,000 \\ &\quad \times \left(\frac{P}{F}, 12\%, 10 \right) - 1,250,000 \\ &= (475,000 - 100,000) \times 5.6502 \end{aligned}$$

$$\begin{aligned} &+ 80,000 \times 0.322 - 1,250,000 \\ &= \$894,585 \end{aligned}$$

(c) Calculate the annual worth for both sites:

$$AW = A + S \left(\frac{A}{F}, i, N \right) - P \left(\frac{A}{P}, i, N \right)$$

$$\begin{aligned} AW \text{ site A} &= (600,000 - 125,000) \\ &\quad + 150,000 \left(\frac{A}{F}, 12\%, 10 \right) \\ &\quad - 1,500,000 \left(\frac{A}{P}, 12\%, 10 \right) \\ &= (600,000 - 125,000) + 150,000 \\ &\quad \times 0.0569 - 1,500,000 \times 0.1769 \\ &= \$218,185 \end{aligned}$$

or

$$\begin{aligned} AW \text{ site A} &= P \left(\frac{A}{P}, i, N \right) = 1,232,145 \\ &\quad \times 0.1769 = \$217,966 \end{aligned}$$

Note the small error from \$218,185 due to rounding.

$$\begin{aligned} AW \text{ site B} &= (475,000 - 100,000) \\ &\quad + 80,000 \left(\frac{A}{F}, 12\%, 10 \right) \\ &\quad - 1,250,000 \left(\frac{A}{P}, 12\%, 10 \right) \\ AW &= (475,000 - 100,000) + 80,000 \\ &\quad \times 0.0569 - 1,250,000 \times 0.1769 \\ AW &= \$158,427 \end{aligned}$$

or

$$\begin{aligned} AW \text{ site B} &= P \left(\frac{A}{P}, i, N \right) \\ &= 894,585 \times 0.1769 = \$158,252 \end{aligned}$$

Note the small error from \$158,427 due to rounding.

(d) Calculate the future worth for both sites:

$$FW = S + A \left(\frac{F}{A}, i, N \right) - P \left(\frac{F}{P}, i, N \right)$$

$$\begin{aligned}
 \text{FW site A} &= 150,000 + 475,000 \left(\frac{F}{A}, 12\%, 10 \right) \\
 &\quad - 1,500,000 \left(\frac{F}{P}, 12\%, 10 \right) \\
 &= 150,000 + 475,000 \times 17.5487 \\
 &\quad - 1,500,000 \times 3.1059 \\
 &= 3,826,783
 \end{aligned}$$

or

$$\begin{aligned}
 \text{FW site A} &= P \left(\frac{F}{P}, i, N \right) = 1,232,145 \\
 &\quad \times 3.1059 = \$3,826,919
 \end{aligned}$$

Note the small error from \$3,826,783 due to rounding.

$$\begin{aligned}
 \text{FW site B} &= 80,000 + 375,000 \left(\frac{F}{A}, 12\%, 10 \right) \\
 &\quad - 1,250,000 \left(\frac{F}{P}, 12\%, 10 \right) \\
 &= 80,000 + 375,000 \times 17.5487 \\
 &\quad - 1,250,000 \times 3.1059 \\
 &= \$2,778,388
 \end{aligned}$$

or

$$\begin{aligned}
 \text{FW site B} &= P \left(\frac{F}{P}, i, N \right) = 894,585 \\
 &\quad \times 3.1059 = \$2,778,491
 \end{aligned}$$

Note the small error from \$2,778,388 due to rounding.

- (e) Which alternative should be chosen? Why? Choose site A because it has a much greater group of values or worths.

6.4 Internal Rate of Return

The (IRR) is the rate for which the sum of the worths of all cash flows equals zero:

$$\sum \text{PW} = 0 \tag{1}$$

The IRR has many names such as target rate, hurdle rate, and profitability index. These descriptive names are accurate because the IRR is the return an investor will get if the cash flows used in the engineering economics problem prove true. Thus, the IRR is often compared to

the MARR since the MARR was chosen by an investor as the minimally acceptable level of return. The rules for how to compare IRR to MARR follow:

If IRR is greater than MARR, the project is a good investment.

If IRR is less than MARR, the project is a bad investment.

These rules can be easily explained. If the IRR (the return expected from the project) is more than the MARR, then one is making more than expected or hoped for, and thus the project is a good investment. Conversely, if the IRR (the return expected) is less than the MARR, then one is making less than hoped or expected, and one should not proceed with the investment.

The drawback is that IRRs of different projects cannot be compared directly. In order to compare the IRR of more than one project, one must perform incremental analysis on each set of projects and then choose the best project based on the following rules:

If $\text{IRR}_{\text{beta-alpha}} > \text{MARR}$, then beta is the best choice.

If $\text{IRR}_{\text{beta-alpha}} < \text{MARR}$, then alpha is the best choice.

Example 3 provides details on solving an IRR problem.

Example 3. A company is deciding between three different projects with properties as listed below. All projects have a MARR of 15% and will occur over 15 years.

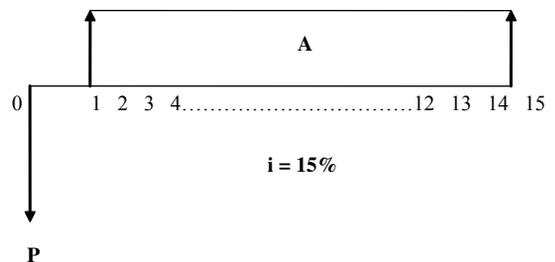

- Draw the generic cash flow diagram for the projects involved.
- What is the best project using MARR?
- What is the best project using IRR?

The data for this example are as follows:

Projects	P	Annual	IRR
B	500	110	20.7
C	725	149	19
D	885	170	12

Solution

- (a) The generic cash flow diagram is as follows:

- (b) To determine the best project using MARR, calculate the net present value (NPV), also called present worth, for each alternative:

$$\text{NPV} = -P + A \left(\frac{P}{A}, i, N \right) + S \left(\frac{P}{F}, i, N \right)$$

$$\begin{aligned} \text{NPV}_B &= -500 + 110 \left(\frac{P}{A}, 15, 15 \right) \\ &= -500 + 110 \times 5.847 = 143 \end{aligned}$$

$$\begin{aligned} \text{NPV}_C &= -725 + 149 \left(\frac{P}{A}, 15, 15 \right) \\ &= -725 + 149 \times 5.847 = 146 \end{aligned}$$

$$\begin{aligned} \text{NPV}_D &= -885 + 170 \left(\frac{P}{A}, 15, 15 \right) \\ &= -885 + 170 \times 5.847 = 109 \end{aligned}$$

Project C is the best since it has the greatest NPV.

- (c) IRRs cannot be compared directly. Thus, the information provided in the problem statement about IRR is immaterial. Use the NPV equation of part (a) to solve for IRR, only this time set NPV equal to zero as stated in Eq. 1:

$$\begin{aligned} \text{NPV} = 0 &= -P + A \left(\frac{P}{A}, i^*, 15 \right) \\ \text{NPV}_{dc} = 0 &= -885 - (-725) \\ &+ (170 - 149) \left(\frac{P}{A}, i^*, 15 \right) \\ 160 &= 21 \left(\frac{P}{A}, i^*, 15 \right) \\ 7.62 &= \left(\frac{P}{A}, i^*, 15 \right) \end{aligned}$$

Use interest rate tables (see Refs. 2 and 3) to search for P/A at $N = 15$ nearest to 7.62. *Note:* Interpolate between 8 and 10% in the table to find i^* :

$$i^* = 9.97\% = \text{IRR}$$

The rule states that, for NPV, alpha - beta = $0 = -P + A(P/A, i^*, 15)$:

Choose alpha if $i^* > \text{MARR}$.

Choose beta if $i^* < \text{MARR}$.

Project C is the best since $\text{IRR} < \text{MARR}$. Now compare project C to B:

$$\text{NPV} = 0 = -P + A \left(\frac{P}{A}, i^*, 15 \right)$$

$$\begin{aligned} \text{NPV}_{C-B} = 0 &= -725 - (-500) \\ &+ (149 - 110) \left(\frac{P}{A}, i^*, 15 \right) \\ 225 &= 39 \left(\frac{P}{A}, i^*, 15 \right) \\ 5.77 &= \left(\frac{P}{A}, i^*, 15 \right) \end{aligned}$$

Use Table 2 to search for P/A at $N = 15$ nearest to 5.77. *Note:* Interpolate between 15 and 18% in the table to find i^* :

$$i^* = 15.28\% = \text{IRR}$$

The rule states that, for NPV, alpha - beta = $0 = -P + A \left(\frac{P}{A}, i^*, 15 \right)$:

Choose alpha if $i^* > \text{MARR}$.

Choose beta if $i^* < \text{MARR}$.

Project C is the best since $\text{IRR} > \text{MARR}$. Therefore, C is the overall best project.

6.5 Benefit-Cost Analysis

Benefit-cost analysis provides a ratio of benefit to costs, which indicates a measure of worthiness for competing projects. Generally governments and other public entities use this figure of merit for determining between projects involving capital expenditures with minimal projected profits. If the BCR is greater than 1, the benefit exceed the costs, which would indicate a good investment. If, however, the BCR ratio is less than 1, than the costs would exceed the benefits which would indicate a poor investment choice. Just as with IRR, the drawback is that BCRs of different alternatives cannot be compared with one another.

The equation for BCR is listed in Eq. (2) below. Benefit B are favorable monetary consequences. Dis-benefit D are unfavorable monetary consequences. The initial cost is I . Cash disbursements C are costs such as operating and maintenance. Cash receipts R are fees such as tolls. Lastly, the key to BCR analysis is to have all units be consistent. Thus, all costs must either be annualized or brought to the present worth:

$$\text{Conventional BCR} = \frac{B - D}{I + (C - R)} \quad (2)$$

The first step in doing a comparison among projects using BCR is to calculate BCR for each project. If any project has a BCR ratio less than 1 (indicating a poor investment), that project should be eliminated from further analysis. Then, just as was done with IRR, each set of projects is compared and evaluated according to a set of rules until only one project remains:

When looking at individual projects: If $B/C < 1$, eliminate that project.

When comparing projects:

If $B/C_{X-Y} > 1$, choose Y.

If $B/C_{X-Y} < 1$, choose X.

Example 4. A company is examining projects W, X, Y, and Z. The details of each project are outlined below. Determine which project should be picked based on the BCR as the figure of merit.

Projects	PW of Benefits	PW of Costs	B/C ratio
W	60	80	0.75
X	150	110	1.36
Y	70	25	2.80
Z	120	73	1.64

The first step is to examine the BCR ratios to see if any fall below the critical limit of 1. Since the BCR of project W is 0.75 and thus below 1, project W can be eliminated from further study. The next step is to compare the remaining alternatives using Eq. (2) and the rules governing benefit-cost analysis to determine the best project:

$$B/C_{Z-Y} = \frac{120 - 70}{73 - 25} = 1.04 > 1$$

Therefore select project Z. Now compare project Z to a remaining alternative, project X:

$$B/C_{X-Z} = \frac{150 - 120}{110 - 73} = 0.81 < 1$$

Therefore select project Z. Thus, of projects W, X, Y and Z, the BCR analysis showed that project Z was the best alternative to pursue.

7 ADDITIONAL ANALYSES IN SELECTION PROCESS

After calculating the figure of merit for alternative projects, one might also want to determine the breakeven point, sensitivity analysis, or risk analysis of each project.

7.1 Breakeven Analysis

Breakeven analysis shows the point at which if we go to one side of the point we choose one alternative, but if we go to the other side we choose the competing alternative. Thus at the breakeven point, total revenues equal total costs, and an increase in sales will lead to profit. Conversely, if sales fail to meet expectations and fall below the breakeven point, the company will experience a loss. An example of breakeven analysis might be to determine how many "widgets" need to be produced and sold before the company breaks even and shifts from the debt-making to the profit-making

side of the breakeven point. Breakeven analysis could also be used to determine a lease-versus-buy solution as well. In this case, an analysis of the expenses associated with ownership is compared with those fees associated with leasing in order to determine the optimal solution. This type of analysis would be commonly used when the choice among alternatives is dependent mainly upon a single factor such as utilization of the equipment.

7.2 Sensitivity Analysis

Engineering economy studies are about the future, and as such uncertainty about prospective project results cannot be avoided. Which factors are of specific concern for analysis will vary from project to project, but generally one or more of them will need to be further analyzed in order to come to the best decision. Thus, *sensitivity analysis* can be used to determine which parameters are the most sensitive to a project's economic feasibility. By knowing which items are the most sensitive, one can examine more closely the details of the project in order to have greater confidence in the calculated figures of merit. Therefore, this technique makes clear the impact of the uncertainty when two or more project factors are of concern on the figure of merit (e.g., present worth).

The first step in a sensitivity analysis is to calculate the base-case figure of merit (i.e., present worth), which is developed using the most likely value for each input. The next step is to change one variable of interest by some percentage above and below that used in the base case while holding the remaining inputs constant. The last step is to calculate the new figure of merit for the new input values. Results of the sensitivity analyses can be displayed in both tabular and graphic forms. In tabular form, the item with the greatest numerical value as a sensitivity would have the greatest impact on the pertinent figure of merit. In graphic form, the item with the largest slope would have the greatest impact. Thus, the items highest in sensitivity would be the inputs that would affect the final outcome the most.

7.3 Risk Analysis

Risk analysis is founded on the application of probability theory where one compares the risk propensity of alternative investment opportunities. These kinds of risk analysis activities occur when there is a lack of precise knowledge regarding the future business conditions surrounding, or involved in, the project under consideration. In these cases, the probabilities of the occurrences are estimated. There are risk problems where probabilities of various possible outcomes can be estimated using decision rules such as dominance, aspiration level, and most probable future value. Decision trees and laws of expected value and variance share similar concepts of describing risk and the estimates of various possible outcomes. Lastly, simulation techniques, such as the Monte Carlo method, can

be used as ways of imitating real-life situations and occurrences with models to produce risk profile for projects under review.

The discussions on risk analysis as well as the specific details on breakeven and sensitivity analysis are beyond the scope of this handbook. For more information the reader is referred to Ref. 4.

8 CAPITAL RECOVERY, CAPITAL COST, AND REPLACEMENT STUDIES

Many decisions in business are based around equipment and their *retirement and replacement studies*. For example, when should a company retire a facility, or specific equipment, or when is the technical limit of an asset reached? Perhaps a more important question surrounds when the economics of keeping and maintaining an item becomes more expensive than purchasing new and replacing the item. How does one determine this critical time period? These types of analyses are called retirement and replacement studies and are probably the largest class of cost studies performed by companies and organizations.

Since there is usually no profit from replacing an item, only savings over time, replacement problems are considered "least-cost" problems, where one wants to minimize costs and choose the alternative with the least cost (i.e., the smallest negative number). The two major cost elements in replacement studies are capital recovery costs and operating and maintenance costs.

The capital recovery (CR) of an investment is the cost of recovering the initial cost of investment. It is a uniform series representing the difference between the equivalent annual cost of the first cost and the equivalent annual worth of the salvage value. This annualized return usually declines over time:

$$CR = P \left(\frac{A}{P}, i, N \right) - S_N \left(\frac{A}{F}, i, N \right) \quad (3)$$

Operating and maintenance costs behave in the opposite direction to capital recovery costs. See Fig. 3. While capital recovery costs normally decrease over time, operation and maintenance costs generally increase over the lifespan of a facility or piece of equipment. This happens as parts get harder to find and labor skilled on the workings of the equipment disappears. Breakdowns also become more frequent as an object ages and complete overhauls become necessary. Thus, one must calculate the EUAC, or AC, (which is simply a negative annual worth) of the operations and maintenance costs in addition to the capital recovery costs for each year of possible ownership until time period N . Factors used for the EUAC include the present worth ($P/F, i, j$); the cumulative sum of the present worth, $\sum A_j(P/F, i, j)$, and the annualized cost to convert the present worth to an annuity ($A/P, i, n$). Note that n is the total years for the asset in question and j runs from 1 to n .

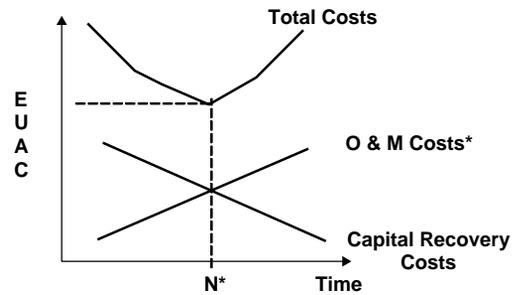

Fig. 3 EUAC versus time to determine total costs.

As mentioned, retirement and replacement problems are least-cost calculations with the goal being to minimize the EUAC. Since capital recovery decreases over time and operation and maintenance costs increase over time, there is usually an intersection of the two costs. This is the point (N^*) at which it is economically ideal to retire the item or replace it. See Fig. 3. The detailed calculations of these studies are beyond the topics in this handbook. For more details the reader should refer to Ref. 5.

8.1 Capital Cost

Related to capital recovery [Eq. (3)] is capitalized cost (CC). Capitalized cost analysis can be used for investments whose life is very long, generally greater than 30 years. Items with long lives include bridges, tunnels, and highways and therefore have lives that can be assumed to be infinite as opposed to finite. While capital recovery was an annual worth, capitalized cost is a present worth. Capitalized cost is the equivalent present worth of the initial cost plus a series of periodic cash flows (maintenance, tolls, operating costs, major overhauls, etc.) extended to infinity. Thus, capitalized cost can be thought of as the amount of money that one needs to set aside now (at some interest rate) to provide the funds needed to operate the project indefinitely. And when one can assume that the project runs indefinitely then N runs to infinity. This assumption of infinity introduces negligible errors to the problem and allows the cash flows to simplify and reduce to the equation

$$P = A \left(\frac{P}{A}, i, \infty \right) = \frac{A}{i} \quad (4)$$

which yields the equation for CC:

$$CC = P + \frac{A}{i} \quad (5)$$

For further discussion of capital cost see Ref. 5.

9 CONCLUSION

In addition to being part of the fundamentals in engineering (FE) exam and the professional engineering

(PE) exam, engineering economics is a topic commonly encountered by engineers faced with design decisions dealing with alternative designs, methods, or materials; and the choice of these influence the majority of the costs of manufacturing or construction. So beyond designs, method materials, function, and performance, alternative solutions must also be viable economically. It is for these reasons that Arthur Wellington⁶ define engineering as “the art of doing well with one dollar what any bungler can do with two.”

In many instances what an engineer designs has the requirements of being designed and built at some expense for the benefit or revenues that may occur from the design over time. The design alternatives and their comparison, therefore, can maximize benefit or minimize costs and show which projects are worthwhile and which are not or which projects should be given higher priority than others simply based on their economic impact. This chapter provides the tools to choose a suitable economic criterion for the problem and analyze and solve these decisions from an economic perspective. If one understands the decision-making process and can make accurate economic comparisons between alternatives, one can make better, more fiscally responsible decisions.

Engineering economics is therefore the application of economic analysis techniques in the comparison of engineering design alternatives. As such, one can only practice engineering if one also knows engineering

economics. The Forty-Fifth Annual Report of the Engineers Council for Professional Development define engineering as a profession in which knowledge of mathematics and science is applied to economically solve problems, create products, and so on. And the U.S. Department of Labor⁷ states that engineers should apply the principles of science and mathematics to develop economical solutions to technical problems. Thus, engineering by definition is a trade-off among science, engineering, and economic constraints to efficiently use capital to minimize costs and maximize benefits

3 TYPES OF DATA	1262		

1 INTRODUCTION AND SCOPE

It is the purpose of this chapter to aid engineers and materials scientists in locating reliable sources of high-quality materials property data. While sources in hard-copy form are referenced, the main focus is on electronic sources that provide well-documented searchable property data.

To identify useful sources of materials data, it is important to have clearly in mind at the outset (a) the intended use of data, (b) the type of data required, and (c) the quality of data required. These three factors are key in narrowing a search for property data and improving its efficiency. Therefore, as an introduction to the identification of some specific potentially useful sources of materials data, we will discuss those three factors in some detail and then describe the options available in types of data sources.

It is beyond the scope of this chapter to attempt to provide a comprehensive list of all of the several thousand sources of materials data in various forms and formats. Readers interested in a more comprehensive list of sources and of more discussion of the technology of

material property data technology and terminology are referred to Westbrook's extensive treatment of these subjects in Refs. 1 and 2 and the *ASM International Directory of Material Property Databases*.³

2 INTENDED USES FOR DATA

Numeric material property data are typically needed for one of the following purposes by individuals performing the respective functions as part of their jobs:

- Mathematical modeling of material or product performance
- Materials selection (finding candidate materials for specific applications)
- Analytical comparisons (narrowing the choices)
- Preliminary design (initially sizing the components)
- Final design (assuring performance; setting performance specifications)

- Material specification (defining specification for purchase)
- Manufacturing process control (assuring processes to achieve desired product)
- Quality assurance (monitoring manufacturing quality)
- Maintenance (repairing deterioration/damage)
- Failure analysis (figuring out what went wrong)

It is useful to note some of the differing characteristics of data needed for these different functions.

2.1 Mathematical modeling of Material and/or Product Performance

To an increasing extent, mathematical modeling is used to establish the first estimates of the required product performance and material behavior and even in some cases the optimum manufacturing process that should be used to achieve the desired performance. The processes and/or performance analyzed and represented may include any of the issues addressed in the following paragraphs, and so the types of data described under the various needs are the same as those needed for the modeling process itself.

2.2 Materials Selection

The needs of materials specialists and engineers looking for numeric materials data to aid in the selection of a material for some specific application are likely to be influenced by whether they (a) are in the early stages of their process or (b) have already narrowed the options down to two or three candidates and are trying to make the final choice. The second situation is covered in Section 2.3 on analytical comparisons.

If the materials engineers are in the early stages of finding candidate materials for the application, they are likely to be looking for a wide variety of properties for a number of candidate materials. More often, however, they may decide to focus on two or three key properties that most closely define the critical performance requirements for that application and search for all possible materials providing relatively favorable combinations of those key properties. In either case, they may not be as much concerned about the quality and statistical reliability of the data at this stage as much as the ability to find a wide variety of candidates and to make direct comparisons of the performance of those candidates.

In cases where there is interest in including relatively newly developed materials in the survey, it may be necessary to be satisfied with only a few representative test results or even educated “guesstimates” of how the new materials may be expected to perform. The engineers will need to be able to translate these few data into comparisons with the more established materials, but at this stage they are probably most concerned with not missing out on important new materials.

Thus, at this early stage of materials selection, the decision makers may be willing to accept data rather widely ranging in type and quality, with few restrictions on statistical reliability. They may even be satisfied with quite limited data to identify a candidate that may merit further evaluation.

2.3 Analytical Comparisons

If, on the other hand, the task is to make a final decision on which of two or three candidate materials should be selected for design implementation (the process defined here as “analytical comparison”), the quality and reliability of the data become substantially more important, particularly with regard to the key performance requirements for the application. It will be important that all of those key properties, for example, density, tensile yield strength, and plane strain fracture toughness, are available for all of the candidate materials that may be the next cut in the list.

The search will also be for data sources where the background of the data is well defined in terms of the number of tests made, the number of different lots tested, and whether the numbers included in the data source are averages or the result of some statistical calculation, for example, that to define three σ limits. It would not be appropriate at this stage to be uncertain whether the available data represent typical, average values or statistically minimum properties: it may not be important which they are, but the same quality and reliability must be available for all of the final candidates for a useful decision to be made.

In addition, the ability to make direct comparisons of properties generated by essentially the same, ideally standard, methods is very important. The decision maker will want to be able to determine if the properties reported were determined from the same or similar procedures and whether or not those procedures conformed to American Society for Testing and Materials (ASTM) International, International Organization for Standardization (ISO),⁴ or other applicable standard test methods.

One final requirement is added at this stage: The materials themselves for which the data are presented must all represent to the degree possible comparable stages of material production history. It would be unwise to base serious decisions on comparisons of data for a laboratory sample on one hand and a commercial-size production lot on the other. Laboratory samples have a regrettable history of promising performance seldom replicated in production-size lots.

Thus, for analytical comparisons for final candidate material selection, specialists need databases for which a relatively complete background of metadata (i.e., data about the data) are included and readily accessible.

Incidentally, it is not unusual at this point in the total process to decide that more data are needed for a particular candidate than are available in any existing database, and so a new series of tests are needed to increase confidence in the comparisons being made.

2.4 Preliminary Design

Once a decision is made on a candidate material (or sometimes two) for an application, the task of designing a real component out of that material begins. The requirement for statistical reliability steps up, and the importance of the availability of a data source that provides applicable metadata covering quality, reliability, and material history becomes even more important.

At this stage, the statistical reliability required includes not only a minimum value but one based upon a statistically significant sample size, ideally something comparable to the standards required in the establishment of MMPDS (previously known as MIL-HDBK-5) A or B values.⁵ In MMPDS terminology, an A value is one that would be expected to be equaled or exceeded by 99% of the lots tested with 95% confidence; the B value provides for 90% of lots tested equaling or exceeding the value with 95% confidence. Furthermore, the MMPDS guidelines require that A and B values be based upon predefined sample sizes, representing a minimum number of lots (normally 100 or more) and compositions (normally at least 3) of a given alloy. The provision of such statistical levels needs to be a part of data sources used for design purposes, and the description of the statistical quality needs to be readily available in the data source.

For preliminary design, then, the data sources sought will include both statistically reliable data and well-defined metadata concerning the quality and reliability of the data.

2.5 Final Design

Setting the final design parameters for any component or structure typically requires not only data of the highest level of statistical reliability but also, in many cases, data that have been sanctioned by some group of experts for use for the given purpose. It is also not unusual that at this stage the need is identified for additional test data generated under conditions as close as possible to the intended service conditions, conditions perhaps not available from any commercial database.

Databases providing the level of information required at this stage often contain what are characterized as "evaluated" or "certified" values. Evaluated data are those that, in addition to whatever analytical or statistical treatment they have been given, have been overviewed by an expert or group of experts who make a judgment as to whether or not the data adequately and completely represent the intended service conditions and, if necessary, incorporate their own analysis into the final figures. This technique has been widely used in digesting and promulgating representative physical property data for many years; examples are the thermophysical property data provided by Thermophysical Properties Research Center (TPRC).⁶

Other databases may be said to provide "certified" data. In this case, the database or set of data going into

a database have been evaluated by a group of experts and certified as the appropriate ones to be used for the design of a particular type of structure. Two examples of this are the aforementioned MMPDS values,⁵ which are approved for aircraft design by the MMPDS Coordination Committee, consisting of aerospace materials experts, and the American Society of Mechanical Engineers (ASME) *Boiler and Pressure Vessel Code*,⁷ with properties certified by materials experts in that field for the design of pressure vessels and companion equipment for high-temperature chemical processes.

As noted, it is often the case when designers reach this stage (if not the earlier preliminary design stage) that they find it necessary to conduct additional tests of some very specialized type to ensure adequate performance under the specific conditions the component or structure will see in service but for which reliable databases have not previously been identified or developed. The net result is the creation of new materials databases to meet highly specialized needs in a manner that provides the appropriate level of statistical confidence.

2.6 Material Specification

Material specification typically includes specific property values that must be equaled or exceeded in tests of those materials that are being bought and sold. The properties that one requires in this case may differ from those needed for other purposes in two respects. First and foremost, they must be properties that will ensure that the material has been given the desired mechanical and thermal processing to consistently achieve the desired performance. The second requirement is that, while in most cases there may be only one or a very few properties required (most often tensile properties), they are required at a very high level of precision and accuracy, similar to or better than that required for the MMPDS A properties defined earlier.

Examples are the material specification required for the purchase of commercial aluminum alloy products.⁸ These are usually only the chemical composition and the tensile properties. So while many of the other properties needed for design are not required as part of the purchase specification, those properties that are required are needed with very high reliability. In the case of aluminum alloys, the requirements for tensile strength, yield strength, and elongation are normally that 99% of lots produced must have properties that equal or exceed the published purchase specification values with 95% confidence and they must have been defined from tests of more than 100 different production lots from two or more producers.

In many cases, the databases needed to generate material specification properties are proprietary and are contained within individual companies or within the organizations that set industry specifications. However, the resultant statistically reliable specification properties are resident and more readily available in industry or ASTM material standards.^{4,8}

2.7 Manufacturing Process Control

The properties required for manufacturing purposes may be the most difficult to find in commercially available databases because they typically involve the specialized treatments or processes utilized by specific producers or suppliers of the specific products in question. Sometimes these processes are proprietary and closely held for competitive advantage. An added complication is that once some semifabricated component (e.g., aircraft sheet) has been purchased, it will require forming to very tight tolerances or finishing at some relatively high temperature. The fabricator may require data to enable the process to be carried through without otherwise damaging or changing the properties of the component but may have difficulty representing the fabricating conditions in meaningful tests. That fabricator may well have to carry out its own tests and build the needed database to provide the desired assurance of quality and to provide a source of information to which its own employees can refer to answer specific questions. Typically such databases never become commercially available, and new situations will require compiling new data sources.

Some processing data sources are available, of course. The Aluminum Association, for example, provides to all interested parties a data source defining standard solution heat treating, artificial aging, and annealing treatments for aluminum alloys that will assure the proper levels of properties will be obtained.⁸ In some cases, ASTM and American National Standards Institute (ANSI) material specification will also contain such information.

2.8 Quality Assurance

Quality assurance may be considered to be the flip side of material specifications and so the types of data and the data sources themselves required for the two functions are essentially the same.

Purchasers of materials, for example, may choose to do their own testing of the materials once delivered to their facilities by materials producers. If so, they will use exactly the same tests and refer to exactly the same data sources to determine compliance. The one difference may be that such purchasers may choose to gradually accumulate the results of such tests and build their own databases for internal use, not only by their quality control experts, but also by their designers and materials experts who must establish safe levels of performance of the structures. These types of databases also tend to be proprietary, of course, and are seldom made available to the outside world, especially competitors.

2.9 Maintenance

The principal value of material data in connection with maintenance concerns is for reference purposes when problems show up with either deterioration of surface conditions by local corrosion or the suspicion of the development of fatigue cracks at local stress raisers.

In both cases, the important features of the types of data desired to address such issues are more likely to be those based upon exposures representing service experience, and so the user may be more concerned about the degree of applicability than upon data quality and statistical reliability (though both features would be desired if available). Typically such data are hard to find in any event and once again are more likely to be buried in proprietary file than in published databases.

In the case of engineers and technicians needing databases comprised of service experience, they may well be faced with building their own data sources based upon their organization's production and service experience than expecting to be able to locate applicable external sources.

2.10 Failure Analysis

The occurrence of unexpected failure of components in a structure usually calls for follow-up study to determine the cause and possible ways to avoid further loss. In such cases it is inevitable that such failure analysis will involve both (a) a review of the old databases used to design the part and (b) a search for or the development of new data sources that may shed more light on the material's response to conditions that developed during the life of the structure that had not been anticipated beforehand.

The types of databases sought in this case will likely be those containing statistically reliable data, but recognizing the unexpected nature of some problems, an interest in a wider range of data sources and a willingness to consider a lower level of data quality may result. Databases for failure analysis studies may need to be wider in scope and to cover subjects such as corrosion that are not always easily treated by statistical means. In fact, sources covering failure experience may be the most valuable, though hardest to find because historically engineers and scientists do not publish much detail about their mistakes.

The net result is that when dealing with failure analysis, the search may be quite broad in terms of data quality, and the focus most likely will be more on applicability to the problem than on the quality and structure of the compilation. As in the case of maintenance engineers and technicians needing databases comprised of service experience, failure analysts may well be faced with building new data sources based upon their organization's production and service experience.

3 TYPES OF DATA

It is useful at this stage to note that there are several basic types of materials databases, that is databases containing significantl different types of information and, hence, different data formats. Note that this is different from the type of platform or presentation format (e.g., hard copy, CD, online, etc.); these will be discussed in Section 6.

The two fundamental types of databases discussed here in are *textual data* and *numeric data*. In fact, many

databases represent a combination of both types, but there are some basic differences worth noting as in the next two paragraphs. The concept of metadata will also be described in more detail in this section.

3.1 Textual Data

The terminology *textual data* is generally applied to data entries that are purely alphabetic in nature with numbers used only as necessary to complete the thoughts. Textual databases are typically searched with alphabetical strings, for example, by searching for all occurrences of a term such as *aluminum* or *metallurgy* or whatever subject is of interest.

The subjects of textual databases are predominantly bibliographies and abstracts of publications, but they may reflect other specific subjects such as descriptions of failures of components. Bibliographic databases seldom reflect the final answers to whatever inquiry is in mind but rather references to sources where the answers may be found.

The majority of all databases in existence in any form (see Section 6) are textual in nature, even many of those purporting to be property databases. Searchers of such textual property databases are searching based upon strings of alphanumeric characters reflecting their interest, not on numeric values of the properties except as they are expressed as strings. This is quite different from the case for numeric property databases, as we shall see in Section 3.2.

3.2 Numeric Databases

Databases classed as numeric (a) have data stored in them in numeric format and (b) are searched numerically. For example, numeric databases may be searched for all materials having a specific property equal to or greater than a certain value or within a certain specific range; this would not be possible in a textual database. To provide such searchability, almost all numeric databases are electronic in nature (see Section 4) though many hard-copy publications also contain extensive amounts of numeric data.

To accommodate numeric searching, the properties must be entered into a database digitally as numbers not simply as alphanumeric strings. And to be useful to material specialists and designers, they must have meaningful precision (i.e., numbers of significant figures) and units associated with each number. The numeric number of a property is of no value if it does not have the applicable unit(s) associated with it.

3.3 Metadata

The concept of metadata as “data about data” was introduced earlier, and it is appropriate at this stage to describe the concept and its importance in greater detail.⁹ It is vital, especially for numeric databases and independent of their platform, to have ample background information on the numeric properties included

in the database and closely associated with the individual properties.

Examples of metadata include:

- Original source of data (e.g., from tests at ABC laboratories)
- Test methods by which data were obtained (e.g., ASTM methods, size and type of specimen)
- Production history of the samples for which the data are applicable (e.g., annealed, heat treated, cold worked, special handling?)
- Exposure experienced by the samples tested, if any, prior to the test (e.g., held 1000 h at 500°F)
- Conditions under which the properties were determined (e.g., tested at 300°F, 50% humidity)
- Number of individual tests represented by and statistical precision of the values presented (e.g., individual test results; averages of x number of tests, statistical basis)
- Any subsequent evaluation or certification of the data by experts (e.g., ASME Boiler & Pressure Vessel Committee)

It should be clear that the value of information in any database, but especially in a numeric database, is greatly diminished by the absence of some and potentially all of these types of metadata. For example, a listing of the properties of an alloy is of no value at all if it is not clear at what temperature they were determined. It should be clear that metadata are an integral part of every material property database. Similarly, the properties of a material are of virtually no value if it is not clear how the materials were mechanically and thermally processed before they were tested.

4 SUBJECTS OF DATA SOURCES

It is next useful to note some of the major categories of data available and illustrate the manner in which they are likely to be classified or structured. From this point on, the discussion will focus primarily upon numeric materials property data of interest to the engineer and scientist.

The total breadth of properties and characteristics may reasonably be illustrated by the following four categories:

- Fundamental (atomic level) properties
- Physical properties (atomic and macro/alloy levels)
- Mechanical properties (macro/alloy level)
- Application performance (macro/alloy or component levels)

To provide greater detail on the first three categories, it is helpful to utilize the taxonomy of materials information developed by Westbrook¹ and illustrated

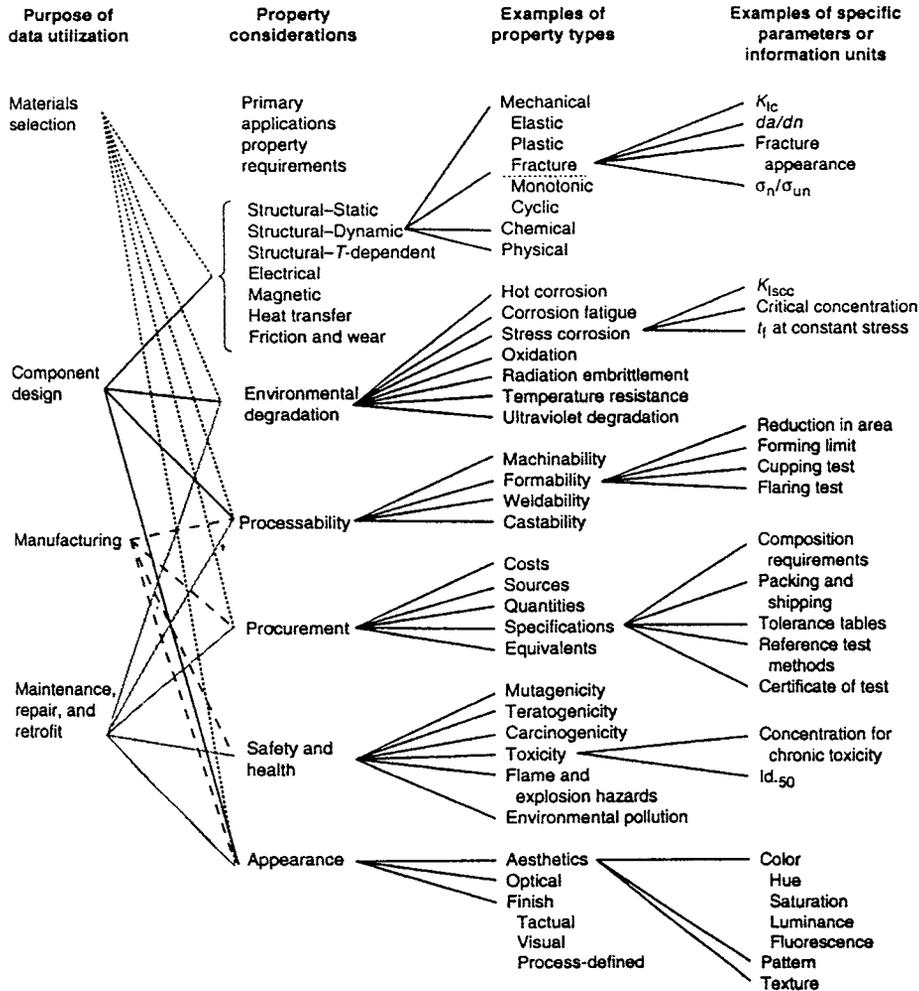

Fig. 1 Taxonomy of materials information. From *ASM Handbook, Vol. 20: Materials Selection and Design* (1997), ASM International, Materials Park, OH, Fig. 1, p. 491.

in Fig. 1. While the entire list of potential uses of data described above is not included, the taxonomy in Fig. 1 illustrates the variety of subject matter quite well.

The fourth major category identified above, referred to as application performance, incorporates several individual types of information:

- Fabrication characteristics (sometimes called the “ilities”)
 - (a) Fabricability (“workability”)
 - (b) Forming characteristics (“formability”)
 - (c) Joining characteristics (“joinability”)
 - (d) Finishing characteristics (“finishability”)

- Service experience
 - (a) Exposure conditions
 - (b) Service history
 - (c) Failures observed and their causes

What is necessary is not to discuss these categories individually but simply to recognize that specific databases may well focus on only one or a few of these subjects and that rarely if ever would all subjects be included in any one database.

5 DATA QUALITY AND RELIABILITY

It was noted in Section 2 that individuals doing preliminary material selection or screening may have different needs with regard to quality and reliability than

those doing design functions. It is appropriate at this stage to review the major factors that go into judgments of data quality and reliability.¹⁰ There are two parts to such a discussion: (1) the two major factors affecting the data themselves and (2) the degree to which those factors are reflected in database content.

The two major factors affecting quality and reliability include (a) the manner in which the data were obtained and (b) the statistical reliability of the data presented.

First and foremost, the users of a database for whatever purpose will want to know that consistent standards were applied in assembling the data for that database and that the properties of one material may reliably be compared with those for another. They would also prefer that those properties have been generated by well-known standard methods such as those prescribed by organizations such as ASTM and ISO.⁴ They may also be quite interested in knowing the specific source of the original data; realistically some laboratories [e.g., the National Institute of Standards and Technology (NIST)] have a more widely recognized reputation than others.

The second major factor affecting how the user applies information from a specific database is the statistical reliability of the values included therein. The user will be interested in which of the following categories best describes the values presented:

- Raw data (the results of individual tests)
- Average of multiple tests (how many tests represented?)
- Statistically analyzed (at what statistical definition and with what confidence?)
- Evaluated/certified (by whom? for what purpose?)

Of equal importance to the user of any database for whatever reason is the degree to which those factors affecting quality and reliability as noted above are presented in the database itself and, therefore, can be fully understood by the user. In some instances there may be one or several screens of background information laying out the general guidelines upon which the database was generated. This is particularly effective if the entire database represents properties of a common lineage and character. On the other hand, if the user fails to consult this upfront information, some important delimiters may be missed and the data misinterpreted.

Another means of presenting the metadata concerning quality and reliability is by incorporating them within the database itself. This is especially true for such factors as time-temperature parameters that delimit the applicability of the data and units and other elements of information that may restrict its application (see Section 3.3). The incorporation of such information is also especially important in instances where the

individual values may vary with respect to their statistical reliability. While the later case may seem unlikely, it is actually quite common, as when “design” data are presented; in such cases, the strength values are likely to be statistical minimum values while moduli of elasticity and physical properties are likely to be average values, and the difference should be made clear in the database.

6 PLATFORMS: TYPES OF DATA SOURCES

The last feature we will consider before identifying specific data sources is the variety of platforms available for databases today. While it is not necessary to discuss them in detail, it will be obvious that the following choices exist:

- Hard copy (published books, monographs, etc.)
- Self-contained electronic (CDs, DVDs, etc.)
- Internet sites (online availability; perhaps downloadable)

The only amplification needed on these obvious options is that the last one, the Internet, has become an interesting and sometimes challenging resource from which to identify and locate specific sources of materials data, and that trend will likely continue to increase. Two large caveats go with the use of Internet sources however: (a) a great deal of “junk” (i.e., unreliable, undocumented data) may be found on Internet websites and (b) even those containing more reliable data seldom meet all users’ needs with respect to covering the metadata. It is vital that the users themselves apply the guidelines listed earlier to judge the quality and reliability of sources located on the Internet.

7 SPECIFIC DATA SOURCES

It is beyond the scope of this chapter to provide an exhaustive list of data sources because there are thousands of them of varying presentation platforms, styles, and content. What we will do here is highlight a few of the potentially most useful and highest quality sources, in the sense that their coverage is relatively broad and/or they represent good places to go to look for new and emerging sources of materials data.

The descriptions below will include the following four groups:

- ASM International, a technical society for materials engineers and specialists that produce and provide a wide range of textual resources and materials databases in hard copy and several electronic formats (see Section 7.1)
- STN International, a service of the American Chemical Society, providing (for-fee) access to several numeric databases as well as a great many textual/bibliographic databases on materials-related subjects (see Section 7.2).

- Knovel, a division of William Andrew, providing online access via www.knovel.com to more than 800 published scientific texts and databases.
- Other online Internet websites. (see Section 7.3).

For readers interested in more extensive listings, reference is made to the article "Sources of Materials Property Data and Information" by Jack Westbrook in Volume 20 of the *ASM Handbook*¹ and to the *ASM Directory of Databases*.³

7.1 ASM International

ASM International has emerged as one of the strongest providers of both textual and numeric data, and those sources are usually available in at least three formats: hard copy, CD, and online. For example, one of the most extensive sources of high- and low-temperature data for aluminum alloys is available in book form, *Properties of Aluminum Alloys—Tensile, Creep, and Fatigue Data at High and Low Temperatures*,¹¹ on a CD, and online as part of the Alloy Center.

Most impressive is the emergence of the ASM International website, www.asm-international.org, as a portal to a wealth of materials data, including but not limited to the following:

- The *ASM Handbook*¹²—covering the 20-volume handbook; versions are also available for single or networked workstations.
- A research library of thousands of technical publications, including technical books, CDs, and DVDs, articles from magazines and journals, and life-long learning support.
- The Alloy Center, including:
 - (a) Data sheets and diagrams—include thousands of data documents from publications such as *Alloy Digest* and *Heat Treater's Guide*, along with time-temperature curves, creep curves, and fatigue curves.
 - (b) Alloy finder—includes alloy designations and trade names from around the world, enabling users to locate compositions, producers, and tensile properties.
 - (c) Materials property data—include numeric databases of mechanical and physical properties and processing information for most industrially important alloys; include graphs of data as functions of time and temperature.
 - (d) Coatings data—feature detailed information on commercial coating systems that can be searched by trade name, manufacturer, or process of coating type.
 - (e) Corrosion data—feature corrosion information for alloys in specific environments, searchable by either category.
- Materials for medical devices—a comprehensive and authoritative set of mechanical, physical, biological response, and drug compatibility properties for the materials and coatings used in medical devices, including carbonaceous materials, ceramics, metals, and polymers.
- Materials for micro electro mechanical system (MEMS) packaging—a comprehensive and authoritative set of mechanical and physical properties, processing, and component data to facilitate materials selection and design for MEMS packages. Includes capability to search, select, and report features for composites, metals, and polymers as well as getters and solders.
- Alloy phase diagrams—About 28,000 binary and ternary phase diagrams, also available in hard-copy or CD versions
- Micrograph center—A comprehensive collection of micrograph images and associated data for industrially important alloys, including material designation and composition, processing history, service history, metallographic preparation/technique, magnification significance of the structures shown, selected materials properties data, and other relevant data.
- Failure analysis center—Features over 1000 case histories along with authoritative handbook information on failure mechanisms and analysis methods, enabling the user to find specific information to help solve failure analysis or materials performance issues.

The access and availability of the ASM sources is more cost-effective with membership in the society. For more information on any aspect of the ASM International resources, readers are referred to www.asm-international.org.

7.2 STN International

STN International is the online worldwide scientific and technical information network, providing one of the most extensive sources of numeric materials property data.¹³ Built and operated by the American Chemical Society at its Chemical Abstract Service site in Columbus, Ohio, STN International includes about 25 numeric databases, including several developed during the collaboration with the Materials Property Data Network.^{14–16} Of great interest to professional researchers, STN International has the most sophisticated numeric data search software available anywhere online. Thus the data sources may be searched numerically, that is, using numeric values as ranges or with "greater or less than" types of operators, making it possible to search for alloys that meet required performance needs.

The disadvantages of using STN International to search for numeric data are twofold: (a) the primary search software is keyed to a command system best

known to professional searchers and engineers and scientists will need patience and some training to master the technique and (b) use of the STN International system is billed via a time- and content-based cost accounting system, and so a private account is needed.

For those able to deal with those conditions, a number of valuable databases exist on STN International, including the following representative sources:

- Aluminium—Aluminum Industry Abstracts (textual: 1868–present)
- ASM DATA—ASM Materials Databases online version
- BEILSTEIN—Beilstein Organic Compound Files (1779–1999)
- COPPERLIT—Copper and Copper Alloy Standards & Data
- CORROSION—Cambridge Scientific Abstracts databases of corrosion science and engineering (current)
- DETHERM—Thermophysical Properties Database (1819–present)
- GMELIN—GMELIN Handbook of Inorganic Chemistry (1817–present)
- ICSD—Inorganic Crystal Structure Database (1912–present)
- MDF—Metals Datafil (1982–1993)
- PIRA—PIRA and PAPERBASE Database (1975–present)
- RAPRA—Rubber, Plastics, Adhesives, and Polymer Composites (1972–present)
- WELDSEARCH—Literature about joining of metals, polymers, and ceramics

For more information on STN International, readers are referred to the website www.cas.org.

7.3 Knovel

Another online source of materials information that has grown significantly over the last decade is www.knovel.com, a product of William Andrew Publishing in cooperation with a number of publishers of scientific information, including John Wiley & Sons, McGraw-Hill, and Elsevier. On the [knovel.com](http://www.knovel.com) website, the sources are enhanced with time-saving analytical tools to help analyze and manipulate the data, so users can analyze and reorganize the data from over 800 full-text engineering and scientific reference works, handbooks, and databases. They can sort, filter, and export data from “live tables,” resolve equations, plot graphs, capture values from existing graphs, and perform “what if” experiments on the data. Knovel’s unique and powerful search engine has a user-friendly browse capability to allow the user to discover and analyze data in relatively intuitive ways.

The specific content areas recognized on [knovel.com](http://www.knovel.com) include:

- Adhesives, coatings, sealants, and inks
- Aerospace and radar technology
- Biochemistry, biology, and biotechnology
- Ceramics and ceramic engineering
- Chemistry and chemical engineering
- Civil engineering and construction materials
- Earth sciences
- Electrical and power engineering
- Electronics and semiconductors
- Environment and environmental engineering
- Food science
- General engineering and engineering management
- Mechanics and mechanical engineering
- Metals and metallurgy
- Oil and gas engineering
- Pharmaceuticals, cosmetics, and toiletries
- Plastics and rubber
- Textiles

7.4 Other Internet Websites

As indicated earlier, there are many websites on the Internet with materials information content. The challenge is to determine which have useful, reliable, and relatively easily accessible data. In the interests of readers, we will focus on guidance on these latter points developed by Fran Cverna, Director of Electronic and Reference Data Sources at ASM International, who produced and presented a survey of the scope and quality of materials data content found on Internet websites.¹⁷

Among the most useful websites of the several hundred screened by Cverna and her ASM resources are the following:

www.about.com	Internet search engine—search materials and properties
www.nist.gov/publicaffairs/database.htm	NIST—standard reference database
www.tprl.com	TPRL—thermophysical properties data
www.campusplastics.com	Campus consortium—plastics database
www.matweb.com	Matweb databases by Automation Creations
www.copper.org	Copper Development Association—copper alloys database
www.brushwellman.com/homepage.htm	Brush Wellman—supplier materials database
www.timet.com/overviewframe.html	Timet—supplier materials database

www.special-metals.com	Special Metals—supplier materials database
www.cartech.com	Cartech—supplier materials database (compositions)
www.macsteel.com/mdb	McSteel supplier materials database (limited)
www.aluminum.org	Aluminum Association applications—publications' limited data

Of the sources above, three merit special mention: www.about.com, the National Institute for Science and Technology databases, and www.matweb.com

The about.com site provides an excellent means of locating materials data sites and provides a subcategory called "Materials Properties and Data" if you search for such information. Many sites are identified some of which overlap the ASM survey, but others are unique to that site. Many included in the ASM survey are not included here, so the two are supplementary in scope. A wide range of properties may be searched, ranging from physical and mechanical properties, and support calculations for densities, unit changes, and currencies are provided. In addition there are links from about.com to many other materials sites, including one called aluminum.com that also provides materials data for a variety of metals, but often without adequate citation and metadata.

The NIST database site www.wst.gov/public-affairs/database.htm provides direct online access to the highest quality, carefully evaluated numeric data from the following databases, among others:

- Standard Reference Data—reliable scientific and technical data extracted from the world's literature assessed for reliability and critically evaluated
- Ceramics WebBook—evaluated data and access to data centers as well as tools and resources
- Chemistry WebBook—chemical and physical property data for specific compounds
- Fundamental Physical Constants—internationally recommended values of a wide range of often used physical constants
- Thermophysical Properties of Gases for the Semiconductor Industry.
- MatWeb—designed, developed, and maintained by Automation Creations, the website www.matweb.com provides access to the properties of over 65,000 materials, including metals, polymers, ceramics, and composite materials. The search engine is relatively flexible, permitting searches by property, composition, and/or material, and in the latter case, material designations ranging from trade names to Unified Numbering System (UNS) designations may be used.

To summarize the Internet discussion, there are many sources of numeric materials data available from Internet sites. It remains for the potential users of the data, however, to approach each site with caution, look for the pedigree of the data in terms of quality and reliability, and make certain that the source used meets the requirement of the intended use.

 Light sensors (photodetectors/photosensors), 1019–1022
 Limit analysis (plasticity), 477

- Lines:
 geometry, 203–204
 moments about, 311
 plane analytic geometry, 221–223
 solid analytic geometry, 231–235
- Linear acceleration, table of conversion factors for, 79
- Linear active electric circuits, 891–905
 dependent sources, 891–895
 operational amplifier, 895–905
- Linear dependence, 176
- Linear elastic fracture mechanics, 495–496
- Linear elastic stress-strain relationships, 437–439
- Linear models, 709–714
 converting from I/O to phase-variable form, 714
 I/O form, 709–712
 state-variable form, 712–714
- Linear systems analysis:
 state-variable methods, 735–737
 transform methods, 714–735
 response to periodic inputs using, 725–735
 transient analysis with, 719–725
- Linear theory method (pipe networks), 594
- Linear transformations, 177–178
- Linear velocity, 78
- Line integrals, 253–254
- Liquids:
 saturated, thermal properties of, 824
 ultrasonic properties of, 534–542
- Liquid crystal displays (LCDs), 1018
- Liquid crystalline polyesters (LCPs), 411–412
- Liquid measure, 76
- Liquid penetrants (nondestructive testing), 511–513, 612
- Liter (L), 59
- LMCTs (lateral MOS-controlled thyristors), 1096
- Logarithms, 166–167
 of exponentials and hyperbolic functions, 24–25
 table of, 23–24
- Logic-level simulation, 1051
- Loudness (sound), 1186–1187
- Loudspeakers, 1198
- Low-cycle fatigue, 499–501
- Low-pass filters, acoustic, 1170
- Lumber, nominal and minimum dressed sizes of, 157–158
- Machine screws, 152
- Mach number:
 critical, 675–676
 variation in expanding flow, 696
- Magnesium:
 alloys, 369, 388
 mechanical properties of, 446
- Magnetic bubble memories, 1008
- Magnetic field intensity, table of conversion factors for, 92
- Magnetic flux, 65–67
 absolute practical unit of, 68
 table of conversion factors, 91
- Magnetic flux density, 65, 66, 92
- Magnetic induction, 66, 67
- Magnetic intensity (magnetizing force), 65–67
- Magnetic materials (electronic components), 1006–1008
- Magnetic moment, 66
- Magnetic particle inspection, 526–527
 capabilities of, 612
 continuous vs. noncontinuous fields, 527
 demagnetizing the part, 527
 inspection process, 527
 magnetizing field, 526–527
- Magnetic position trackers, 1025
- Magnetic potential, table of conversion factors for, 92
- Magnetic quantity, 66
- Magnetizing force, table of conversion factors for, 92
- Magnetomotive force (mmf), 66, 92
- Magnetostatic potential, 66
- Maintenance, materials data for, 1262
- Mannequins, 1026
- Manufacturing process control, materials data for, 1262
- Mass, 308
 table of conversion factors, 80
 units of, 58, 59, 335
- Mass per unit volume, table of conversion factors for, 81
- Materials data:
 quality and reliability of, 1264–1265
 sources of, *see* Sources of materials data
- Materials selection, materials data for, 1260
- Materials, mechanics of, 209
- Material specification, materials data for, 1261
- Mathematics, 51
 algebra, 163–181
 arithmetic, 160–163
 complex analysis, 288, 302–303
 differential calculus, 238–248
 differential equations, 258–269
 finite-element method, 269–286
 geometry, 191–213
 integral calculus, 248–257
 Laplace transformation, 286–301
 plane analytic geometry, 221–230
 set algebra, 181–182
 solid analytic geometry, 230–237
 statistics and probability, 182–191
 trigonometry, 213–221
 vector analysis, 303–306
